Morris Huntington, æt. 56, a painter, fell from the roof of a three-story house, through a tree to the sidewalk. He was at once taken to the City Hospital, but lived only a few hours. A fracture of the wrist was observed, but he was so nearly moribund that it was not interfered with. I was invited, by the kindness of the staff, to make the autopsy. This was done by simply removing the skin from the posterior surface of the wrist, extending to the sides, thus coming at once upon the annular ligament. The end of the styloid chisel protruded through a rent in the ligament. This was carefully touched by Drs. Whitbeck, Montgomery, Little, Langworthy, Ely, Mallory, and others. It was precisely, in all its details, as before observed, and as I described it ten years since.

The next move in the dissection was the removal of the skin on the anterior aspect of the arm, and the division of the muscles and tendons down to the bones. These were then lifted up just far enough to see the end of the ulna. The triangular fibro-cartilage was torn out at the pit of the styloid, and the internal lateral ligament torn off with the end of the styloid, as in the other cases. I now present you this specimen in its wet state. The rent and luxation can be seen, and the styloid chisel is almost precisely the same in shape as that of O'Hara's.

This case confirms all previous observations. It would not unlikely have been a compound luxation but for the fact that the ulna was broken about three inches from the wrist, for the radius presents a condition of extraordinary comminution.

These five cases present all that I have seen. There are others that have not come under my own observation, and which were imperfectly observed, but which I thought best not to add. In four of these cases the peculiar rupture of the styloid was identical. Two of them you have before you. The fifth has been modified by time. As these are the only cases I have seen, and as they are all alike, I feel sure now of having described a luxation that has been overlooked. Luxations of the ulna have been noted, but they have been regarded as irregular and having no definite character. In the discussion upon this topic at the meeting of the National Association held at Buffalo, I took the ground that for every compound luxation of any joint we will have a

large number of simple ones. In the absence of statistics, which are not possible, I asseverated the round number of fifty. I repeat it on the ground that it could not be an exception to all our observations of other joints. A distinguished author replies that this could not be said of dislocation of the astragalus. But I rejoin that there is no analogy. The only analogue of the tarsus is the carpus. The ulna is a long bone, and must find its analogue among

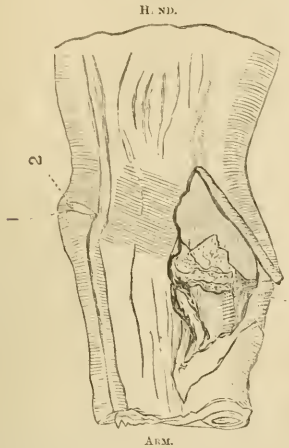

FIG. 5.—1, Button-hole in the posterior annular ligament; 2, broken styloid caught in button-hole; 3, fracture of radius.

the long bones. It requires very great violence to produce a compound luxation at any place. Less force produces the simple luxation, and this we have very often with Colles' fracture.

Thus far my paper has referred only to the evidence bearing on the question of the existence of luxation of the ulna at the lower end—evidence that is purely demonstrative, and beyond the reach of argument. But I feel justified in adding some inferences of observation on the living subject. In my previous paper I called attention to the position of the tendon of the extensor carpi ulnaris. It runs alongside of the head of the ulna and behind the styloid. When the luxation does not exist, and the fracture does, the head of the bone maintains its relation with the tendon but little disturbed. When, however, the luxation does occur, the tendon will appear to lie over the head. I feel quite sure that this does not result from any twist of the hand carrying the fragment of the radius. I find proof of the correctness of this proposition in the specimen before us. The dead tissue presents the tendon curved out of its place. In the living, under muscular contraction, this would be a straight line, and lie over the head of the ulna. I find also in what I deem cases of luxation, a mobility of the end of the ulna incompatible with the integrity of the ligamentous apparatus. Every observer has recognized a difference of the form of the wrist in different cases. Some are curved backward—the genuine silver-fork shape; others have the hand carried more laterally. My convictions are, that those that present the wrist well curved back, are more apt to be those of luxation of the ulna with fracture, but the lateral bend implies generally shortening of the radius from fracture without luxation of the ulna. In my previous paper I proposed a form of traction and circumduction which is intended to disentangle the ulna and carry it up in its place between the tendons of the extensor carpi ulnaris and extensor minimi digiti. I by no means wish to say that this is always necessary, for the great point should be not to relax any effort until complete restoration should take place. The gentle handling that is ordinarily employed in the management of the fracture is out of place here. Great force is often necessary to restore the symmetry of the parts. We must keep in mind that a luxation is to be reduced, and should not cease our traction until the end is attained. Besides, the muscles will produce consecutive luxation instantly if the parts are not held firmly until the dressing is complete. With the thumb of the surgeon under the ulna, and the hand beneath, and the fingers upon the back of the wrist holding with great firmness, I apply my dressing. This, it will be remembered,

FIG. 6.—Position of roller compress.

consists of a simple roller from half to three-quarters of an inch in diameter and two inches long. This is to be carefully placed under the ulna, abutting against the pisiform bone and slowly displacing the thumb. Then a strip of adhesive plaster of the same width is drawn with as much force as it will bear around the wrist and pinned to prevent relaxation. The band of plastered cloth is carefully adjusted so that the distal edge is brought around on a line with the end of the radius. It is manifest that this bandage will grasp the broken fragment, and hold it to the end of the ulna. The rule of loose dressing at first is distinctly violated for a purpose. I repeat that I draw it as firmly as I can, often breaking the plaster cloth. The dressing is entirely complete by the use of a sling which must not be more than three inches wide. This must be placed over the roller, and is made of this width to cause the whole bearing to come on the roller, which is both compress and splint. The hand is brought down and allowed to hang naturally. Thus its weight and that of the forearm is used to press the ulna upward into its proper place.

If all this is successfully accomplished, the broken fragments of the radius are easily kept in place.

The full length of the arm is maintained if the ulna does not fall down and the tendons that run over the back of the wrist are as closely parallel as to make the best possible splint. I do not continue to quote a violation of the primary rule in dressing

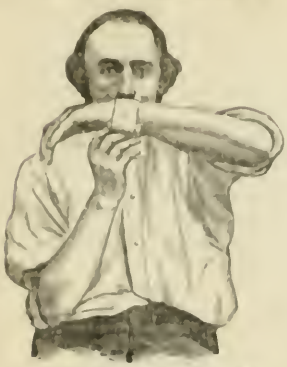

FIG. 7.—Roller, with adhesive strap applied.

fractures, as to retain the bandage in its tight condition; but, after six hours, cut it by thrusting one blade of a pair of scissors under it on the back of the wrist, dividing it completely. The few hours of such retention seem to be sufficient. The meagreness of the appliance has startled some who have attempted its

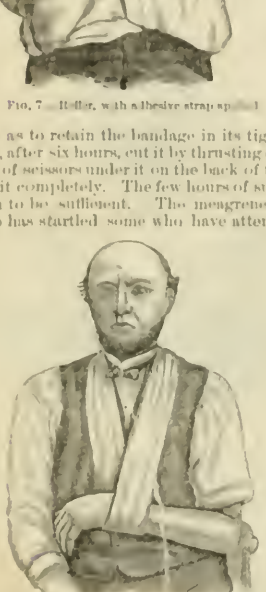

FIG. 8.—Colles' fracture; dressing complete.

use. But any addition that I have made has injured it. I find there is a strong disposition on the part of the patient to hit up the hand with the sound one. With unintelligent patients this is often troublesome, and a splint of iron, thin, such as hoop-iron, bent so as to come over the back of the wrist and hand, and bound upon the forearm but not upon the hand, will guard against this error. I am careful not to bind the hand to it, for I desire the constant action of gravity. The position can be maintained, even in the recumbent posture. The slight motion in the joint which will necessarily be produced by allowing it to hang freely, prevents the stiffness that is so often a very serious inconvenience after the treatment of this fracture.

There is another question to be answered: How good are the results? My experience has been considerable, as my professional brethren have shown me their cases when treated after my method. When there is much comminution there will be some absorption of the bone. This will produce a slight deflection. But if the fracture is transverse, deformity can hardly be said to exist. As in other luxations, the union of the ligaments is apt to result in their elongation, making, when the cure is perfected, a certain laxity and mobility of the head of the ulna after the fracture is perfectly firm. When the fracture is transverse, I have removed the bandage at the end of two weeks, but in other cases the treatment has been extended to four weeks.

I would remark that the reputation of the pistol-shaped splint, Bond's, Levis's, and most others, can be explained. If great pains is taken to restore the parts, the flexed position of the hand will have a tendency to keep the restored ulna in place, especially if suitable compresses are used. These can be well adjusted in Bond's and Levis's splints. Moreover, in those cases in which there is no luxation, the results are apt to be good in the fixed position, for the full length is obtained because the ulna is not disturbed. Where luxation occurs, the muscles have a constant tendency to displace the ulnar head, and when slipped downward the least, it is apt to remain. I therefore prefer gravity to any fixed splint, for the compresses, even if applied tightly, will yield, and any relaxation of the retentive force is apt to be accompanied with displacement. Moreover, by my simple dressing, the parts are under view without its derangement. I would urge the profession to banish the fear of its use as leading to disaster, with the full conviction, founded on the experience of my friends, that once understood and practised, no other would be thought of.

DIAGNOSIS AND TREATMENT OF DIPHTHERIA.

By NATHAN JACOBSON, M.D.,

SYRACUSE, N. Y.

As designated by the title of this paper, we are to restrict ourselves in the discussion of diphtheria to two of the more important questions—its diagnosis and treatment. It shall be our object not so much to advance any new ideas as to review the position of the profession and to establish what is positively known. The vast extent of the subject will require extreme brevity in many particulars. In the consideration of the diagnosis, it is of primary importance to appreciate the fact that diphtheria is not necessarily accompanied by pharyngeal disturbance. This necessitates a division of the question into, 1st, simple or pharyngeal; 2d, laryngeal; 3d, cutaneous; 4th, nasal; and 5th, secondary diphtheria.

SIMPLE OR PHARYNGEAL DIPHTHERIA.

Modern writers subdivide this form into, 1st, a mild or catarrhal; 2d, a severe or croupous; and 3d, a gangrenous variety. Each of these, in turn, is to be distinguished from other troubles.

Before entering upon a further discussion of the diagnosis in particular cases, it is well to make the general assertion that no single symptom taken alone is diagnostic.

The mildest form is often difficult of recognition. In simple catarrhal tonsillitis we have, in addition to redness and swelling of the mucous membrane, a yellowish, sticky mass, which can be wiped away; not membraniform, and may be seen to dip into the follicular depressions. The exudation, however, may be in strips. Furthermore, there may be erosions of the mucous membrane, and ulcerations, with suppurating bases, with distinct borders, and loss of substance, which Oertel considers diagnostic, inasmuch as there is no such loss of substance in the mild form of diphtheria.

Trousseau adds, by way of diagnosis of what he terms herpetic or membranous sore throat, that when you have learned that an acute burning pain in the throat has for several days been preceded by general symptoms of illness, febrile discomfort, and disorder of the stomach, you may conclude that you have a case of simple membranous sore throat. Generally speaking, diphtheria is far more insidious, and, as a rule, fever has scarcely made its appearance when throat trouble is recognized. But, more than all, the coexistence of herpes labialis will at once exclude diphtheria. Yet he recognizes cases where time alone can make a diagnosis positive.

As opposed to this, there appears at points upon the tonsils, in the mild form of diphtheria, a seromucous matter, becoming more adherent to the mucous membrane, which is slightly hyperæmic and swollen, growing more dense and yellowish, increasing in size, soon coalescing and becoming slightly elevated. Thus, in a period varying from a few hours to a few days, in different cases, there is presented a real membrane, its removal producing hemorrhage, and followed by another reproduced in its stead. The general symptoms are usually mild. Despite treatment, this form may develop into a severer type. Mild cases of diphtheritic pharyngitis, without even the occurrence of the membrane, may at a later period in their history disclose their real nature by the sequelæ they may present.

Upon superficial examination, aphthæ may be mistaken for diphtheria, especially where the broken vesicles may run together and form ulcerations.

With the *severer* type we may have quite extreme general symptoms; high fever, great prostration, cerebral disturbance, tumefaction of the spleen, and some other typhoid process, may be suspected. The examination of the pharynx, however, will clear up all doubt.

Prior to the appearance of the exudation, the mucous membrane will be darkly reddened, swollen, and dry. After a few hours its surface will either in part or entirely become peculiarly gray. In time the exudation assumes the appearance of real membrane, of a white, dull silvery, or gray color, and raised above the contiguous surface. Whatever its microscopical construction may be, its macroscopic appearances are sufficiently characteristic and known to every one present. From here, involving the entire soft palate, it may extend downward into the œsophagus or air-passages, and upward into the nares, Eustachian tube, and middle ear; or, furthermore, involve the entire cavity of the mouth, and even the tongue. After the second day the glands of the neck are swollen. With time we may have the kidneys, heart, or lungs involved, or paralytic or nervous phenomena. Wunderlich tells us that in no disease is the thermometer of as little service in diagnosis as in diphtheria.

From this form we have to diagnosticate, first of all, scarlatina. When accompanying this variety we have erythema of the neck and chest, a diagnosis may be difficult. Meigs and Pepper, and likewise Wagner, remark that neither ocular nor microscopic examination of the deposit in the throat can distinguish these two diseases, assuring us that we must look to the general symptoms for a diagnosis. As to the erythema of diphtheria, "it appears at irregular periods, is partial, appears suddenly in patches, does not gradually deepen in intensity, is of a uniform, erythematous redness, and without the punctated appearance peculiar to scarlatina." The albuminuria of diphtheria occurs at an early period, usually increasing in quantity as the disease reaches its height, or may disappear suddenly. It maintains no relation to the severity of the remaining symptoms. In the sequelæ there is, furthermore, the widest difference both as to the paralyses and the dropsy.

The third subdivision of this group is not difficult of recognition. We no longer have the simple exudations above described, but find, either supervening upon the preceding or assuming these characteristics from the commencement, "a dark, discolored, pulpy, broken-down mass, or more firmly attached sloughs, with the peculiar odor of gangrene, often cadaverous," at first destroying parts of the soft palate, but later followed by more extensive destruction, the tonsils entirely sloughing out, as noted by Henroz. Extending into the nares, there will be severe hemorrhages. Extreme swelling of the lymphatic glands is present. Usually death follows from exhaustion, high fever, or septicæmia. Scarlet fever alone presents a condition at all akin to this. The history of the cases, together with the general symptoms, will usually make the diagnosis.

LARYNGEAL DIPHTHERIA.

The literature of our subject reveals the fact that there is hardly a point which is not disputed, whether it be upon the etiology, pathology, diagnosis, or treatment. Laryngeal diphtheria is not only no exception, but furthermore affords almost the greatest diversity of opinion. Can we diagnosticate membranous croup from laryngeal diphtheria, or are they identical?

Wagner considers them but different degrees of severity of the same disease. Bristowe makes no attempt at a diagnosis. Meigs and Pepper, after asserting that there is no pathological difference, proceed to say that clinically the differences between the two forms are not sufficiently marked to constantly establish their diversity, and that in their opinion the vast majority of cases of pseudo-membranous laryngitis are cases of primary laryngeal diphtheritis, with constitutional symptoms not marked, the faucial deposit overlooked, or, having been present, had disappeared before examination; while Lewin considers it impossible to make a diagnosis clinically, and insists that the only differences are recognized pathologically.

Hillier, after quoting three cases—the first evidently pharyngeal diphtheria, in which the disease had extended into the larynx; the second, a case of laryngitis with membrane, in which death occurred, without pharyngeal or general disease, from asphyxia; the third, apparently a case of non-contagious laryngitis, with albuminuria after the ninth day—insists, in an argument covering many pages, upon their identity. Dr. Jenner, formerly a strong advocate of their non-identity, seems recently to have been converted to the opposite faith. Prof. Jacobi also maintains their identity, and Thursfield, Luzsinsky, and Küster profess the same belief; while Loeb, Letzerich, and

others, assert that they have found the two processes at the same time in the same larynx, and Zoerl reports an epidemic of [illegible]

Among the strong advocates of their non-identity are Thost, Niemeyer, Oertel, Treitz-Isenbiehl, Cohen and Oppolzer. As diagnostic points the following are pointed upon:

1. [illegible] 1. [illegible]
2. [illegible] 2. [illegible]
3. [illegible] 3. [illegible]
4. [illegible] 4. [illegible]
5. [illegible] 5. [illegible]
6. [illegible] 6. [illegible]
7. [illegible] 7. [illegible]
8. [illegible] 8. [illegible]
9. [illegible] 9. [illegible]
10. [illegible] 10. [illegible]

Time will not permit an extended analysis of these points and the objections thereto, further than to remark that many able observers have seen albuminuria supervene upon "membranous croup;" that pharyngeal patches are considered an essential characteristic of simple membranous laryngitis, in France; that we have paralyses occurring after many other affections, and that, if the laryngeal disease appear early, there need be no marked fever or asthenia.

A question of considerable importance must not be overlooked here. It is the *laryngoscope* as an aid to diagnosis. With it, first, the presence and extent of the disease in the larynx can be made out; secondly, its absence, where from hoarseness or aphonia it had been suspected, can be distinguished. Under this head, Czermak reports a case where the attendants were preparing for tracheotomy, because of attendant suffocative symptoms, which was not undertaken, as the laryngoscope failed to detect any laryngeal diphtheritis. Lewin has with it seen the disease spread from pharynx into larynx. Fieber has diagnosticated catarrhal laryngitis in a case complicated with pharyngeal diphtheria. Martin has seen diphtheritic disease associate itself with catarrhal laryngitis which had existed an entire month previously. Polypi have been discovered as the cause of laryngeal symptoms in diphtheria. At a later stage paralysis of the epiglottis has been detected, or other paralyses have been revealed, and colloid degeneration of the cartilages witnessed. Its use in young children is, of course, impracticable.

NASAL VARIETY.

Usually diphtheria appears in the nose as an extension of the disease from the pharynx. Bretonneau and others, however, describe it as occasionally a primary affection. Scott reports, in the *Glasgow Medical Journal* in 1869, four cases of primary nasal diphtheria in one family.

During an epidemic of diphtheria we have in a given case the symptoms of ordinary coryza. Soon after, however, the marked adynamic condition of the patient, the high fever, the enlarged lymphatic glands of the neck, the changed secretion into one of a muco-purulent character or a foul-smelling, brownish colored or bloody discharge, excoriating the tissues over which it passes, with resulting ulcerations covered with characteristic membranes, renders a diagnosis unmistakable. Here also the rhinoscope may distinguish, at an early stage, characteristic marks in the posterior nares or at the base of the skull.

CUTANEOUS DIPHTHERIA.

A word will suffice for this variety. Its diagnosis depends upon the appearance of the membrane upon an abraded portion of the skin. Instances of this occurrence as a primary affection are not wanting. Frölich reports a case of a woman who had lost three children with diphtheria. Having a sore upon the nasal septum of their youngest, as a poultice, and diphtheria of the fingers, with subsequent general infection and death, resulted. Caspary, the case of a boy with excoriation of the nates, having diphtheria associate itself thereto. Subsequent paralysis resulted therefrom. We might multiply examples. Cases of primary diphtheria of the vulva are by no means rare, in which at a later period the general symptoms make their appearance.

Mention of another class of cases must here be made. Diphtheria often follows operations in surgical cases. Before mentions it as a frequent appearance in the Charité, saying that, when occurring with plastic operations, they were rendered more dangerous to life than amputations of the leg. With burnt up the membranes never appeared upon the new surfaces, but always upon the mucous membrane of the mouth. Two cases are recorded by Billroth in the *Wiener medicinische Wochenschrift* of 1870. In the first, diphtheria of the wound occurred after a resection of the inferior maxilla, followed on the fourth day subsequently by pharyngeal and tracheal diphtheria, and death on the sixth. The second, a man, in whom an exarticulation of the shoulder-joint followed a dog-bite, a pyæmic condition of the wound necessitating it. He died on the eighteenth day thereafter, the post mortem revealing diphtheritic membranes upon the tonsils, arches of the palate, and in the larynx, trachea, and bronchi. It was impossible to trace the source of the disease in either case.

SECONDARY FORM.

Among the most dangerous circumstances under which, generally speaking, diphtheria can occur, is when it is found to follow or be added to some pre-existing disease. It has been known to appear in patients afflicted with measles, scarlet, typhus, and typhoid fevers, whooping-cough, bronchitis, pseudo-croup, pyæmia, puerperal fever, erysipelas, and also with disease of a more chronic nature, as in tuberculosis of the lungs, diseases of the kidneys, suppurative inflammation of the joints, and chronic diseases of the liver. In most of the cases there is an aggravation of the general condition. There is no fixed method of its appearance, other than in the primary forms: at times with more prominent local, again with more marked general symptoms. There is usually no difficulty in its recognition.

Before closing with the diagnosis of diphtheria, there are yet to be considered the diagnoses of several complications that may appear in the course of the disease.

1st. *Heart-clot.*—Pain in the pit of the stomach; difficulty of respiration; at times peculiar, intense dyspnœa; anxiety; agitation; face at times livid, at times pallid; great prostration; coldness of the extremities; feeble, small, irregular pulse; dull, weak, or muffled heart sounds, with an occasional murmur; ordinary pulmonary sounds normal, but occasionally emphysema. Cases of this kind are reported by Chisholm, Armand, and others. Bengelsdorf mentions one of a boy of eight, who, during convalescence, was suddenly attacked with vomiting, followed by collapse, a quickened, irregular, and weakened

heart's action, systolic murmur at the apex, increased lateral dulness of heart's area, cyanosis, and death. Clots in both ventricles.

2d. On the fifth or sixth day of the disease, occasionally earlier or later, there may be a sudden rise in temperature, enteralgia, nausea, meteorismus, a decided decrease in the amount of urine passed, sensitiveness over the region of the kidneys. Children under five years of age may have convulsions, others appear drowsy. The urine, upon examination, is found albuminous, with casts, and thus disease of the kidneys is diagnosticated.

3d. A more rare appearance is one that requires but its mention to secure its diagnosis: emphysema of the skin, without tracheotomy. Güterbock reports five cases. Traube and Virchow consider it indicative of interlobular emphysema of the lungs. No cases affected with it have been known to recover.

4th. The paralyses occurring with diphtheria are not difficult of recognition. The nasal, its most frequent form, announces its presence by the production of a nasal voice, then regurgitation of food through the nares. The soft palate becomes relaxed, and fails to respond to any irritation. Diphtheritic paralysis may become quite general; cases are on record of paralysis involving the ocular muscles, the ciliary muscle, epiglottis, muscles of the larynx, face, extremities, back, and scapula—in fact, almost all parts of the body. Even locomotor ataxia has been noted, the history of the case and the concomitant symptoms alone rendering a diagnosis positive. The vagus also is at times affected, and establishes its diseased condition clinically after the following manner: paleness; coldness of extremities; præcordial distress; gasping; breathing with normal respiratory murmur; irregular pulse; instead of heart-sounds, weak murmurs. Electricity properly applied by Duchenne relieved these distressing symptoms.

The extension of the disease into the Eustachian tube is diagnosticated by the pain in the ear it produces, especially with swallowing. Diphtheria of the œsophagus cannot be diagnosticated clinically (Steffan).

Considering the *prophylaris*, we must bear in mind the established contagion; remember that deleterious hygienic conditions favor it, promoting the production of the disease and increasing the susceptibility thereto. The sewers should be carefully inspected; defective ventilation corrected; overcrowding of people in dwellings checked; excretions properly disinfected; the isolation of cases secured; members of the family free from the disease not permitted to convey the disease to others; all instruments used thoroughly disinfected before use in non-diphtheritic cases; the general health cared for; the resisting power increased.

Furthermore, the sad experience of the many physicians who have lost their lives, acquiring the disease while attending those afflicted with it, and of the equally large number who have conveyed it to their families, must ever remind us that we are but mortal.

In 1872, in Siebenbürgen, they succeeded in stamping out an epidemic only by means of the extreme isolation we practise in small-pox.

Local treatment.—The advocates of the local treatment claim with it, 1st, to restrict the disease, by those favoring its local origin, to prevent general infection; 2d, the speedy removal of the membranes; 3d, the maintenance of the health of the surrounding tissues.

The abstraction of blood is harmful, leech-bites a new seat for the disease. Rehan urges scarification. Ice is strongly recommended by a large number of observers, for local application and internal use. Kunze, however, objects to it. Oertel says its object is only to relieve pain, especially useful when there is much engorgement. Letzerich favors the frequent removal of the membrane, following it by strong cauterization of the abraded surface. Generally, however, this is disapproved. Strong cauterizations, with whatever substances, tend—despite the evidence of a few—in the eyes of the vast majority, to increase the infiltration of the tissues, favor the diffusion of the disease into the depth of the affected parts, gain a more ready entrance into the circulation for the virulent matter—in fact, aggravate the disease generally. J. Solis Cohen considers chlorine the best remedy locally and internally, as do also Balfour and Dyes, of varying strength according to the age. But few local remedies are used so largely, and approved so highly, as the tincture of the chloride of iron.

Of the other disinfectants used, the following have each their warm advocates, as well as their opponents: salicylic acid, carbolic acid, sulphurous acid, sulphur, permanganate of potassium, and chloral hydrate. A second class of medicaments are the solvent. At their head lime-water must be placed, somewhat improved in its action by the addition of a caustic alkali, about 2 gtt. to the drachm. Lactic acid, alcohol, bromine and its compounds, the salts of sodium and lime, pepsin, chloride of ammonium, must undoubtedly be considered inferior. Another class still are the astringents, of which tannin, sulphate of zinc, and Monsell's salt in powder, are to be given the preference. Furthermore, these have been applied with doubtful effect: the tr. of iron, the various balsams, the cyanide of silver, calomel, and turpentine.

The chlorate of potassium has, until recently, enjoyed quite a specific reputation. At present, however, it is being quite generally discarded. Prof. Jacobi advises its use in cases where catarrhal stomatitis is also present, in order that the surrounding tissues may be rendered healthy.

Carbolic acid has been injected into the tonsils by Traube, in three per cent. solution. The above-mentioned astringents, disinfectants, and other chemicals, have been used as gargles, washes, insufflation in powder form, and in every imaginable way and of varied strength.

Of late Eidam and Oertel have been advocating the use of steam. The latter argues in its favor, at great length, in Ziemmsen's Cyclopedia, claiming for it the production of an increase in suppuration, with a consequent line of demarcation, even within twelve to eighteen hours after its use; no further spread of the local disease; a rapid separation of the membrane, with no reproduction thereof. This plan, furthermore, by producing a layer of pus next the mucous membrane, renders impossible all further absorption of the diphtheritic poison, which, in his mind, keeps alive the disease. As medicated solutions, he uses alcohol properly diluted, chlorine water, fifteen to thirty per cent., permanganate of potassium, 1½ to 2½ grs. to the ounce, or carbolic acid, 2½ grs. to the ounce, usually as gargles, as with the steam they are too irritating. The steam inhalations are kept up for a quarter of an hour at a time, and repeated every half-hour or hour.

Schwanda, of Vienna, acting on the principle of the local origin of diphtheria, as explained by the

germ theory, and the fact that electricity has the power of affecting lower organisms, has used the electrical treatment in simple cases of diphtheria. Among noted patients treated in this manner were the renowned Professor Gustav Braun, of Vienna, and the Duchess of Wurtemberg, in both of which cases he reports cures after two or three applications, and improvement with each sitting.

Whatever pathological opinions the profession may entertain, all are united in the conclusion that, of itself, local means are inefficient, and that our main reliance must be upon general treatment.

As to the *agents* for this disease:

1. Swearingen, of Fort Wayne, regards as such, prompt cinchonism.

2. Schetten, of Dresden, with sulphurous acid internally, has delivery once on the third day and no attendant implication of the lymphatics.

3. Of late, L. W. Chapman, of Brooklyn, claims for the early use of alcohol a specific effect. He uses as much as can be tolerated without producing excitation. He considers it an antidote, and hence does not await any signs of depression. Oertel, however, finds that its premature use may produce an effect contrary to what has been expected, increasing the frequency of the pulse, elevating the temperature, irritating the brain and cord, and exhibiting serious nutritive disturbances. Hillier also has seen bad results with it. While a case of my own, a child twenty months old, died despite the fact that during two weeks she took a gallon and a half of Rhine wine and a large amount of old cognac.

4. The fourth specific of recent origin is the natron benzoicum, or benzoate of sodium. First recommended by Buchholz, later endorsed by Klebs and Braun, it seems, further, to have stood the test of Max Schüller in the *Deutsche medicinische Wochenschrift*, Nov. 11, page 123, for the year 1878. Its administration was followed not only by prompt defervescence, but also an apparent check was put upon the progress of the disease. The use of ten to twenty grammes, or 3 ijss. to 3 v. in the course of the day, was practised. Prof. Jacobi, who has used the drug in diphtheria, reports it a useless remedy. It is, however, the subject of considerable controversy today in Germany, but more particularly in Austria.

5. Sansom, in the *British Medical Journal*, Dec. 24, 1870, extols the virtues of the sulpho-carbolate of sodium. He relies upon it exclusively in the treatment of diphtheria, using it with an adult in doses of twenty to thirty grains, three times daily, and occasionally even in drachm doses every four hours.

Henoch, dividing the disease into three grades of severity, says the milder cases are cured with any, and without any treatment; the more severe, by no treatment as yet known can be prevented from becoming still more severe; whilst the most severe, including the gangrenous and most cases of laryngeal disease, are fatal under any treatment.

The disease has a tendency to terminate fatally, because of asphyxia, high-fever, asthenia, hemorrhages, exhaustive vomiting, or diarrhœas, syncope, and complications arising from disease of the kidneys, heart, lungs, or other internal organs, and arterial or nervous systems. These must furnish the indications for treatment.

The following principles are well established: first of all, that there be in the sick-room pure air, as few attendants as possible, the temperature of the room about 68° to 70° F. The high fever is to be held in check by sponging, baths, quinine, salicylic acid, mineral acids, or other antipyretics. All exhaustive discharges to be checked. All tendency toward exhaustion struggle to be fought with highly concentrated nourishment, strong stimulants, and tonics. The toleration of stimulants in severe cases is marvellous. Flint mentions the case of a girl of fourteen, who took one half ounce of brandy hourly. Oertel has given as much as a gallon in the course of the day. Their moderate use is absolutely necessary prior to the appearance of exhaustion.

Iron and quinine are constantly indicated. Of the former, the tinctura ferri chloridi is generally used—as a rule, fully as well as the dialyzed iron. In extreme cases Bertenchiff's preparation, containing one per cent ferri chlorid, dissolved in one part of ether and three of alcohol, combining as it does, stimulant and tonic properties, is recommended. Dr. Slade is under the impression that with preparations of cinchona and alcohol only has he seen real improvement. Hallier's acid is an excellent tonic in some cases.

Good diet must form a great feature of the treatment, and, when the stomach alone fails to accept enough, rectal alimentation must be resorted to.

When extreme exhaustion seems to threaten life momentarily, Demme has seen excellent results and permanent cures follow the transfusion of blood.

Aside from these established rules, we have the French claiming good results from calcules in large quantities; Lasserre urging the early and extensive use of diaphoretics; a large number of observers claiming good results from the internal use of sulphurous acid, permanganate of potassium, chlorine-water, and other disinfectants, and a large number of equally reliable authorities denying their utility. With many the sulphites are the *sine qua non*.

Against the long-continued and extensive use of the chlorate of potassium internally, Prof. Jacobi, at the last State Society meeting, raised his voice, claiming that, when used to exceed one-half drachm in twenty-four hours, with a child less than three years of age, or more than two drachms in an adult, we were sure to have nephritis. Furthermore, he argues that it does not furnish oxygen to the blood, as it has been repeatedly proven to leave the body chemically unchanged. The tendency to syncope must not be forgotten. Hence, exertion of whatever kind, excitement, or other causes that might occasion it, must be carefully avoided.

Where the nares are involved, either primarily or secondarily, in addition to the general measures above-mentioned, the local measures applicable to the throat are to be used. Cleanliness, disinfection, a free supply of steam, or water with the douche or syringe, are the special points indicated.

Cutaneous varieties are not to be disregarded. In addition to the local, general treatment is to be instituted. The secondary forms in particular, because of their fatal tendency, will require the utmost care and the best of engineering with reference to sustaining measures.

The presence of heart-clots need not cause us to despair, as Robinson has seen well-marked cases recover. Produced as they are, probably, by hyperinosis, the salines, the citrates and acetates, ammonia either in liquid form or as the carbonate, or the injection of alkaline solutions into the veins, are indicated, while general sustaining measures are to be vigorously pushed.

Where kidney complication is present, the acetate of potassium in addition to digitalis internally, or applied locally in the shape of fomentations with

the infusion, render good service. Letzerich suggests hot applications to the region of the kidneys, while Browning urges the local application of electricity, especially where there is a cessation of the urinary secretion.

The paralyses are usually cured with strychnia and time. If not, other tonics and electricity here also help us out. As much as a thirtieth of a grain of strychnia has been given a child three years of age three times daily.

Finally, we are to consider the treatment of laryngeal complications. The tendency to death is by asphyxia. Among the means for securing relief are emetics to cast off the false membrane and alkalies to perhaps gain its solution. Albu injects lime-water into the larynx and trachea to gain this last point.

When, however, vomiting no longer secures relief, emeties are helpless, stenosis increases, the remissions between the asphyctic attacks disappear, anæsthesia of the skin appears, it is time to consider the question of tracheotomy. If then, the beginning asphyxia be not of spasmodic origin, susceptible of relief from chloroform or belladonna, or produced by œdema of the aryepiglottidean folds relieved by incision, or of loose membranes which can be removed by the forceps, the operation is indicated.

Age is no contra-indication. Dujardin has operated on children one year of age; Bourdillat at ten months, Foster at eleven months, Isambert at sixteen months—all successfully. Archambault, in fifty-three cases, where there was complete insensibility, was successful in saving seventeen lives. One of these was a child of thirteen months. Many observers have seen cases where the disease had not only spread into the larger bronchi, but also into the more minute ramifications; have witnessed congestions of the lungs, broncho-pneumonias, and many other complications present at the time of operation, and not impede their recovery. Indeed, Trousseau says there is no contra-indication.

Of a vast number of statistics now before me, it is a frequent observation to find operators with thirty-three per cent. successes, and occasionally those fortunate enough to save half their cases.

As to the method of operation, the low operation is usually avoided. As a rule, it is considered better to at once cut down to the trachea. Bourdillat, with this plan, saw ten recover out of sixteen operated upon, and the Hospital of St. Eugene had thirty-five per cent. successes in 1866 and forty per cent. in 1867. Time forbids further discussion of this question.

Hofmokl tells us to remove the tube when defervescence occurs, when on closing the tube a candle can be extinguished with the breath at a distance of fifteen to twenty centimetres, and whispered words can be uttered. No trial attempts in its removal are to be made. In all cases a normal voice and no stenosis of the trachea resulted.

V. Koepl, in discussing the after-treatment, reports a case carried out into the open air, no medicine given, and a cure resulting (Transactions of Physicians of Steiermarkt, 1871). Steiner, however, restricts the diet, creates a warm, moist atmosphere, secures a free amount of oxygen, binds a moist cravat about the neck, which is constantly remoistened, and secures extreme cleanliness of the tube and wound. Busch, Settegast, Monti, and others, keep up steam inhalations of lime-water, and watch carefully the general symptoms.

PROGRESSIVE PERNICIOUS ANÆMIA:

A Disease of the Vaso-Motor System.

By HERBERT W. LITTLE, M.D.,

HOUSE-PHYSICIAN AT THE PRESBYTERIAN HOSPITAL, NEW YORK.

Cases of progressive pernicious anæmia are not of very common occurrence, and are generally of sufficient interest to demand some little attention on the part of the practitioner. The following case occurred during the service of Dr. Burrall:

Mary Ann C——, aged twenty-seven, was admitted into the Presbyterian Hospital, October 1, 1879. She was a single woman, had lived in the country most of her life, and had been in comfortable surroundings, although she had acted as a domestic. Her family history, as far as was known, was good. She had always been a temperate, hard-working woman, and had enjoyed excellent health up to last June. At that time she suffered severely from intermittent fever while residing in a malarious district in Westchester County, N. Y. She lost her appetite at this time, and had slight frontal headache and general malaise for three days at the commencement of the attack, followed on the fourth day by œdema of the legs and feet; no ascites. Lost much of her hair subsequently, but felt no other after-effects. She was quite well again until three weeks ago, when she was thoroughly wet in a storm, and went home feeling chilly, and generally miserable. The following day vomited much, and has continued to do so at intervals since. Became very anæmic; lips and nails colorless; slight headache; lost her appetite; passed urine freely.

When she came under observation, she was a woman of medium size; hair black, sprinkled with gray. Body well covered by fat; extremely anæmic; slightly jaundiced; some œdema of feet and legs. No fever. Tongue large, papillæ pale and flabby. Slight attacks of pain in the abdomen, extending from the epigastrium to the back and lumbar regions. Frequent nausea, and vomiting of food, with a clear, yellow fluid. Bowels constipated. Heart, lungs, and kidneys normal; liver and spleen somewhat enlarged. Sleeps well. Venous murmur in the neck; pulse weak and gaseous. She feels extremely weak. Urine abundant (forty-one ounces in twenty-four hours), which, on examination, gave a negative result. A few drops of blood were taken from the finger for microscopical examination, which showed that the red corpuscles were few, and did not cohere in rouleaux; the white corpuscles were not in excess.

The œdema of the feet and legs disappeared while the patient remained in bed. Vomited a greenish fluid, and about all she ate; appetite poor. On the 10th the œdema of the eyelids, which appeared four days previously, disappeared, and the vomiting was somewhat checked. She seemed to be a little better; a slight tinge of color appeared in her cheeks.

On the 15th vomiting again appeared, also bleeding from the gums. Passed urine frequently; getting weaker. Vomiting and weakness gradually increased until the 17th, when she had a sudden change for the worse, becoming very restless, and asking to sit up in a chair. Sank rapidly, and at 6.40 A.M. she died.

Necropsy, made by Dr. W. H. Porter, thirty hours after death. Body apparently not much emaciated; but when section was made, the apparent plumpness of the body was due, to a great extent, to the œdematous condition of all the tissues.

Pericardium and heart.—The sac was normal, but contained eight ounces of clear serous fluid. Heart weighed ten and a half ounces; fatty and anæmic. Valves free.

Pleuræ and lungs.—Extensive pleuritic adhesions were found over the entire surface of the right lung; left, free from adhesions. On section, both lungs were found normal, with the exception of a small cheesy nodule at the apex of the right lung. Weight of both lungs, thirty six ounces.

Spleen.—Enlarged and flabby; weight, sixteen ounces.

Alimentary tract and bladder.—Normal.

Kidneys.—Weight of left kidney, six ounces; weight of right kidney, five ounces. Capsule non-adherent. On section, the surface was very pale, almost white, and looked fatty. Numerous small ecchymotic spots were seen in the pelvis, such as are seen in the yellow kidney of scarlatinal nephritis. On microscopic examination they were found fatty, the epithelium swollen and granular, indicating extensive parenchymatous changes. Numerous small, round corpuscles were also observed.

Liver was considerably enlarged; weighed sixty-six ounces. Portal circulation free. Gall-bladder contained two gall-stones with irregular surfaces. On microscopical examination the liver was found fatty and studded with small, round corpuscles.

Bones.—All the bones of the body were very soft, especially the ribs, which could be easily cut with a knife.

Treatment has effected but little in these cases, and this case followed the usual course. She received iron at first, but as vomiting came on it was discontinued. The success of the treatment by transfusion has been so slim that it was not deemed advisable to resort to it in this case, and as the patient was apparently improving, it was hoped she would continue doing so, and there would be no necessity for such interference. Unfortunately, however, she had a change for the worse. In all of Quincke's* cases the patients died, and in one case the transfusion was the cause of hemorrhages in the brain, heart, stomach, etc. Pepper† has also seen dangerous symptoms follow transfusions. Treatment by phosphorus has been quite as unsuccessful. Bradbury‡ reports an interesting case in which phosphorus had been used, but to no effect. Pye Smith‖ relates a case in which improvement had been slight under the use of phosphorus.

Now, then, comes the question of the etiology of the disease. Within a few years the etiology of diseases has been traced back until they have been placed, probably, in their proper category, and until many of them have been classed under disorders of the nervous system.

Basedow's disease was considered by Basedow himself, Hiffelsheim, and Beau to be due to a modification of the blood analogous to chlorosis; but recently the theory is that which attributes Basedow's disease to an affection of the sympathetic system (Rosenthal). Addison's disease, generally supposed to be a chronic inflammation of the suprarenal capsules and not connected with the nervous system, is now gradually being considered as a disease of the latter. According to Risel, Addison's disease consists of a paralysis of the abdominal sympathetic plexuses from a propagation of the inflammatory processes developed in the suprarenal capsules. This gives rise to general anæmia on account of the stasis of blood in the abdominal viscera (Rosenthal). And now even chlorosis is regarded as a disease due to a disorder of the nervous system.

Why, then, is not progressive pernicious anæmia a disease of the nervous system? We are inclined to think it is, and of the vaso-motor system. It consists of an irritation of the vaso motor nerves, causing contraction of the arterial muscles. It may occur directly or indirectly. Directly, from the action of cold upon the arterial muscles, causing contraction, with paleness of the skin, etc. Indirectly, as from inflammation of the spleen. In the majority of cases of progressive pernicious anæmia reported, whether or not the patient had suffered from malarial poisoning, there had been hypertrophy of the spleen. This hypertrophy may be due to a retention of the cellular elements, and not to their multiplication, as are enlarged spleens from malaria due. As the red globules are below the normal proportion in this disease, we presuppose the destruction of the same. But whether this destruction takes place in the spleen or liver, or when malaria has poisoned the system it is due to its pernicious influence on the red blood-corpuscles, it is of a secondary nature. Or, again, the irritation may be transmitted from the centre of vaso-motor nerves.* Rudge says the centre of vaso-motor nerves lies in the cerebral peduncles; others say in the cerebrum, higher up; still others, in the medulla oblongata, and that they have special nerve-centres (Wagner). Goltz and Heubelt say, besides the medulla oblongata the spinal cord is also an independent central organ for vaso-motor nerves. However, leaving the situation of the vaso-motor nerve-centres open for discussion, it will be shown farther on that this irritation may be transmitted. Brown-Séquard first demonstrated that, by electric irritation of the sympathetic, conditions opposite to those caused by its division resulted, but more slowly—namely, contraction of the vessels, paleness and lowering of the temperature of the part. According to Dubois-Reymond (*Arch. f. Anat., u. s. w.* 1860, *p.* 461), those cases of migraine in which the affected half of the head is pale, etc., depends upon a tetanus of the muscles of the part. It is a fact that vascular spasm will produce paleness, and if long continued will give rise to anæmia. Trousseau† mentions a case of a young girl who, in the enjoyment of very good, health received a sudden fright during the night. The next morning her health was affected, and four days later she came into his wards with all the signs of confirmed chlorosis. Also a girl who, consequent upon, and some days after, a violent mental emotion, became chlorotic. Then he goes on to say: "These cases show you how little importance can be attached to the primary state of the blood; and how important it is to place anæmia among the secondary causes of chlorosis. Dr. Barlow‡ mentions a case of intense anæmia in a child seven years of age, directly following a severe fright.

The indications of a nervous affection in this disease are: frequent cephalalgia, vertigo, syncope, neuralgic pains, dyspepsia, vomiting, diarrhœa, mental depression, muscular weakness, pallor of skin, and reduction of temperature (although there is a rise in some cases). The symptoms of anæmia are paleness, lower temperature, and diminished function of the affected parts (Wagner). The pallor

† Clinical Medicine.

‡ Brit. Med. Jour., 1876.

and all disorders of innervation can be readily explained as due to the arteiral spasm, caused by an irritation of the vaso-motor nerves. It is a well-known physiological fact that powerful irritation of the centre of vascular innervation produces contraction of the cerebral arterics, and the irritation may be propagated to the neighboring centres in the medulla oblongata. These are vaso-motor disturbances.

Broadbent * says pernicious anæmia might be described as Addison's disease, without the disease of the suprarenal capsules, and without the bronzing of the skin. If, then, we accept the theory of Risel, that it is a paralysis of the abdominal sympathetic plexuses from a propagation of the inflammatory processes developed in the suprarenal capsules, it only serves to corroborate our belief that it is a disease of the vaso-motor system. Quincke says that we have not to do with a single diseased state, but pernicious anæmia, like anæmia in general, is the product of the most different morbid processes, and represents, as it were, the highest development, the ultimate stage of anæmia.

Certainly, this anæmia cannot be explained by the usual causes—loss of blood and insufficient nourishment. For in but a few of the cases reported have the patients been subject to losses of blood, or have they been on a "starvation diet" (the apparent plumpness of the patients being averse to this).

We think as Purser † does, that to consider pernicious anæmia as if the whole change resided in the blood, is absurd. "The blood does not make itself, it does not consume itself, and it is to the organs of its formation and consumption," or to its nerves, "that we must look to as the source of its changes." The fatty condition of the body and organs may be explained as due to deficient combustion from imperfect oxygenation, from a lack of red blood-corpuscles. And it is well known that chlorotic girls often become quite fat.

ON GIACOMINI'S METHOD OF PRESERVING THE BRAIN.

By WM. OSLER, M.D., M.R.C.P., London,

of mcgill university, montreal.

A method by which brains could be permanently preserved as dry preparations has long been a desideratum to anatomists and physiologists. I should like, therefore, to call the attention of those interested in the subject to the following method devised by Prof. Giacomini, of Turin, and communicated to the Academy of Medicine in that city in 1878. A summary of his article, by Prof. Turner, appeared in the *Journal of Anatomy and Physiology* for January, 1879. I was struck with the description, and though somewhat sceptical, determined to give the process a trial. The results have greatly exceeded my expectations, and I am able to state that by this method the brain can be permanently prepared in the dry condition, retaining the external form and general characters in such a way that it appears like a beautiful wax model. I exhibited a set of brains thus prepared, at the Saratoga meeting of the American Association for the Advancement of Science, and from the numerous letters which I have received from various quarters respecting the process, I feel sure that its publication in full will be satisfactory to many.

As the *Journal of Anatomy and Physiology* has a very limited circulation on this continent, I will give Prof. Turner's condensation in full:

"In the first stage, the fresh organ, still enveloped in its membranes, is immersed in a saturated solution of zinc chloride. In this it floats with a little of its surface above the fluid; and so, while its form is not interfered with by pressure, it must be turned two or three times a day, in order that all parts may be uniformly acted on. If the subject has been dead for some time, 600 grammes of the solution may be injected through the carotids under slight pressure, so as to give a firmness to the somewhat softened brain before its removal. After forty-eight hours the surface is hard enough to have the membranes removed. Let this be done without taking the organ out of the solution, or, if it be taken out, let it be put into water immediately, so that it may the less lose its form by pressure. After having been cleaned, let it remain in the solution till, as the hardening proceeds, it begins to sink no longer, and then remove it. At this stage it will be firm, slightly diminished in volume, the fissures a little opened, and the color whitish, unless the membranes have been left on too long, in which case the course of the large vessels will be stained of a rusty color from the blood-pigment. Now it is immersed in alcohol of commerce for not less than ten or twelve days, but it may be for an indefinite period; here it sinks and must be often turned to avoid deformity by pressure on the bottom of the vessel, and it is well to renew the spirit two or three times—the oftener the sooner the process is required to be finished. After the alcohol, the consistence is greater, the size a little less, and the convolutions somewhat closer together.

"Now comes the second stage. Let the organ be immersed in glycerine of commerce, with one per cent. of carbolic acid added. When first put in it floats with some of its upper surface above the surface of the glycerine; but, gradually becoming heavier as the alcohol evaporates and glycerine is imbibed, it sinks deeper and deeper until it is just level with the liquid; then it is taken out. In this part of the process neither surface, color, consistence, nor volume are altered, but it becomes heavier. A brain should gain from 150 to 200 grammes in from twenty to thirty days, according to its volume. Now it is set aside for several days until the surface is dry, and then cover it with several layers of gum-elastic varnish, or, better still, marine glue diluted with a little alcohol. This varnish is not to prevent evaporation—the glycerine does that—but is simply a protection against the dust and injury."

I have followed the details of the process very closely, and have nothing essential to suggest in alteration. Less than a saturated zinc solution will suffice. I have some well-prepared specimens in solution of the same strength as Burnett's fluid 50 per cent. The ordinary alcohol, or methylated spirit, as we use it in Canada, will serve. In these fluids the organ remains of a natural grayish white color, but in the glycerine it becomes of a light brownish yellow. The purer the glycerine the less alteration in color.

In varnishing I have used the ordinary crystal varnish, which answers the purpose very well, and leaves a nice light surface. A solution of gum caoutchone in chloroform makes a good coating, but is darker.

The most troublesome part of the process is the removal of the membranes. From the lateral parts of the hemispheres they strip off readily enough; but on the occipital lobes and cerebellum the pia mater is thin, and after two days' immersion is very adherent,

* Practitioner, January, 1875.
† Dub. Med. Jour., November, 1877.

so that it requires great care to remove it without tearing the brain-substance. In the preparation of a base to show the superficial origin of the nerves, great care is needed, and the dissection is very tedious. In several instances in which the brains were very firm, I removed the membranes before placing them in the zinc solution, and found this answer equally well. Brains taken from patients dead of chronic wasting diseases, or from old persons, make the best preparations, as the fissures and sulci are wide, and the convolutions very distinct.

With the convolutions on one side labelled, and Ferrier's centres mapped out with red paint on the other, a brain prepared in this way makes a beautiful museum specimen, and is, moreover, exceedingly useful for demonstration in anatomical, physiological, and even medical lectures. Spots of cortical softening or hemorrhage on the surface can be very well shown, the lesion preserved, and its position accurately defined. Sections can be treated in this way, but when dried and varnished the contrast between the gray and white substance is not very marked. Still, vertical sections, made after Pitrè's method, retain their characters sufficiently to show the relation of the basal ganglia and the ventricles, and they are much more convenient to handle than moist preparations. The process answers very well for mammalian brains; not quite so satisfactorily, Prof. Ramsay Wright, of Toronto University, informs me, for those of invertebrates.

Progress of Medical Science.

Benzoate of Sodium and Benzoate of Magnesium in Tuberculosis.—Prof. Klebs, writing to the *Allg. Wiener med. Zeit.*, No. 1, 1880, gives the results of a series of investigations, with the following conclusions: tuberculous miliary eruptions can be made to proceed to self-limitation or retrogression by the internal administration of the benzoates, particularly the benzoate of magnesia.

In apex infiltrations, unless of very long standing, even when accompanied by hectic fever and preceded by hæmoptysis, the exclusive application of soda benzoates by inhalation (grm. 10 a day), or by insufflation (grm. 2-3 per day), together with the internal administration of benzoate of magnesia, accomplishes a permanent lowering of temperature, cessation of catarrhal manifestations, and increase of the bodily weight. The latter may be considerable. In one case a gain of ten pounds in three weeks was observed.

In some cases, however similar in character, no benefit is obtained by this treatment. In such cases there is destruction of lung-tissue, probably. Yet, even in these cases, large doses of benzoate of magnesia sometimes successfully combat the fever, where comparative trials with salicylic acid have shown the merely temporary effects of this drug.

Klebs also recommends the hypodermic injection of pilocarpine (one-sixth gr.) in place of the expectorants still in vogue. He also favorably mentions the inhalation of guaiacum in decoction. Both methods are applicable to cases of persistent catarrh due to cavities. The cavities once thoroughly cleansed, the sputa no longer containing micrococci, improvement generally lasts. Mild febrile and catarrhal attacks, which are apt to appear, may be similarly treated, the patients not losing in body weight.

There remain cases which even this method will fail to affect in a favorable manner. Finally, the author calls attention to the noteworthy fact of the entire absence of amyloid degenerations observed in twelve fatal cases. These cases had been marked by profuse discharges and advanced emaciation.

In conclusion, Klebs remarks that he can lay no claim to the discovery of an agent that will cure tuberculosis; but in numerous instances it will be found that by his method the progress of the disease is checked, and an ultimate cure may be established.—*Allg. med. Cent.-Zeit.*, Jan. 10, 1880.

Laryngoscopic and Rhinoscopic Examinations in Children.—In a recent article on this subject, Dr. Schrotter, of Vienna, urges the universal adoption of instrumental examinations for the accurate diagnosis of the various nasal, pharyngeal, laryngeal, and tracheal affections of childhood. Very erroneous views of the difficulty of manipulating children for this purpose are still entertained. With the ordinary precautions, equally necessary for such local inspection in adults, a truly valuable aid to diagnosis is obtained. He has performed laryngoscopy in a child six months old, and was thus enabled to positively assert the absence of a supposed croupous laryngitis. He has also experienced no difficulty in performing intra-laryngeal operations in children, and cites illustrative cases.—*Monatsch. fur Ohrenheilkunde*, Nov., 1879, No. 11.

On some Cases of abnormally High Temperature.—To refute the idea that the occurrence of a very high temperature is not always indicative of grave consequences which may follow, Dr. Donkin reports eight cases occurring in hospital practice, in which there was a very marked increase in the degree of heat. The following is selected as being the most interesting: A nurse, aged nineteen, at the end of an attack of enteric fever, had a rise in her temperature one afternoon to 105°, and in the evening of the same day, at half-past eight, to 109.4°. After remaining in a bath at 90°, which was gradually cooled down to 60°, the temperature in the mouth, at the end of ten minutes, was found to be 97.6°. After this time all typhoid symptoms disappeared, but there were remarkable fluctuations of temperature for several months after. On Jan. 25, 1878, the temperature at midnight was 110°; soon after it fell to 109°, as registered by another thermometer. When the first thermometer was again used, it indicated 108.4°. A third thermometer in the mouth showed 108°, but at 12.30 only 98°. After this it remained at 99°. The skin, at this time, was not hot to the touch. On another occasion, when the temperature was high, the number of respirations was increased, and at least on one occasion the skin was hot to the touch. D. claims that these increases in temperature were evidently of short duration, because it was difficult to obtain a high registration on two successive occasions. At one time, the temperature in the right axilla was 107.2°, in the left 107.8°, the pulse 192, the respiration 32, and the skin felt hot when the hand was applied to the surface. Five minutes afterward the temperature in the right axilla was 98.6°, in the mouth 98.8°, and the respiration sank to 24. The highest temperature recorded at any time was 111.6°. These high temperatures were "generally unaccompanied by any discoverable constitutional symptom other than a feeling of 'flushing,' or 'rushes of heat,' described by the patient." She suffered from no organic disease, but had a retroflexion of the uterus and displacement of the left ovary.

In all the cases pain was a prominent symptom. Seven out of the eight cases reported occurred in females. All the cases ended in recovery. D. believes, as far as his observation goes, that these cases are of nervous origin.—*Brit. Med. Jour.*, Dec. 20, 1879.

On the Relative Paralyzing Action of Atropia and Pilocarpine on the Heart.—After a series of experiments with atropia and pilocarpine, Drs. Ringer and Morshead, of London, arrive at the following conclusions with reference to the above drugs: Sulphate of atropia applied locally is almost as powerful a paralyzer of the heart as pilocarpine. Atropia either paralyzes the excito-motory cardiac apparatus, or the cardiac muscle, or both. Extract of muscaria paralyzes the cardiac muscular substance, and probably the excito-motory apparatus. Atropia antagonizes, in part at least, the action of muscarin, by possessing for the cardiac structures a stronger affinity for muscarin, whereby atropia, a cardiac paralyzer, replaces muscarin, which has the same property, but in a greater degree. When this takes place, the weaker paralyzing effect of atropia is substituted for the stronger paralyzing power of muscarin, so that a heart weakened or arrested by muscarin becomes strengthened, or commences beating again on the addition of atropia. Pilocarpine, which weakens or arrests the heart's action, also antagonizes the action of muscarin, and still more powerfully paralyzes the heart. It is suggested by Ringer and Morshead that this antagonism is due to the fact of pilocarpine displacing muscarin, the former having a stronger affinity for the excito-motory apparatus and muscular substance, its weaker paralyzing action being substituted for that of muscarin. Atropia, having a stronger chemical affinity for the structures of the inhibitory apparatus, displaces muscarin, and substitutes its paralyzing action for the stimulant action of muscarin. Pilocarpine causes the heart to cease to beat in a much shorter time than atropia followed by muscarin.—*The Journal of Physiology*, Dec., 1879.

Czerny's Operation for the Radical Cure of Hernia.—Of the many operations advocated for the radical cure of hernia, none have been proposed, thus far, that are free from objection of one kind or other. The advantages claimed by Czerny for the operation adopted by him are, that the results are more certain, as the fibrous columns of the external ring are drawn close together, and an exact application of the sutures can be made, causing a narrowing of the internal aperture. The operation is as follows: An incision is made along the whole length of the hernia. If intestinal and reducible, the contents of the sac are returned to the cavity; if irreducible and intestinal, they are dissected loose and reduced, the sac being ligatured at the neck and cut off. When the contents are omental, they are included in the ligature with the sac. The fibrous columns of the external rings are drawn together by an uninterrupted suture of strong carbolized catgut. After the insertion of a drainage-tube, the wound is closed with sutures and dressed antiseptically. This mode of procedure has been adopted in nine cases of inguinal hernia, without the occurrence of peritonitis. The first recorded case of the operation in this country was in a man who had an irreducible hernia, that rendered him unable to pursue his occupation, as he could not wear a truss. The result, by Dr. E. W. Lee, was successful.—*Chicago Medical Gazette*, Jan. 20, 1880.

The Prevailing Epidemic of Measles in West London.—As the result of a personal analysis of twelve cases of measles, Dr. W. B. Cheadle arrives at the following conclusions: No immunity is afforded by a previous attack of the disease. Nine of the patients had the disease previously, eight within a year of the first appearance. The coryza was very slight, as also the sneezing, the latter sometimes being absent. The laryngeal catarrh was severe, and the cough very violent and incessant at the height of the disease, so much so as to prevent sleep or any kind of rest for a number of hours. Another prominent feature, commencing with the first symptoms and lasting until the decline of the eruption, was the vomiting, said to be caused by the measles poison, and not by the cough. The eruption was profuse, more raised and papular than is usually the case, and confluent in patches on the face and extremities. Severe earache supervened on the fourth or fifth day after the eruption first made its appearance; it lasted several hours, and disappeared without discharge or other sign of otitis. As to the recurrence of the disease in the same individual a second time, C. asks whether there may not be two distinct diseases (apart from Rötheln), each of which confers immunity from a second attack of the same variety, while affording no protection against the other.—*British Medical Journal*, Dec. 20, 1879.

Long-continued Ileus cured by Large Injections of Ice-water.—Dr. Kormann, of Coburg, reports the following case: A woman, forty-five years of age, was seized suddenly with violent pain in the right inguinal region, accompanied by continued vomiting and constipation; examination revealed increased resistance and dulness in the ileo-cæcal region. The bowels were moved, at first, by injections, and the pain was controlled by hypodermics of morphine, but the vomiting and the tenderness in the iliac region persisted. On the sixth day, after a large dose of calomel and jalap, a distinct sausage-shaped tumor formed in the right side of the abdomen over the site of the cæcum, and the patient fell into a state of collapse. The bowels had not moved for four days, and a soft, doughy mass, consisting probably of retained fæces, could be felt above the tumor. Large injections of warm water were given repeatedly without result, and on the tenth day, when the patient's condition was most desperate, Dr. Kormann decided to try ice-water. He accordingly injected about two quarts of ice-water into the gut, and then manipulated the tumor gently with his hand, and while doing so felt it disappear with a distinct gurgling noise. The patient at once felt relieved from the intense pain that she had been suffering, and two hours later she had a large, soft passage from the bowels. The right side of the abdomen remained tender for a few days, but the patient rapidly recovered, and was able to leave the hospital at the end of two weeks. The passages were examined for pieces of necrosed intestine, but none could be found. Dr. Kormann thinks that this case began with a slight intussusception of the ileum into the cæcum, the lumen of the gut still remaining partially open, and that the purgative forced down a larger portion of the ileum, producing complete obstruction. The case is notable both for the duration of the intussusception and the facility with which it was relieved by the ice-water injection.—*Berliner klin. Wochen.*, No. 48, 1879.

The Spread of Small-pox.—In the week ending March 6th, there were 5 deaths from small pox in Philadelphia, 2 in Worcester, and 1 in Washington.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, March 20, 1880.

PROFESSIONAL INTERFERENCE AND THE ABUSE OF MEDICAL CHARITIES.

THE more the subject is discussed the more apparent does it become that there is a great deal of interference on the part of the conductors of college and other clinics with the patients of other practitioners. Why this should be so it is difficult to understand, except upon the supposition that clinical material must be obtained at all hazards. There is no doubting the fact that there is a great demand in our colleges and hospitals for interesting cases to bring "before the class." As the value of the clinic itself, and the consequent reputation of the lecturer, depend upon the number of such cases, it is very easy to yield to the temptation of asking of the patient as few questions as possible concerning previous medical attendance. It is bad enough when a patient who can pay another practitioner strays into a dispensary or college clinic, and gets advice for nothing; but still worse when the same patient is already under the care of a physician as a private case. In the latter instance there is such a temptation to thoroughly analyze the symptoms and make an acceptable diagnosis that the attending physician always appears, comparatively speaking, at a disadvantage. The patient generally goes away with the impression that no one could possibly understand his case better than the professor. Dr. White or Dr. Jones, who previously attended him, had no such instruments, never thought of sounding him so thoroughly, and, in fact, did not ask one-third the number of questions. And besides, did not the professor tell the young doctors that the disease was not in his kidneys, but in his heart! It does not appear that the professor himself may be mistaken, and the family physician may be right. This being assumed by the patient, it is easy to understand how the slightest hint as to the nature of the disease before the patient may be of the greatest damage to the attending physician. And yet this appears to be so little considered by the lecturers, that they practically consider every case that strays into their clinics as their own professional property.

It is not fair, however, to lay all the blame upon the lecturer or the hospital attendant, as much of the responsibility of selecting the proper and worthy cases falls upon his clinical assistants who first examine them. If proper care was exercised by these gentlemen, there would be no need for the number of complaints which reach us regarding the treatment of patients of other practitioners. In the hurry of sorting the cases, of getting a record of the name, age, and general symptoms of the patient, the possibility of being already under the care of a practitioner is seldom thought of, and the interesting case is passed on with the rest.

When the treatment in such a case appears to have been unsuccessful, and the result a bad one, it is easy to understand what an excellent text it makes for some general remarks on the want of skill of ordinary practitioners. After the battle has been lost, it is very easy for one who was not present, to look over the field and say what ought to have been done. The patient is generally on the side of the head-doctor, and not only is the regular attendant dismissed, but frequently a suit for malpractice is invited. It may be granted that these are extreme cases, and that they seldom occur. But that they should ever happen at all shows that the system of clinical teaching and the method of managing the patients that apply, need some very radical reforms.

The fact that advice is given so freely is not lost on the people. The patient who has had a free operation at the college or hospital advertises the institution and the operator to others needing similar services, and so the abuse continues. Hence it is that the hospitals and colleges are apt to absorb all the interesting cases, and the regular attendants suffer not only in the loss of experience and of the chances of reputation which these cases may give them, but of the fees which they could likewise collect. From all parts of the vicinity of New York we hear the complaint that no operations, however trivial, can be performed by the rural surgeons. This is not because there are not good operators and competent men in those districts, but that the patients know they can confer a favor on hospitals and colleges by offering themselves as subjects for free operation. Can such patients be blamed for such a preference, when, besides having the operation performed for nothing, their board bill, while under treatment, is paid by the metropolitan attendant! All this gives the country practitioner, who wishes to gain a local reputation, a very poor chance.

But to return to the pure etiquette of this question of professional interference. It is clearly the duty of every hospital attendant or college professor to in-

form himself beforehand whether or no he is giving advice or treatment to the patient of another practitioner without the knowledge or consent of the latter. He owes this to his fellow-practitioners, not only by virtue of his public position, but because of the known liability of patients of other physicians applying to his clinic for free advice. When he discovers that a patient has strayed from the family attendant it is just as much his duty to decline to give his advice as if the solicitation made by one who came under the same circumstances to his private office.

A NATIONAL VETERINARY BUREAU.

THE current statement that unless measures are taken to suppress the lung-plague among cattle, our country is liable at almost any time to lose $60,000,000 annually from that disease, has justly excited much attention. The statement is an authentic one, and facts in support of it are now being laid before Congress, with a request for national legislation upon the matter.

We suffer a great annual loss already from the various contagious diseases among domestic animals, notably from hog-cholera, and we are in constant danger of their wider spread. The lung-plague, however, seems to claim more especial attention, for it affects the live stock which we export. Its prevalence last year caused an embargo to be put upon the animals in English ports, and the disease is liable at any time, by a sudden increase, to disturb business relations very seriously.

The lung-plague now is confined to the east. It does not exist as an epidemic west of the Alleghanies. Most of our live-stock comes from the west, and is driven into the stock-yards and stables of the eastern cities, where the animals become liable to infection before they are exported or otherwise disposed of. The damage, therefore, is now done in the east, but the great danger lies in the fact that at any time the contagion may be carried west and get among the herds on the plains. Once there, the difficulty of eradicating it would be almost insurmountable, and the loss it would occasion among our 37,000,000 head of cattle would, of course, be immense.

Since the danger is largely to western cattle, while the disease is in the east, it is claimed that State interference will not be vigorous enough to deal with the matter properly. A national veterinary bureau is therefore recommended. It is proposed that such a bureau have power to make scientific investigations of the disease, and collect facts concerning the same. It should also have power to co-operate with the State authorities and to quarantine or kill infected animals wherever found, awarding compensation to the owners. Such a veterinary bureau would be modelled largely after the National Board of Health, but would make its reports to a department instead of to the President.

There are certainly great advantages in a scheme of this kind. It has already received the indorsement of the Secretary of the Treasury, and has been laid by him before Congress.

We foresee, on the other hand, that such a bureau would soon have very great power placed in its hands. The Texas fever, trichinosis, and hog-cholera, for instance, are diseases affecting widespread interests and enormous capital. Now, the work of investigating all these diseases, and of using preventive measures upon them, would presumably fall largely into the hands of veterinary surgeons. Veterinary science is rapidly advancing, and has already some very able representatives; nevertheless, as a whole, it is still in a crude state, and the great mass of those who follow it practically are without any thorough education, either scientific or otherwise. There is but one legally chartered veterinary college, at least in this State, and that has hardly more than a nominal existence. The other schools, although some of them are excellent ones, are really only licensing bodies, and their diplomas and professorships are such by courtesy, not by law. In addition to this, a large per cent. of veterinary doctors are self-educated, and totally without scientific training. It would be well, therefore, to act carefully in a matter which may throw much responsibility and authority upon these men. In addition to this, we believe it a safe rule not to increase bureaus or departments, or create special commissions when there is already executive machinery enough for the purpose which is to be attained. The Treasury Department now has bureaus which might take charge of the matter, and the Department of Agriculture has shown itself energetic and capable of doing scientific work, although it is unpopular enough as a whole. It has recently asked for a veterinary bureau.

We look at the subject in this conservative light, not because we fail to appreciate the necessity of getting rid of the lung-plague, but because there is need of caution in framing laws which might, in the end, bring only confusion between national and local authority, and reproach upon veterinary and sanitary science. The danger is not, perhaps, so very alarming and imminent. Local boards have shown that they can be very energetic and efficient.

At any rate, national legislation upon this question should be made with great care. If a national commission is eventually decided upon, it should have plenty of money and the best scientific aid that can possibly be afforded. With the proper men, money, and authority, the lung-plague could be exterminated and valuable contributions to pathological science be made. The question will be, then, whether Congress is able and ought to furnish these things.

REPORT ON THE REVISION OF THE PHARMACOPŒIA.*

The report, which, to the language of its title-page, is "a rough draft of the general principles, titles, and working formulæ proposed for the next Pharmacopœia," commends itself to the thoughtful consideration of every physician and pharmacist of progressive proclivities. Assuming that it will be favorably considered by the convention, and that it will be adopted after some amendment, we propose to discuss some of its merits and point out some of its more obvious defects.

First then, it is proposed to abandon the present division of remedies into primary and secondary classes, and to arrange all articles of the materia medica alphabetically in one list. This will probably excite some discussion, but it should be adopted.

The first convention, sixty years ago, established a primary list for "articles of decided reputation or general use," and a secondary for "those, the claims of which are of a more uncertain kind." To quote further: "In doubtful cases they have preferred to swell the subordinate rather than the primary catalogue, especially as this arrangement will be most likely to prompt further investigations into the character of the substances in question."

There can be little doubt that this plan, instead of promoting investigation, has continually checked it.

The very fact of an article being found in the secondary list has seemed sufficient to place it in contempt in the estimation of the profession generally, and this, too, whether its properties have ever been thoroughly investigated or not. Add to this the fact that the position of a drug seems often to have been decided by fashion or caprice, as evinced by the frequent changing of the same article from one to the other list, and then back again, and sufficient grounds for the proposed improvement will be apparent.

This brings us naturally to the question of dropping articles from the Pharmacopœia. As Mr. Rice says in the report, "it is necessary to be careful in this matter." We fear, however, that he and his associates have not been sufficiently careful in this respect. While we would not wish to appear in the light of champions of catnip, pennyroyal, rue, and tansy, we would still mildly protest, upon principle, against their exclusion, not simply because many less efficient articles are still retained, but because they have certain medicinal properties which have kept them in use for generations. Cataria, Hedeoma, Monarda, Ruta, and Scutellaria possess the general properties of the order Labiatæ to which they belong. The Pharmacopœia would be no better without them; it might even be improved by adding other plants from the same order, as indeed is proposed in the case of Pycnanthemum (species?), but Collinsonia Canadensis has even better claims. Coptis, Erigeron, Magnolia, Sabbatia, and Trifolium have had, and probably still have their advocates. The same remark might apply with equal justice to nearly all the drugs marked for exclusion.

In our present state of uncertainty as to the action of medicines daily employed, and especially in view of the revival of interest in therapeutics, we should be careful not to condemn any drug until its inefficiency has been fully proved. At the same time a wise discrimination should be exercised in the admission of new remedies.

One cannot fail to notice that while many vegetable remedies are marked for exclusion, the list of chemical preparations is to be largely increased. While we shall not enter into a discussion of the merits of the proposed additions, many of which are absolutely necessary, we invite attention to the apparent discrimination against medicines of vegetable origin. This may be satisfactory to pharmacists, but will it be equally so to physicians?

Another point worthy of notice is the nomenclature of vegetable remedies. While there is an evident intention to keep pace with the advances of chemistry in the nomenclature of chemical preparations, is it judicious and wise to reject altogether the claims of botanical science? It is proposed to add to the botanical names of plants the name of the author; but is this the only improvement possible or desirable? The generic name of a plant leads as naturally to its place in nature as does the basic term of a chemical compound, while the specific designation is almost as necessary as the second part of a chemical combination. Many of our vegetable remedies are now known by their generic names only, others by the specific, others by neither. There is absolutely no system whatever. This is susceptible of improvement, and should receive it. Then the student or physician could group in his mind vegetable remedies of like properties as easily as he can the preparations of iron or mercury, and not be obliged as now to exercise his memory arbitrarily. We do not advocate a sweeping change in this respect, but as much of an improvement as possible without producing confusion.

We have nothing but commendation for the proposition to abandon all measures of capacity, expressing quantities in parts by weight; and also to make tinctures, etc., of certain definite percentages of strength.

The report justly says that "there seems to be a growing demand among physicians for certain tinctures prepared from fresh plants;" and we may add that this demand is likely to become more imperative year by year. The proposition to make such tinctures officinal we consider one of the most important of the whole report, and we hope to see the plan applied to as many articles as possible.

Of the articles proposed for addition to the Phar-

* Report on the Revision of the U. S. Pharmacopœia, preliminary to the Convention of 1880, etc. Prepared and compiled by Charles Rice, Chairman of the Committee (Amer. Pharmaceutical Association).

macopœia, some will doubtless excite discussion; it is to be hoped that such discussion will be characterized by candor and not by prejudice. If Pulsatilla and Bryonia, for instance, have reasonable claims to efficiency, by all means let us have them.

To conclude our somewhat diffuse remarks, we commend the report to the careful study and thoughtful consideration of all interested in the Pharmacopœia, as in this way only can one become acquainted with its many merits and few defects. With it as a substantial basis, there is every reason to hope for a better Pharmacopœia than we have ever had.

SANITARY PROGRESS IN MEMPHIS.

A supplement to the *Bulletin of the National Board of Health* for March 13th, contains the full report of the committee charged with making a sanitary survey of Memphis. A preliminary report was made in November last, and the suggestions made at that time were subsequently adopted by the authorities of the city. The present report gives a full statement of the condition of Memphis as revealed by a house-to-house inspection.

The committee found as the result of their work the following condition of affairs: The city is insufficiently supplied with water, most of it being from wells or cisterns. Although naturally well adapted for a good system of sewerage, there has been radically none at all. The streets are not kept clean, and a great deal of garbage accumulates in them. Many of the buildings are illy constructed and ought to be destroyed. Many more need such changes as will allow of more cleanliness and better ventilation. There are very few tenement-houses, and but little overcrowding exists, but the sanitary evils are caused largely by shanties and cabins.

In nearly one-half of the buildings having cellars the sanitary condition was very bad. Privy-vaults and cisterns exist in the same basements, and often not far removed from each other; three-fourths of the five thousand cisterns and wells being so situated.

The mortality in Memphis has always been high. During three non-epidemic years, from 1875 to 1878, it was 35 per thousand; in 1879 it was 51 per thousand, two-fifths being due to yellow fever.

In regard to the present and future condition of the city, we learn that much is being done in the way of improvement. A system of sewerage and water-drainage has been adopted and is being actively introduced. It will probably be sufficiently advanced by May next to drain a large part of the city. The privy-vaults are being filled up; houses are being thoroughly cleaned and disinfected; a system of registration of disease is to be introduced, and, if a case of yellow fever appears this summer, there will be at once prompt and complete isolation. Any radical change in the method of supplying the city with water is impossible just now. Indeed, the city works under the greatest financial embarrassments. Still it is doing its very best, and it is more than probable, as a result of the work done, that yellow fever will be kept away during the coming summer. There is nowhere a more stricken place than Memphis, or one that more strongly claims our sympathy. We should be glad to see a little of the charitable enthusiasm now expending itself on the Irish turned toward our own country's unfortunates.

Reviews and Notices of Books.

THE FALLACIES OF POPULAR CLINICAL MEDICINE. By DR. J. S. WIGHT. New York: G. P. Putnam's Sons. 1880.

In an address delivered at the Long Island College Hospital, in February last, Professor Wight shows very clearly the insufficiency of the present mode of clinical teaching, and advocates giving much more practical bedside instruction. No one can take exception to the professor's views, but it is doubtful whether the ambition to graduate experienced practitioners can ever be realized.

ON SOME OF THE USES OF ANTISEPTICS IN OBSTETRICS AND GYNECOLOGY. By T. A. ASHBY, M.D.

DR. ASHBY thinks that antiseptic midwifery has won the day and is entitled to the recognition of the profession. The statistics given in regard to ovariotomy are especially strong in favor of this view.

TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA, at its Thirtieth Annual Session, May, 1879. Vol. XII., Part II.

THE address in surgery on the treatment of wounds, by Dr. Charles T. Hunter, forms one of the more interesting papers in this bulky volume. The subject of ligatures is discussed, and preference given to carbolized catgut. Nerve-suture and its results are referred to, and the various methods of dealing with wounds described. Dr. Hunter employs and recommends the method with dry and infrequent dressings, and free and continuous drainage. He speaks well of the open method, but declines to give any positive opinion about Listerism, except that it will probably have only a limited application.

Dr. Goodell says, in an article on spaying, that in carefully selected cases it will prove the sole means for curing many mental and physical disorders of menstrual life.

Dr. Isaac N. Klein has a paper on Juvenile Insanity. The fact that this disease is progressively affecting the younger members of society makes this article timely.

In the Address in Medicine, Dr. Andrew Fleming describes what he calls emotional fever. The name is bad, but the collection of facts under it will prove a very satisfactory one. Emotional fever should, and we hope will, take some of the weight off malaria which now takes the burden of all obscure pyrexial conditions.

One of the most elaborate papers is that by Dr. Oscar H. Allis, on the Signs and Treatment of Dislocation of the Hip.

One-half of this volume is taken up by reports of county societies. These contain some histories of cases, but their value is chiefly local.

The Society, on adjourning, elected Dr. Andrew Nebinger, President; Dr. Wm. B. Atkinson, Permanent Secretary; Dr. C. H. Chetson, Recording Secretary; and Dr. O. H. Allis, Corresponding Secretary.

TRANSACTIONS OF THE MEDICAL SOCIETY OF NEW JERSEY FOR 1879.

The address of the President, Dr. John S. Cook, upon The Problem of Life, is a much more sound and sensible treatment of that recondite subject than is generally given us by medical authors.

The contributions that follow are in the form of essays, and are all prepared with evident care. That of Dr. Peter V. P. Hewlett, on The Criminal Use of Chloroform, is particularly valuable. He discusses, among other things, the possibility of producing anæsthesia by chloroform on a sleeping person, without awakening him. This is proved to be possible in a certain per cent. of cases when the drug is expertly administered, the per cent. being larger in children. Practically, however, it must be extremely rare that anæsthesia can be produced successfully in this way.

Dr. John W. Corson, in an essay, On the Healthy Impulse of the Heart as a Valuable Sign of Comparative Safety in the Use of Anæsthetics, states that when the cardiac impulse is moderately firm and healthy, and there is no evidence of organic disease of the heart or lungs, one may feel perfectly free, with proper precautions, to use chloroform.

A very exhaustive essay by Dr. A. Clendenin is entitled Résumé of Yellow Fever.

Reports of district societies, and obituary notices, fill up the last part of the volume.

A compliment is due to the printer, who has put these transactions on excellent type and paper.

For the year 1880, Dr. Alex. W. Rogers is President; Dr. William Elmer, Jr., of Trenton, Corresponding Secretary.

Reports of Societies.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Feb. 19, 1880.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

THE FEMALE PERINEUM: ITS ANATOMY, PHYSIOLOGY, AND PATHOLOGY.

DR. T. GAILLARD THOMAS read a carefully prepared paper having the above title. The following is a brief abstract: The conventional description of the female perineum had been that it was the floor of the pelvis, that which fills the space extending from the inferior commissure of the vulva to the anus, and composed of skin, cellular tissue, muscles, and the mucous membrane of the vagina. Tyler Smith had spoken of the anatomy of the female perineum as having great interest, and yet gave it a description like the above. Playfair dismissed the subject, which he said was of great interest and importance, with less than eight lines, which were *three* more than given by Leischman and *four* more than written by Meadows. The French writers were usually quite full upon anatomical descriptions, yet Cazeaux dealt with it in three and a half lines. In this country, Meigs did not describe the female perineum at all, while no mention whatever had been made of it by either Bedford, Byford, or Miller. The defence for the omission might be that the obstetrician did not write upon anatomy. Turning to anatomists, Cruveilhier limited his remarks to an enumeration of the muscles and the fascia, but said nothing with regard to its function or shape or relationship to surrounding organs. Sappey had not mentioned it, and Wilson and Gray had not done better. Holden *promised* better things, yet nowhere appeared one word about the female perineum, except with relation to its blood vessels, and for those the reader had been referred to the description of the male perineum. In not one systematic work on gynecology had any mention been made of the anatomy, physiology, and pathology of the female perineum, except in the last edition of his own work, where it was described, he regretted to say, in a very incomplete and unsatisfactory manner. We owed to Dr. Savage the demonstration that the perineum in the female was a triangular, wedge-shaped body composed of fascia, areolar tissue, muscles, etc., which filled the space between the backward curve of the rectum and the forward curve of the vagina. Savage was the first to clearly demonstrate that the perineum was a triangular body and draw our attention to its significance and its uses. At this point Dr. Thomas referred to the diagram ordinarily used to illustrate the description given to the female perineum, a diagram that distorted and made a false representation of the relationship which it held to the pelvic organs, and yet it was the one employed by Gray, Wilson, and many others, and commonly copied into works which dealt with the subject in a special manner. In the living or the dead body the vagina never was an open canal; the vulva never was distorted in the manner represented unless distended by a foreign body, which separated wall from wall. The normal vagina was a collapsed canal, the anterior wall lying directly upon the posterior and sustained by it.

Attention was then directed to a figure which represented what he regarded as the true relation which the vagina, the bladder, the uterus, the rectum, and the perineum sustained to each other. In it the uterus was represented as occupying a position in the pelvis considerably lower than illustrated in the diagram by Dr. Savage, and more inclined forward, and the vagina, instead of consisting of a canal, having a simple curve from behind forward, presented a double curve: first, a decided curve from behind forward, then a lesser one downward and slightly backward; and second, a slight curve from above downward and backward. Instead of being a flat surface consisting of skin, areolar tissue, etc., filling the space between the anus and the vulva, it was seen as a perineal body, triangular-shaped, and composed of strong layers of adipose and elastic connective tissue, etc. It was a concavo-convex triangle, with its anterior side slightly convex, sustaining the superior wall of the vagina, while its posterior side, decidedly curved, supported the anterior wall of the rectum, which was supported by the base of the triangle and thus prevented from prolapsing into the vagina and out of the vulva. At its upper portion the vagina furnished a depression which received the cervix uteri, so that, to a certain extent, the uterus was sustained by a shelf-like action.

The functions of the perineal body were the following:

1. It sustained the anterior wall of the rectum, thus sustaining the equilibrium between the rectum, vagina, cervix, and body of the uterus.

2. It sustained the posterior wall of the vagina.

3. Upon the posterior vaginal wall rested the anterior, and upon that the bladder, and against the bladder the uterus—all of which, to a great degree, depended for support upon the perineal body.

4. It preserved the proper line of projection of the contents of the bladder and the rectum, and thus prevented the occurrence of tenesmus, which was a frequent cause of pelvic displacements.

Dr. Thomas then referred to what he denominated

THE KEYSTONE ACTION OF THE PERINEAL BODY.

Upon this part of his subject he dwelt at some length; first illustrating, in an exaggerated manner, by means of two diagrams, the action of the wedge-shaped body, and the results following its removal, and those were followed by two diagrams showing the effects produced, not exaggerated, by the loss of the triangular body; second, demonstrating the mechanical principles upon which the triangular body, with its base downward, could operate as a keystone in preventing a destruction of the equilibrium of the pelvic organs in a condition of health. He recognized the fact that the base of the keystone was downward, yet had reached the conclusion that upon its integrity depended the proper support of the pelvic organs.

What were the influences which most commonly disabled that wedge and rendered it inefficient and worthless, and caused the triangular body to lose its tonicity and power for giving support? 1, constitutional feebleness; 2, feebleness from prolonged overdistention; 3, subinvolution; 4, senile atrophy; 5, laceration. Dr. Thomas then spoke of the manner in which each of these causes operated.

Laceration was a splitting of the perineal body, and had been divided into three degrees: first degree, when split for only a short distance; second degree, when split to its centre; and third degree, when it was divided entirely through, and at once removed the keystone from the arch. It did not take away support from the uterus, but it altered the shape and removed support from the vagina, and the secondary effect was direct traction upon the uterus. The relation which the perineal body sustained to obstetrics was next mentioned, and the fact stated that gynecological practice originated largely in the lying-in chamber, and rupture of the perineum, furnished one of the most fruitful sources for the introduction of septic material, for the development of engorgements, rectal and vesical, prolapse, etc., to be found in obstetrics.

The doctrine that, so long as the rupture did not involve the anal sphincter it was a matter of but little moment, he regarded as very dangerous. Suppose it was torn down to the sphincter muscle, the immediate consequence was an exposure of an extensive raw surface, indisposed to heal by first intention, and quite near an abundance of blood-vessels, chains of lymphatic glands, and over that surface semi-putrid animal fluid must steadily pass for two or three weeks. It was a wonder that so many cases escaped septicæmia, when there was so perfect an arrangement favorable for the absorption of poisonous material. If all the cases of lacerated perineum were followed up closely from the lying-in chamber, the list of evils found would be a long one; some occurring at once, and others developing even at a very remote period. The evils enumerated were the following: septicæmia; anterior and posterior uterine displacements, prolapsus, cystocele, rectocele, chronic cystitis, chronic urethritis, uterine engorgement and hyperplasia, subinvolution of the uterus and vagina, destruction of the power of the uterine ligament, development of a tendency to abortion, impaired sexual gratification, and neuralgia affecting the site of rupture.

As a rule, *immediate closure* of the wound, both as an immediate preventive of septicæmia, and a remote preventive of all the evils just enumerated, was advisable. If it failed, no harm was done; but if it succeeded, great benefit followed.

But the question might be asked, if, in the non-puerperal state, the perineum be cut completely down to the sphincter muscle, will prolapse of the vaginal and rectal wall necessarily occur? No, not necessarily, but probably in time it would. Not in all cases of laceration of the perineum did prolapse occur; for, despite the laceration, involution might go on and the parts remain in tolerably good position, though they lacked the support of the perineal body; but such an occurrence was the exception and not the rule. The paper being before the Academy,

Dr. A. J. C. Skene remarked that he fully appreciated the value of the paper, and felt confident that all present would become better practitioners, both of obstetrics and surgery, for having listened to it. There was one point with reference to pathology to which he called attention, and that was the effect upon the muscular tissue especially, which took place after laceration had existed for a long time and was produced by atrophy and fatty degeneration, thus rendering complete restoration impossible. The perineum could be restored as far as possible in certain cases of long standing, and yet it was almost useless. He therefore raised the question: how long after laceration has occurred can the operation be delayed, and yet, when it is done, result in giving the woman a serviceable perineum? He thought that after a time all the muscles connected with the perineum underwent fatty degeneration and atrophy, and became useless for all future purposes.

Dr. H. J. Garrigues remarked, that he had just been studying the subject of Dr. Thomas's paper, and had therefore listened to it with very great interest. In preparing an article for the *American Journal of Obstetrics*, on "The Treatment of the Perineum," he had had occasion to study the anatomy of the part, and he would therefore remark upon points where his observation did not coincide with that made by Dr. Thomas. In the first place, it was a mistake to say that Sappey had not given the anatomy of the female perineum. True, it was not found in his description of the genital organs; but a full and exceedingly good description could be found in connection with his description of the rectum. In the second place, the expression perineal body was due to Savage, but Savage had himself stated that the excellent word was suggested to him by reading a description of this part written by the German anatomist Henle. Again, as represented correctly in one of Dr. Thomas's diagrams, the vagina was naturally a closed canal, but the illustrating acuteness of the angle between the uterine and the vaginal canal, he thought, was exaggerated. If so acute as indicated, he thought the introduction of a sound in comparatively healthy women would be more difficult than it was. He also thought that while Dr. Thomas was correct in placing the uterus lower down than illustrated in the old diagram of Gray and others, he had exaggerated it somewhat, and placed it a little too low. It had also appeared to him that the perineal body was not so triangular as represented, but

that it was more rounded, the lower part of the body corresponding to the bulbous extremity, and the other to the head of an alembic.

Again, the superior sphincter of the rectum was not illustrated in Dr Thomas's diagram, and the anus was represented as opening directly downward, while in reality it pointed more backward, and in the upright position it was about as much backward as downward, due to the fact that the rectum made a decided curve backward, thus influencing the shape of the perineal body, and contributing to give to it the alembic-shaped curve.

With reference to the *perineal body acting as a keystone*, he thought it true that as soon as an arch was suspended, the keystone lost all its power as a keystone. In the case of the perineal body, the base of the keystone was not only placed downward, but all the pressure came upon the point of the wedge.

Dr. Garrigues then referred to masturbation in young girls as a possible cause of relaxed perineum. He regarded the question as settled in Europe, and, for the most part, in this country, that it was the duty of the obstetrician to close a ruptured perineum as soon as possible. It was, at least, in the highest degree desirable, and that because it was so extremely rare that union did not take place when the torn surfaces were at once united. Out of *thirty* cases in which no operation was performed, there was only a single *one* in which union occurred to such an extent that the perineal body was entirely restored; in the *twenty-nine* there was but slight union.

Again, two-thirds of all the gynecological cases had their origin in laceration of either the cervix or the perineum. For the reasons, then, that it did not unite properly without some special closure of the parts, and that so large a proportion of gynecological cases had their origin in such an injury, the edges of these lacerated wounds should be united as soon as possible.

With reference to the manner in which a ruptured perineum should be united, it was, as a general rule, stated that it should be done by sutures. He thought stitches were not necessary, probably, in the majority of cases. Of course they were necessary in cases of complete rupture. If the laceration extended very far in the direction of the anus, and stretched up high in the vagina, sutures were necessary. If the rent extended high up, even though the skin was not torn at all, stitches must be used. On the other hand, if the laceration did not extend high up, or showed in the perineum for perhaps half its extent, he did not find it necessary to do more than unite the edges of the wound by means of serrestines, first brought to the attention of the profession in this country by Dr. Matthew D. Mann.

As usually made, they were defective in two respects: 1. The legs were too short; they did not catch deep enough; and 2. The legs were much too strong, hence liable to cut through. Those made for him by Tiemann & Co. had long legs with small claws, and the first one he usually attached about one-third of an inch in front of the bottom of the rent, the woman lying on her left side, and others at intervals of about half an inch the whole length of the laceration. A slight suppuration was usually noticed about the teeth near the fourth day, but that soon disappeared, union was rapidly secured, and when complete the serrestines were removed.

Dr. H. T. Hanks remarked, regarding the introduction of the sound, that when the woman was placed in the supine position, and Cusco's or Ferguson's speculum, or even when Sims's speculum was used, we were inclined to retrovert the uterus somewhat, thus rendering the introduction of the sound more easy than would seem possible from an inspection of a diagram. The subject was an important one, and if, by studying the anatomy of the body, we could learn of its necessities, in order to have a healthy condition of its parts, we should study obstetrics more thoroughly, and thereby accomplish something towards removing many of the evils to which woman was liable. He then referred to a case in which a rupture of the perineum existed four years before it was operated upon, and after the operation was performed it was determined that the parts could never be restored to their normal proportions.

The President remarked that he felt great delicacy in speaking upon the subject before the Academy, for no one more than himself highly appreciated the brilliant character of the paper. From the fact that the paper would attract great attention throughout the country, and throughout the obstetric world, it seemed to him that the doctrine brought forward should be subjected to some criticism before being accepted, and he felt less hesitation in offering some suggestions, from the fact of the well-known relation existing between the writer of the paper and himself, and doubtless whatever he might say would be answered most effectively. It, however, seemed due to science if there were any defects that they should be pointed out, and so give the author of the paper an opportunity to defend himself, and to correct those defects, if it should be proved that they existed. He would then say: *first*, that in medicine the mistake was often made, as it seemed to him, of assuming a certain fixed standard, an ideal theory for premises, and then basing all argument upon the ground that that theory was consequent, and therefore the conclusions must be true. Now, concerning an anatomical description of the female perineum and its relations to the pelvic organs, he begged leave to say that it was assumed that it had a relation with a certain ideal standard which was fixed, but which did not find its existence in nature. The relation of those parts was constantly changed—changed as the bladder and rectum were full or empty—changed as the patient was in the erect or the recumbent position, and that was especially true in connection with utero-gestation. In utero-gestation the relation of all pelvic organs was changed; the uterus was increased in weight, there was congestion of the tissues; as the uterus became increased in size it gradually changed its position. Still further, the relation of the parts was entirely changed again, during the period of parturition, especially with regard to the condition of the muscular tissue, etc. Might not those changes, in a certain degree, vary the basis upon which the arguments were made that led to the conclusions reached in the paper? That was thrown out as one of the points which should be investigated before accepting the conclusions that had been reached.

Another point, to which reference has already been made, was the necessity of an immediate operation to effect union when laceration of the perineum had taken place. He was well aware that the doctrine now taught by the most brilliant gynecologists and the most eminent obstetricians, was that it was our duty to at once operate as soon as laceration to any considerable extent has taken place in the perineum. While Dr. Garrigues had qualified the general teaching by saying it was almost universal in this coun-

try, it seemed to him that the doctrine should not be accepted, even so far as related to the simple application of serresfines, without carefully weighing all the attending circumstances. He admitted that, in a certain class of cases where the general conditions were favorable, it was proper to effect union at once, either by the use of sutures or serresfines. The latter Chassaignac introduced in 1843, and he himself had used them more than twenty-five years ago in Bellevue Hospital. The point which he made was, that the simple fact of laceration should not alone decide whether it was proper to operate at once, or wait and allow spontaneous union to take place, and, if it failed, then resort to the secondary operation. In several instances he had seen dangerous symptoms arise from the early operation, though resorted to with great care and prudence. In one case where extensive laceration took place, the patient went through the labor without great exhaustion or severe symptoms, and the physician at once performed the operation, closing the wound by sutures. He had hardly completed it, when the patient had a profuse secondary hemorrhage. In another case of extensive laceration of the perineum, the conditions were such that he argued against the opinion of two physicians, and in favor of deferring the operation until it was determined whether or not spontaneous union would occur. In that case spontaneous union did occur, and the woman had a good perineum as the result. She had subsequently borne a child without suffering from rupture, and had not suffered from descent of the uterus. The point made was, that it was not safe doctrine to teach that we should always resort to the primary operation when laceration takes place. He made the remarks simply to give the author of the paper an opportunity to demolish all that he had said.

Dr. S. T. Hubbard remarked that while he had seen several cases of moderate laceration of the perineum, in a large obstetric practice, he had not yet met with one which required an operation. His method of management was to place the woman upon her side, keep the limbs in close coaptation, the parts clean, and allow the rent to heal naturally.

Dr. Thomas, in closing the discussion, remarked that the point presented by Dr. Skene was a most important one, and that he had had the same experience in a similar class of cases. He presumed the explanation was to be found in the altered nerve state and the fatty degeneration of the tissues involved, sufficient to prevent union. However well these operations were performed, they would sometimes fail.

With reference to Dr. Garrigues' criticism concerning the keystone of the arch, he confessed he felt uncertain upon that point, and therefore took occasion to submit the view to two engineers, both of whom admitted that it was a real keystone of an arch; that is, that portion of an arch upon which the two lateral portions rested. The late Dr. Callender also expressed the opinion that the view was correct. Still, Dr. Thomas admitted the force of Dr. Garrigues' criticism.

Another point mentioned was this: Dr. Garrigues said lacerations did not heal if left alone, while Dr. Hubbard said that they did. Dr. Thomas presumed both were correct, notwithstanding the apparent contradiction; that is, Dr. Garrigues was correct in the rule, and Dr. Hubbard correct in the exception. He thought Dr. Hubbard's method an excellent one, but it was not safe for the reason that the patient could not be placed in a position which warded off the danger of septicæmia.

With reference to the power of the perineum, and its being a factor of support in this case, as mentioned by Dr. Barker, he remarked that, given a woman with a perfect perineum, and the relation of the parts with the pelvis would be perfect in every way; destroy that perineum, and at once the parts would fall out of their proper relationship; restore the perineum, and, as soon as it was perfect, all the pelvic organs would be restored to their normal relation, thus arguing for the theory that the perineal body was a great factor for co-ordinating all the parts in the pelvic cavity. With regard to the immediate operation, he thought Dr. Barker and himself differed by reason of mistaking the statement of one as to the rule and the statement of the other as to the exception. As a rule it was right to resort to the immediate operation, but he had seen cases, such as alluded to by Dr. Barker, where it was utterly improper to sew up the laceration. He would simply state that, as a rule, it was safe to sew up the lacerated perineum as early as possible; but as an exception it was bad practice.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, Feb. 25, 1880.

Dr. Satterthwaite, President, in the Chair.

A PORTION OF THE PANTS A NUCLEUS FOR STONE IN THE BLADDER.

Dr. Otis presented a specimen of stone, with the following history:

Eight weeks before, a man from Newark presented himself at the clinic of Dr. Otis with the history of a deep close stricture, said to be caused by a blow on the perineum. The patient stated that he was skylarking in a bar-room and was pushed against a broken wooden settee in such a manner that he straddled a wooden peg, which wounded his perineum. He suffered a good deal of pain in consequence; subsequently went home and had some retention of urine. A surgeon was sent for, who drew off a small quantity of urine mixed with blood. The patient passed his urine next day without difficulty, and had no special trouble for six months, when he began to suffer from frequent urination with attendant cystitis. These symptoms were supposed to be due to stricture. The patient passed through several hands, and finally came under the care of a physician who brought him to the clinic. On examination by Dr. Otis no stricture was found, but the large steel instrument which was passed into the bladder struck a stone. The latter was found to be of unusual shape. A large, broad, flat surface was felt, and the shape of the stone forbade its removal by cutting. It was accordingly determined to operate by median lithotomy. On putting the finger through the wound into the bladder a flattened stone was encountered, upon the surface of which were mammillated points about the size of a small marble. The size of this mass was two inches in length by one in breadth. It was crushed by the forceps and removed in two pieces. The stone was then found to contain a piece of woollen cloth two inches long and one inch wide. In a separate fragment of the calculous mass another piece of the same cloth was imbedded. The stone weighed in all 360 grains. Dr. Otis stated that he had in his experience a similar case. A man fell upon the upright handle of a pitchfork and also drove a small portion of his pants into his bladder, which formed the nucleus of a stone half an inch square.

He exhibited a second specimen, which was instructive, inasmuch as it showed how small a foreign body passing into the bladder might be a nucleus for stone. A gentleman aged seventy years, whose bladder had been repeatedly washed on account of prostatic trouble, about eight months ago came to Dr Otis complaining of symptoms of stone in the bladder. On examination the stone was found to be small, three-quarters of an inch being its largest grasp. Bigelow's operation of lithotripsy was performed. The first washing brought out a fragment of stone from which a small piece of broom-straw was sticking out. It sank down the evacuating tube and came out without being detached. A second piece of the straw was also found in another portion of the stone.

In connection with that operation, he had an opportunity of trying for the first time an instrument which he had contrived, and which was a modification of Bigelow's evacuating tube. The modification consisted in a slightly upturned knob at the extremity, which, while it did not interfere with the straightness of the tube as a whole, allowed, at the same time of its easier introduction into the bladder.

In answer to a question from Dr. Wyeth, Dr. Otis stated that he had seen a piece of wax half an inch by a quarter of an inch in size pass freely through the evacuating tube. This was in a case operated upon by Dr Allis. Dr. Otis also, in answer to a question from Dr. Wyeth, stated that he had never used the evacuating tube through the wound after a suprapubic operation.

Dr. Wyeth remarked that he had done so with good results.

EPITHELIOMA OF RECTUM.

Dr. Otis lastly presented an epitheliomatous tumor which he had removed by operation from the rectum of a gentleman aged seventy-four years, who had suffered from symptoms of the disease for a year. The mass was nodular, the size of an orange, and presented the usual gross appearances of such growths. It covered almost the entire posterior aspect of the rectum. The extirpation was effected by transfixing the tumor and bringing it down within reach. The result of the operation was very successful. Three weeks subsequently the parts were healed and the patient was apparently as well as ever.

On motion, the specimen was referred to the Committee on Microscopy.

SARCOMA OF THE ILEUM.

Dr. Wyeth presented a tumor occupying the left iliac concavity of a man who died at the age of forty years. About five years before, the patient had a pimple upon the end of his nose. This growth, according to his account, involved all the soft parts of the tip of the organ and eventually destroyed them. About a year ago he fell, striking heavily upon the situation of his left sacro-iliac synchondrosis. He was laid up in consequence for ten or fifteen days, and then went to work again. Six weeks subsequently he was attacked with peculiar symptoms of paralysis in the left lower extremity, from which he never recovered. Dr. Wyeth saw the patient about three weeks before his death, for threatening gangrene of the leg. This did not, however, become a dangerous symptom. The patient appeared to die of septicæmia. After death the tumor was removed, and was found to be about twice the size of the extended hand. The point of interest was whether or no the disease had an independent origin in the ileum. The growth involved the left lumbar and sacral plexus, and pressed upon the iliac artery. Dr. Wyeth stated that the gross appearances resembled those of a sarcoma.

Dr. Satterthwaite, assuming that the tumor was a sarcoma, was inclined to think that the lesion of the bone was primary. It was impossible to account for the disease on the score of metastasis. If the disease in the nose was a carcinoma, as its history indicated, it could have no possible connection with the sarcoma in the ileum. The change from a cancer to sarcoma was not possible in his opinion.

Dr. Ripley referred to a recurring sarcoma which he had seen several years ago. The disease first occurred by the side of the dorsal vertebræ, and was removed by the late Dr. Buck, who likewise excised a large portion of adjoining healthy tissue. The resulting wound was also thoroughly cauterized by carbolic acid. In a short time afterwards the tumor reappeared, and at the end of two years afterwards was removed by Dr. Ripley. Three months subsequently the tumor reappeared. Two years after this, and four years from first operation, the patient went to Dr Clark, who diagnosticated malignant disease of the spleen, which was probably of a sarcomatous nature. Dr. Ripley had seen another case in St. Francis's Hospital. In that instance, however, the disease recurred in the lung after an unusually long period of eighteen years from the time it made its appearance in the breast.

Dr. Satterthwaite stated that the lungs, liver, and spleen were apt to be involved secondarily when the primary disease attacked the periosteum. The period of reappearance was much longer than that of cancer. He believed that a great many secondary sarcomas were as such overlooked in autopsies, for the reason that sufficient pains were not taken to inquire into the previous history of the patients.

AORTIC AND MITRAL DISEASE—CEREBRAL THROMBOSIS WITH SOFTENING.

Dr. Ridlon presented a specimen of the above with the following history:

Lonisa Lewis, æt. 36; English; widow; nurse. Admitted to St. Luke's Hospital, Dec. 26, 1879. Service of Dr. A. H. Smith. For five years has had pain over heart, and palpitation. For two years has had œdema of the feet at times. For some weeks has been passing more than normal quantity of urine—getting up from four to six times each night. The urine contained fifty per cent. albumen (bulk). Sp. gr. 1024, acid. No casts.

Examination of chest showed tumultuous action of heart; hypertrophy—apex-beat being in seventh intercostal space, two inches outside of the mammary line; and both mitral direct and regurgitant, and aortic direct and regurgitant murmurs.

The patient remained in comfortable condition up to the morning of February 2d, when she fell to the floor unconscious. Consciousness returned in a few minutes, when there was found to be paralysis of both motion and sensation, of left arm and leg, left side of face and tongue, external rectus of left eye, and internal rectus of right eye. The pupils were equally dilated. There was no aphasia. There was incontinence of urine, and the bowels were confined. During the night of February 3d she began to breathe stertorously, and in the morning could not be roused. At 10.30 A.M., February 4th, she became paralyzed on the right side. The breathing became almost entirely abdominal. Pupils remained slightly dilated, and continued to react to the light. Twenty-four hours later patient died.

Autopsy was made twenty-five hours after death. The pericardium contained one and a half ounces of serum. The heart was enlarged in its transverse diameter; left ventricle dilated and hypertrophied; leaflets of the aortic opening thickened and twisted so that a triangular opening was left on applying the water-test. There were no vegetations on them, but several minute ulcers could be seen. The papillary muscles of the mitral valve were atheromatous. The valve closed to the water-test, but was roughened and contracted so as only to admit the end of the little finger. Left pleural cavity contained a moderate amount of serum. Lung not adherent, but œdematous throughout. Right pleural cavity contained forty-nine ounces of clear serum (this was not made out during life). Lung compressed, carnified, and adherent nearly all over with old adhesions. Liver was fatty. Right kidney very small, and the cortical portion the seat of numerous cheesy deposits; pelvis dilated, and apices of pyramids stained a deep reddish brown color. Capsule thickened, but not very adherent. Left kidney physiologically hypertrophied. It contained a number of small cysts, and one cicatrix as of an old infarction. Capsule adherent and thickened.

The membranes of the brain were normal. Brain-substance somewhat injected. A thrombus was found in the basilar artery at its anterior extremity, which was loose and easily detached, and of a deep red color. The left sylvian artery and branches were perfectly clear. In the right sylvian artery a thrombus was found commencing at the division into the anterior and posterior branches leading up to the first branch on the cardiac side, and extending to the ultimate portion of that branch as it passed posteriorly in the direction of the optic thalamus and corpus striatum. Externally to the former was a small spot of red softening. Externally to this latter body was found an area of softened tissue of grayish-white color, about 5×4 centimetres in size, in which was found the distended terminal branches of the arteries. No other point of softening was found. No atheroma in any of the cerebral blood-vessels.

Dr. Carpenter asked if any embolism was found in the thrombus.

Dr. Ridlon replied in the negative, stating that the specimen had not been examined microscopically.

Dr. Wyeth thought that the direct cause of death was due to thrombosis of the basilar, while Dr. Satterthwaite believed it to be due to the spot of red softening.

Dr. Wyeth stated that he had collected twelve cases in which death occurred in a similar manner, and in all of which a clot was discovered in the basilar artery.

Dr. Satterthwaite observed that although a clot was found in the basilar, it was not adherent and did not occlude the vessel.

The Society then went into executive session.

The Medical Annals is a new monthly journal published at Albany, and intended to be the organ of the Medical Society of the County of Albany. Its design is at present to be essentially a local paper. The opening editorial is modestly written, and the contents and general appearance of the first number are excellent.

A Centenarian.—Dr. W. S. Field, of Ridgefield, Conn., writes to us that a woman died recently in South Salem at the age of 101 years and 3 months. Her age is well authenticated.

Correspondence.

THE ABUSE OF MEDICAL CHARITIES, AND PROFESSIONAL INTERFERENCE.

To the Editor of The Medical Record.

Sir:—When I heard Dr. F. R. Sturgis read his paper on the "Abuses of Medical Charities," before the New York County Medical Society, in April, 1879, I thought much good would follow, and that the abuses would be stopped, or perhaps mitigated. The discussion that followed the reading of the paper—in which such men as Agnew, Parker, Noyes, Roosa, and other prominent physicians took part—strengthened me in these views. Nearly a year has passed and this paper has borne no fruit.

That the subject is to be again opened for discussion I judge from the letter of Dr. Jones in the Record for February 14th, and in the leading article in the issue of February 21st.

Soon after Dr. Sturgis's paper started men to think—but, alas! not to act—I moved from New York to a city in another State, flattering myself, at the time, that I had escaped from the injuries the dispensaries were doing the profession in the former city. I had not been settled long in the new locality before it became evident that I had deluded myself, and that the dispensaries in New York had extended their limits for miles into New Jersey, and did not confine themselves to the treatment of the paupers of New York City or State.

The dispensary, as I take it, is for the treatment of deserving, destitute poor, and is a part of a system for the relief of paupers. It is supported by the taxpayer or contributor, and its purpose is not to extend relief beyond its district, especially to a non-resident. This, we think, is a comprehensive definition of the business of a dispensary.

Now, as a Jerseyman I have no objection to the New Yorker paying for the care of our paupers, nor will I object if our poor-houses, etc., are moved over the Hudson, and thus relieve me from the payment of a poor-tax; but, as a physician, I must take exception to the New York dispensaries treating my patients who can afford to pay me.

I could mention many instances where persons fully able to pay have been treated in New York gratuitously. The abuses are more flagrant at the special dispensaries and hospitals. As instances, two persons have come to me for treatment, having in their possession the cards of prominent dispensaries for the treatment of eye diseases (these cards being signed by one or another of the well-known specialists). Both of these patients were able to pay the railroad fare of seventy-five cents twice or three times a week. Now, I argue that if they were able to pay this fare, they were able to pay a physician.

One person in town, whose salary is larger than the annual fees of any doctor in this city, sent his daughter to a New York dispensary for advice, and she was under treatment as a pauper for some time.

I am compelled to acknowledge right here that much of this trouble has been brought on us by the action of two or three physicians in this city. They were and are to-day in the habit, when puzzled over some eye or joint case, of sending the patient to New York for a free diagnosis and treatment.

Now, I must object to all this, and think it the

duty of the officers of the New York institutions to refuse treatment to those able to pay, and especially non-residents.

I question the honesty of New York pauper methods in regard to New Jersey paupers, and I especially object to the New York dispensaries pauperizing our people by treating gratuitously those able to pay.

SQUINTUM.

PATERSON, N. J.

BORACIC ACID CONTAMINATED WITH LEAD.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—When I read in a recent number of the RECORD a paper contributed by Dr. Theobald, of Baltimore, on the use of boracic acid in certain diseases of the eye, it reminded me that at a meeting of the Pharmaceutical Society of Paris, two or three years ago (I believe it was in 1877), a member presented a sample of boracic acid containing a considerable quantity of lead; the gentleman directed attention to the fact that boracic acid was freely employed as an antiseptic and in the preservation of food, and to the serious consequences which might result from its use for such purposes when contaminated with lead.

The employment of this remedy in eye diseases is certainly new to many in America, and will, I have no doubt, be freely used by those acting upon Dr. Theobald's recommendation. In the treatment of conjunctival disease with ulcerative inflammation of the cornea or abrasion of its epithelium, the employment of boracic acid containing lead, would, as we all know, be attended by the precipitate of the latter upon the cornea, giving rise to a very marked white stain, which, according to the locality of the deposit, produces more or less impairment of sight.

This remedy may be quite useful, and it is far from my purpose to prejudice any one against its employment, nevertheless, is it not important for us to remember that such a thing does exist as "boracic acid contaminated with lead"?

Respectfully,

J. A. ANDREWS, M.D.

NECROSIS OF HUMERUS, ETC.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—Unfortunately I was not present at the meeting of the Surgical Society following that of December 23, 1879, when the minutes of the latter were read. I see that, probably on account of my inability to express my meaning in English, I have been misunderstood several times, so that some essential points are rendered in a different way from what I wanted to express.

1. In MEDICAL RECORD No. 11, March 13, 1880, page 295 et seq., when mentioning excisions of the hip-joint made at Kiel, five in number, I believe I said instead of "seven weeks," "*several* weeks." I think also that I said, "they died all *except one*."

2. I recommended "cod-liver oil, pure or in combination with syrupus ferri iodidi," not "phosphates."

These two points are of no particular importance, but what I wanted to say regarding the case of necrosis of the humerus is the following:

3. In my case of necrosis of the humerus the necrosis extended in the form of so-called "necrosis dissimulata" through the whole diaphysis, as was shown by the bones presented and a diagram. The elbow-joint was already stiff before the operation, and remained so except a slight amount of motion. As it appears in the report, I think I am made to say the reverse.

Furthermore, when discussing the question, how joints stiffened by inflammation (which, as a rule, accompanies acute osteomyelitis) ought to be treated, with especial regard to *the upper extremities*, where we intend to attain movable joints, I proposed, according to several experiences which I quoted, excision of the joint together with necrotomy, and I emphasized that those excisions were less dangerous on account of the soft parts being less apt to be infiltrated and inflamed. I did not wish to make special reference to the elbow joint, but to joints in general, as far as their being affected by acute osteomyelitis is concerned. I particularly mentioned that, as a rule, the cavities of those joints are obliterated, and perhaps, on account of that, more favorable conditions might exist regarding accidental wound diseases, as erysipelas, etc. The latter idea is not originally my own, but I referred to it as an old experience of which we ought to make use in considering how far the excision of those joints together with necrotomy had to be regarded as complicating and aggravating the surgical procedure.

I would be very much obliged to you if you would find the space to modify the report of the Surgical Society in the above particulars.

Very truly yours,

F. LANGE, M.D.

6 WEST FORTY-EIGHTH STREET.

BORACIC ACID IN EYE DISEASES.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—In the MEDICAL RECORD of February 21st you mentioned that Dr. E. Gruening, surgeon to the New York Eye and Ear Infirmary, had written you a note stating "that Dr. Theobald's claim for originality in the use of boracic acid" (referring to my paper, 'Boracic Acid—A New Remedy in Eye Diseases,' in the RECORD of February 7th), "was unfounded. In fact, that the article has been employed by ophthalmologists for many years, and Alfred Graefe, Wecker, Just, Becker, and others have written about it. The value of boracic acid was brought out in a discussion at Heidelberg and Amsterdam during the past year."

Shortly after the publication of my paper, my attention was called to the fact that Alfred Graefe, in his antiseptic cataract operations, had made use of borated lint or cotton dipped in a solution of boracic acid (as recommended by Lister) *as an antiseptic dressing*, and that he had not depended entirely, as I supposed, upon *carbolic* acid. As soon, therefore, as Dr. Gruening's statements came to my notice I wrote to him, asking whether this was the use of boracic acid by ophthalmic surgeons in Germany to which he referred, or if it had been employed *as a collyrium* in inflammatory affections of the eyes, as I had recommended it, adding that if it had been used as a collyrium, I should feel under many obligations if he would let me know where I could find mention of the fact. After the lapse of a week I received a reply from him, in which he says: "In Hirschberg's *Centralblatt für Augenheilkunde* (1878) *Just* published an article on boracic acid, recommending it strongly in blepharorrhœa saturated solution to be dropped into the eyes) and ulcus corneæ serpens. In that article

he refers to Alfred Graefe's use of the boracic acid pad." He also states that he had employed boracic in his own practice very extensively since the publication of Just's paper (whether as a collyrium he does not say), and that in the Transactions of the Heidelberg Congress of German Ophthalmologists, 1879, I would find "a very extensive literature on the subject."

In the meantime, through the kindness of a member of the Heidelberg Ophthalmological Society, an opportunity had been afforded me of examining the Transactions of 1879, referred to by Dr. Gruening. Instead, however, of *a very extensive literature on the subject of boracic acid, and a discussion in which its value as an antiseptic was brought out*, I found, first, an article by Sattler upon the treatment of keratitis, in which he said he had been led to employ *salicylic* acid in the treatment of ulcers of the cornea (as an external antiseptic dressing) by the example of Horner; that a one-fourth per cent. solution of salicylic acid was not, in his opinion, strong enough for this purpose, but a strength of one per cent. was requisite; that it was, of course, impracticable to employ alcohol or hot water (referring to the slight solubility of salicylic acid in cold water) in order to obtain a solution of this strength, but that by mixing three parts of boracic acid with one of salicylic acid *he had been enabled to obtain a one per cent. solution of salicylic acid.*

Neither in the paper itself, nor in the discussion to which it gave rise, was there further mention of boracic acid, and if Sattler used it for any other purpose than simply as a solvent of salicylic acid, he certainly failed to make it apparent.

And again, in the discussion which followed the reading of a paper by Dor, upon Benzoate of Soda in Purulent Ophthalmia, I found boracic acid referred to by Meyer, of Paris, and by Nieden, the former stating that he used pieces of linen (Leinwandlappen) dipped, formerly, in chlorine water, now, either in salicylic or boracic acid solution (applying them externally to the lids) in conjunctival diseases and affections of the cornea, with the happiest results; the latter mentioning that he also had used boracic acid, presumably in a similar manner, although he does not explicitly state this. Beyond this, no mention of boracic acid could be found, though the transactions were searched through with care.

In the September and October numbers of the *Annales d'Oculistique* (1879), which had been kindly lent me, I had found also an extended report of the proceedings of the *Amsterdam* meeting of ophthalmologists spoken of by Dr. Gruening, and there (on page 187) I had discovered only this reference to boracic acid: A paper on the Antiseptic Method in Ocular Surgery, by Snellen, being under discussion, in which he had recommended as an antiseptic and occlusive dressing pieces of linen soaked with vaseline. Becker spoke favorably of this suggestion of Snellen, and remarked that he had used for the same purpose lint saturated with a solution of boric acid. M. Manolescu also stated that at the clinic of Wecker, in Paris, borated dressings (pansement boraté) had been used with very good effect in habitual secretions of the conjunctiva and light catarrhs.

In the *klinische Monatsblätter für Augenheilkunde*, July, 1878, p. 321, I had also found an abstract of an article upon Moist Salicylic Bandages, by Horner, in which he remarks that since he had learned of Lister's boracic bandage, he believed that in boracic acid lay the future of ophthalmic antiseptics, and that his experience had taught him that the boracic acid solution was well received by the healthy cornea.

In none of these instances, as will be observed, is there mention of the use of boracic acid *as a collyrium*, but simply *as an antiseptic dressing*, as Alfred Graefe had employed it in his cataract extractions in 1877.

The article of Just, in the *Centralblatt für Augenheilkunde*, in which, according to Dr. Gruening, he *strongly recommends* a saturated solution of boracic acid to be dropped into the eyes in blennorrhœa—the title of which, by the way, is the Boric Acid Bandage (Borsäure-Verband) in Ulcus Corneæ Serpens—I have been unable to obtain until yesterday, when it reached me from New York, there being no copy of the journal in which it appeared in this city. It had, however, been kindly examined for me in Washington, where the journal is on file, by one whose knowledge of German is far better than my own, and whose name, if I should mention it, would be a sufficient guarantee that it had been accurately and conscientiously done, and the following report made in regard to it, which I prefer to give rather than my own version: "I have examined Just's article in *Centralblatt für praktische Augenheilkunde*, p. 225 (1878, ii). Graefe's article, referred to by Just, is in *Arch. für Ophth.*, 1878, xxiv., p. 232. It treats exclusively of antiseptic dressings in relation to boracic acid. Just recommends this antiseptic treatment in ulcus corneæ serpens, also in affections of the lachrymal sac, and he goes on to say: 'In the latter case (after probing the sac) I have with each change of dressing dropped a four per cent. boric acid solution in the opening of the eye (Lidspalte), and the action of the dressing appears by this means to be considerably increased.

"'Encouraged by these results, and convinced, from an experiment on my own eye, of the very mild effect of boracic acid on the conjunctiva, I have tried dropping-in of boric acid (Borsäure-Instillationen) in two cases of blennorrhœa of the conjunctiva.'

"He deprecates any positive conclusion from so small a number of observations, but suggests further trials. The rest of the article has no bearing on the point at issue."

Dr. Gruening's rendition of this, that "Just published an article on boracic acid, recommending it strongly in blennorrhœa" (saturated solutions to be dropped into the eyes) "and ulcus corneæ serpens," is, to say the least, rather a free translation.

Clearly, then, as an antiseptic dressing, boracic acid has been used by a number of ophthalmic surgeons for several years, Alfred Graefe having been, I think, the first to so employ it, in 1877; and at least one ophthalmologist, Just, has used it as a collyrium in the manner related.* Whether the favorable results which he obtained from the limited use of it, described in his paper, induced him subsequently to employ it more freely, I have no means of knowing, as he has published nothing further upon the subject; at least, there is no mention of his having done so either in the Index Medicus, or in the report on the Progress of Ophthalmology in Knapp's Archives.

For bringing these facts, of which I was entirely

* Through the kindness of Dr. Keyser, of Philadelphia, I have just received a report of the eye clinic, in Bern, of Prof. Pflüger, for the year 1878; from which it appears that he (Prof. Pflüger) was then using boracic acid, both as a collyrium and as an external dressing in conjunctival and corneal affections, with most excellent results. From his language, it would seem that he had so used it as early as 1877, and had spoken of it in his report of that year. Of this, however, even his neighbor and fellow member in the Heidelberg Ophthalmological Society, Just, appears to have been ignorant in October, 1878.

to-night at the time I wrote my paper to pay attention I have to thank Dr Cornening. Had I been conscious of them, I certainly should have referred to them in my paper, and would have chosen for it a different title. Whether or not, however, they justify the assertion contained in Dr Cornening's note to you, and in his letter to me, I leave to others less interested than myself, and no more capable of judging, to determine.

No doubt, I ought to have been familiar with the fact that boracic acid had been used as an antiseptic dressing in ophthalmic surgery; but, for my ignorance of what Just had written about it, I do not feel myself responsible, as the journal in which his observations appeared has never been within my reach.

I may also mention that I have searched through the list of papers relating to ophthalmology in the Index Medicus, from January, 1879, to the present date, and through the list of those published during the year 1878, in Knapps Archives, without discovering one (if we except that of Just on the boracic acid treatment), the title of which indicated that boracic acid was the subject of which it treated.

I am, dear sir, yours with regard,

SAMUEL THEOBALD.

BALTIMORE, March 12, 1880.

ARMY AND NAVY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from March 7 to March 13, 1880.

MCELDERRY, H., Capt. and Asst. Surgeon. Having reported in person at these headquarters, assigned to duty at camp at White River, Colo. S. O. 19, Dept. of the Platte, March 5, 1880.

WHITE, R. H., Capt. and Asst. Surgeon. Granted leave of absence for six months, with permission to go beyond sea. S. O. 55, A. G. O., March 11, 1880.

[illegible], P. R., Capt. and Asst. Surgeon. Having reported in person at these headquarters, assigned to duty at Fort Hamilton, N. Y. H. S. O. 39, Dept. of the East, March 11, 1880.

MOSELEY, E. B., Capt. and Asst. Surgeon. Granted leave of absence for one month, to take effect on arrival of Asst. Surgeon McElderry at camp at White River, Colo. S. O. 19, C. S., Dept. of the Platte.

Changes in the Medical Corps of the Navy during the week ending March 13, 1880.

Passed Asst. Surgeon H. E. Ames, detached from the Navy Yard, Washington, and ordered to the U. S. S. Saratoga, vice Passed Asst. Surgeon A. T. Magruder, detached and ordered to the Navy Yard, Washington, D. C.

Passed Asst. Surgeon Robert Whiting ordered to the Iron Clads, Brandon, Va., vice Asst. Surgeon R. Ashbridge, detached and placed on sick leave.

THE AMERICAN QUININE MANUFACTURERS continue their efforts to secure a ten per cent. duty on quinine, or in lieu of this a repeal of the heavy taxes and duties now placed on the raw materials. They laid their case before the Ways and Means Committee last week, March 11th.

MR. HENRY C. LEA, the well-known medical publisher of Philadelphia, has retired from business, and the firm is now Henry C. Lea's Son & Co. He speaks his valedictory in the March number of the *Medical News and Abstract*.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending March 13, 1880

Week Ending	Typhus Fever	Typhoid Fever	Scarlet Fever	Cerebro-Spinal Meningitis	Measles	Diphtheria	Small Pox	Yellow Fever
March 6, 1880..	0	6	43	3	144	35	0	0
March 13, 1880	0	4	43	2	121	32	0	0

EXEMPTING PHYSICIANS FROM JURY DUTY.—The legislature of New Jersey has recently passed a bill exempting physicians from jury duty.

THE SAN FRANCISCO BOARD OF HEALTH has denounced Chinatown as a public nuisance and a danger to the health of the city. The board has directed the quarter to be torn down, but the step is too radical a one, and the authorities are waiting.

THE CURE OF CATARACT BY ELECTRICITY, ETC.—Dr. Wecker* says: "If by chance you should light on a number of the *Gazette des Hopitaux* which has appeared within the last few years, telling of the clearing power in the lens of weak continuous currents, you will see with what rapture this wonderful therapeutic agency has been welcomed. But, alas! like so many other marvels in the healing art, it was not, after a certain lapse of time, even mentioned, because, forsooth, it involved the nominal expense of two cells of a Trouvé battery, and the trouble of wearing small discs at night, and keeping the tiny machine by one's side in bed.

"Need I mention to you the preparations of ammonia and of phosphorus with which some persons pretend to restore transparency to opaque lenses? I scarcely think so. There is, however, one incontestable fact, and that is, that patients undergo such courses with admirable patience for periods of ten or twelve years. Certain unprincipled quacks make capital out of the improvement that the retrogressive stages of ripe cataracts afford to vision, and also out of the fact that certain nuclear forms never go so far as total blindness."

OVERCROWDED PROFESSION IN LONDON.—There are so many idle doctors in London that one of the busy ones who recently advertised for an assistant, offering £100 a year, received between 400 and 500 answers.

COMMENCEMENT OF THE COLLEGE OF PHYSICIANS AND SURGEONS.—The Seventy-third Annual Commencement of this College was celebrated in Steinway Hall on the evening of March 12th. The attendance was very large, the number of prizes given was greater than usual, and the proceedings had more than usual interest.

After an opening prayer by Dr. Weston, the degrees were conferred by the President, Dr. Alonzo Clark, and the customary exhortation was delivered by President Barnard.

Dr. Clark then delivered an address, in which he

* Ocular Therapeutics: De Wecker. English Edition, page 328.

dwelt chiefly upon the overcrowding of the profession. He showed that the number of medical students increased in times of great financial depression, and that a marked increase had taken place during the past five years. In 1878 there were 2,708 graduates from our fifty-nine medical colleges. At the present rate of increase, for the 57,000 physicians that we now have, there will be, in thirty years, 86,656, which will be too many.

At the conclusion of the address, Dr. Robert F. Weir, President of the Alumni Association, announced that the Alumni prize of $200 for the best medical essay was not awarded last year, because no essay was offered of sufficient merit. Owing to this fact, the prize had increased to $500, and had been gained by Dr. R. W. Amidon, of New York, by an essay on "The Effect of Willed Muscular Action on the Temperature of the Head as an Aid to Cerebral Cortical Localization—Facts and Figures." By the munificence of Benjamin Cartwright, of Newark, they would be enabled to keep up an annual prize to the same amount. Mr. Cartwright had given $10,000 to the college, half the interest to be applied to a lectureship, and the other half to this prize. Next year, therefore, they would have a Cartwright prize of $500, and in 1882 an Alumni prize of $500. Next year also, a prize of $100 from the Joseph Mather Smith memorial fund would be awarded for the best essay on "The Physiological and Therapeutical Effects of Secale Cornutum."

Professor John J. Curtis, Secretary of the Faculty, awarded the prizes for general efficiency, and the "Harsen" prizes. The Harsen prizes for the best reports in writing of clinical instruction given at the New York Hospital, were awarded as follows: John F. Duffield, $150; Judson C. Brown, $75; N. W. Taylor, $25. The following ten graduates showed the greatest proficiency in examination: J. F. Duffield, L. E. Holt, H. Hungerford, H. J. Kelly, R. B. Kimball, A. J. McCosh, F. W. Murray, G. D. Parmly, H. M. Sherman, and W. M. Thallon. To these were awarded prizes from $100 to $25, or diplomas of examination honors. The Harsen fund had so increased, it was announced by the professor, that the Faculty, by the permission of the Supreme Court, had determined to offer a second series of prizes for competition by the ten "honored" men. These prizes, he said, were the highest honor to which a student of this college could aspire, because of the severity of the examinations for them. The winners of these prizes were G. D. Parmly, $500; H. J. Kelly, $300; H. M. Sherman, $200.

Dr. Frederic T. Hume, of the graduating class, delivered the valedictory address, and the Commencement proceedings were brought to a close with a speech by the Hon. Richard O'Gorman, who spoke in part of the progress of civilization and the mighty advances of science.

Grafulla's orchestral band played selections from various operas during the evening.

The number of graduate was 117.

Commencement at the Medical Department of the University of Pennsylvania.—The annual commencement of this college took place March 15th, diplomas being conferred on 111 graduates. The degree of doctor of dental surgery was also conferred on twenty graduates.

A Sure Proof of Death is said by Dr. Hughes Bennett to be found in the application of electricity. If, when faradism is applied to the muscles of the limbs or trunk five or six hours after supposed death, there be no contractile response it may be certified with certainty that death has occurred. No degree of coma or trance can prevent the evidence of electric muscular contractility.

Dr. William Farr's Superannuation.—A pension of $4,000 per annum has been given to Dr. Farr in lieu of the position of Registrar-General, for which he was thought by the government to be too old.

The New York Public Health Association met March 11th, Professor Chandler presiding. Mr. James Gallatin read a paper on the tenement-house question, in which he showed that considerable progress had been made in improving these dwellings, and also that model tenement houses might be built in New York and give a fair return upon the capital invested. Dr. Janeway reported upon the sanitary condition of the city. He said that there were 28,342 deaths last year, an increase of 1,300 over 1878. This increase was among children, and due largely to scarlet fever. In January and February of 1880 there have been 496 fewer deaths than there were in the corresponding months of 1879.

The Pleuro-Pneumonia Act has been repealed by the New Jersey Legislature, to take effect on and after Wednesday, March 10, 1880. The quarantine against New York has been raised, and all cattle will be allowed to enter New Jersey without permit.

Passage of the Bill to establish a State Board of Health.—The above bill has passed the Senate by an almost unanimous vote. Senator Woodin, who reported the bill from the committee, made a very strong speech in its favor. There is scarcely any opposition to the bill, and its passage through the Assembly seems very probable.

International Sanitary Conference, and the National Board of Health.—The Senate Committee on Epidemic Diseases agreed, on March 11th, to report to the House, with recommendations for passage, the following measures: Joint resolution authorizing the President to call an International Sanitary Conference to meet at Washington, D. C.; Senate bill with amendments "to increase the efficiency of the National Board of Health;" joint resolution to print 10,000 copies of the report of the National Board of Health, and 10,000 copies of the report of the Yellow Fever Commission.

A Plea for Oleomargarine as a Food-product.—Representatives of the oleomargarine industry appeared before the House Committee on Agriculture and Manufactures on March 10th, in opposition to any legislation injuriously affecting their product. They claim that oleomargarine is identified with butter; that both the real butter and oleomargarine butter are simply animal fat, and the difference in the process of manufacture makes no difference in the substance. They stated that the factory in New York is now making 40,000 pounds of oleomargarine butter per day, and that there are eleven such factories in Baltimore, Louisville, Chicago, and other cities. That the exports of oleomargarine oils from the port of New York alone amounts to 5,000 tierces per month. They protested against any discriminating legislation, on the ground that their product is a genuine food-product, pure and wholesome in itself, and a fit substitute for butter.

The Hunterian Museum is about to receive the richest anthropological collection in the world. The gift is from Dr. Bernard Davis, who has for years devoted his time to collecting crania and skeletons from all possible sources.

The Bill to Regulate the Practice of Medicine in Massachusetts has met considerable opposition, and its friends are doubtful of its passage. If passed and rigorously carried out, it will rid Massachusetts of many of its quacks, a class which seems to thrive quite as abundantly in Boston as anywhere else.

New York Dispensary.—Dr A. C. Valentine has been appointed house physician in place of Dr F. R. Starrs, resigned. Salary, $1,200.

Verdict in Regard to the Care of the Insane.—The verdict in the case of Maria Ottmer, who was killed in the Blackwell's Island Lunatic Asylum, has been rendered, and is quite condemnatory of the asylum management on that island. The jurors deliberated for three hours, and in their verdict repeat substantially the complaints that have been reiterated in the columns of the Record. They find a lack of proper system, and general irresponsibility, and say: "In our opinion the commissioners in charge of our asylums and hospitals should be men qualified by education and training for the position, and should be kept separate from the government of penal institutions." They recommend a medical superintendent be speedily appointed to take charge of the Blackwell's Island Asylum, as one man is insufficient for taking proper care of both institutions.

As this very positive verdict was given in the face of powerful efforts to smooth the matter over, it must carry additional weight.

The Kentucky School of Medicine dedicated its new college building on February 9th.

Revision of the U. S. Pharmacopeia.—The Sixth Decennial Convention for the revision of the U. S. Pharmacopœia will meet in Washington on the first Wednesday in May. A number of important changes are proposed.

Medical Department of Iowa State University.—The Commencement exercises of the Medical Department of the Iowa State University occurred at Iowa City on the evening of March 3d, in the New Opera House.

Candidates for graduation had been undergoing for two days previous the annual "public examinations" conducted by six members of the Iowa State Medical Society, the examining committee of this year consisting of Dr. L. P. Fitch, Charles City, Chairman; Dr. H. M. Dean, Muscatine; Dr. A. L. Wright, Carroll; Dr. E. W. Clark, Grinnell; Dr. J. C. Kersey, Stuart; Dr. J. T. Thomas, Walnut, Secretary. The report of the committee, made to the Board of Regents of the University, spoke in terms of highest commendation of the honesty and efficient nature of the work done by the students. The class valedictorian was F. S. Johnson, of Maquoketa. Two ladies and twenty gentlemen received the degree of Doctor of Medicine. The exercises were closed with the "address for the faculty" by the Dean, Dr. W. F. Peck. The class of graduates was formed largely of students who adopted the "three year graded" course at its inception in the school, and the high standing of the class has added to the strong predilection in favor of the three year plan. The examination by an independent board is another progressive feature of this school.

Commencement of College of Pharmacy of N. Y.—The fifteenth annual commencement of the College of Pharmacy was held Tuesday evening, March 16th, at Chickering Hall. The hall was filled with visitors, and on the platform there were Ewen McIntyre, President of the College, Prof. Chandler, Prof. P. W. Bedford, Prof. Fradel, Prof. C. Rice, Prof. Alonzo Wood, Dr. Mollinger, Prof. D. C. Robbins, A. A. Agnew, and G. C. Close. President McIntyre opened the exercises with a brief address, after which Secretary H. A. Carmeber, Jr., read the names of the graduates, forty-four in number. For the highest proficiency in all branches of study, Joseph Feil, of Cleveland, Ohio, received the first prize, a gold medal; Julius A. Risky, of College Point, N. Y., the second prize, silver medal, and Frank L. Morris, of Newark, N. J., was awarded third prize, a bronze medal. Mr Feil was also presented with a special prize—a microscope—for the best thesis on botany. Besides the prize men, the College inscribed upon its roll of honor the names of those students who had answered over eighty per cent. of the questions. These were George Kraft, Jr., J. C. Comstock, A. A. Merritt, H. Breiting, F. Nadler, J. Albert, Jr., O. Klingenburg, H. M. Kolasky, A. Koertage, and W. P. Blair. The Rev. Edward L. Clark then delivered an address, and F. L. Morris pronounced the valedictory.

After the exercises, the Faculty, Alumni, and invited guests, partook of a dinner at Seighortner's.

The toasts with their respective respondents were as follows: The College of Pharmacy, by H. J. Menninger, M.D.; The Examining Committee, by Prof. Chas. Rice; Chemistry, by Prof. C. F. Chandler; Our Editorial Colleagues, by Dr. F. A. Castle; The Medical Profession, by Dr. Geo. F. Shrady; Our Contributors, by Mr. D. C. Robbins; Our Guests, by Mr W. P. De Forest; The Alumni, by Mr. C. A. Robbins.

The Presentation of a Gold Watch to Prof. Chas. Rice.

Prof P. W. Bedford, in concluding the exercises of the evening, referred to the admirable report in the revision of the U. S. Pharmacopœia, the work of Prof. Chas. Rice. In recognition of such distinguished service to pharmacy, the friends of the college, through Prof. Bedford, presented Prof. Rice with an elegant and costly gold watch suitably inscribed, and with chain attached.

Dr. Benjamin Hopkins Catlin, a distinguished physician of Meriden, Conn., died recently at the age of seventy-nine years, of Bright's disease of the kidneys. Appropriate resolutions of respect were passed by the local medical society.

FORTY ATTESTED CASES OF DIPHTHERIA;

With Remarks on Diagnosis and Treatment.

By C. E. BILLINGTON, M.D.,

VISITING PHYSICIAN TO DEMILT DISPENSARY, NEW YORK.

Four years ago I had the honor of submitting to the consideration of this Society* an account of my clinical experience and observations in the treatment of a large number of cases of diphtheria, with certain resulting conclusions as to the true nature and therapeutics of the disease. That report is included in the Transactions of the Academy for 1876. While the reception accorded to it by those who heard it, and by many others who have subsequently read it, has been with scarcely an exception courteous, and, in not a few instances, most flattering, and while its teachings have been warmly endorsed by many intelligent physicians in all parts of the country, yet several causes have operated against its universal acceptance at what I believe to be its full statistical value:

First, its conclusions were in several important respects opposed to the views then held, and perhaps still held, by a majority of the profession.

Second, the results of treatment which it related were very favorable. Medical literature—especially journalistic literature—teems with reports of equally good or still better results obtained by the most diverse, the most opposite, and often the most familiar and the most inadequate means. The hopes awakened by these statements have again and again been found delusive.

Third, there is a notable absence of definite agreement in the profession as to the principles and methods of the diagnosis of this disease. Hence, many of the most judicious, while often perplexed in their own classifications, are naturally distrustful of the enumerations of others, and of those especially in which unusually brilliant therapeutical successes are claimed. It must be admitted that a certain degree of scepticism under such circumstances is as proper and conservative as it is inevitable, and can be successfully met only by convincing proof.

My previous report was mainly compiled from the clinical records of dispensary practice, most of which had been made before their publication had been thought of. Other proof than such facts, considerations, and testimony as I was able to adduce in support of their probability, was then impossible. It subsequently occurred to me, however, that if, in another large series of cases, which should be attested by witnesses of known competence and character, I should be able to report a similar ratio of favorable results from the same methods of treatment, it would doubtless be accepted as placing the substantial accuracy of my previous statements beyond reasonable doubt. To this end I requested Drs. W. T. White and Andrew H. Smith to visit such cases as might be met with in my dispensary practice, and certify to the genuineness of such only as they might consider so well marked as to be unmistakable. These gentlemen were selected not only on account of their fitness, but because their residence was such that they could make these visits without too great inconvenience. They kindly acceded to my request. This was at the beginning of 1877.

Reversing a familiar proverb, it may truly be said that it is a good wind that blows no one any ill. The continued abatement of the prevalence of diphtheria in my dispensary district—the Twenty-first ward—amounting of late to its almost complete disappearance, has rendered the accumulation of test-cases a tedious process, and less satisfactory in point of numbers than could have been wished. This abatement is illustrated by the following figures: In the great epidemic in that district of 1875, which was the occasion and the principal topic of my previous paper, 124 dispensary cases were visited; in 1876, 37, the statistics of which I reported in the Medical Record of January 12, 1878; in 1877 there were 18; in 1878, 18; and in 1879 only 4—not a case having now been seen since last September. This diminution has occurred while the total number of patients visited has increased. It is true that diphtheria has continued to be quite prevalent in some portions of the city; but it should be remembered that epidemics here are frequently, if not usually, more or less local and limited, and those of diphtheria especially, doubtless depend, in part at least, on endemic conditions which are imperfectly understood, and cannot be discussed in this paper.

It will be conducive to clearness and brevity in the narration of these cases to first recapitulate as concisely as is possible the principles and the therapeutical methods which it was desired in them to put to the test of further practical application.

DIPHTHERIA A PRIMARILY LOCAL AFFECTION.

The principle which I believe to be fundamental to all sound theory and practice in diphtheria is that the disease is, to all practical intents at least, to be considered as primarily a local affection, and that all its specific constitutional phenomena are simply secondary results by absorption from that source. I hold this belief for reasons which I must beg leave to reiterate:

First, because in some hundreds of cases of all grades of mildness and malignancy which I have had the opportunity of observing at quite an early stage in ten years of dispensary practice, the local membranous affection has always preceded those constitutional symptoms which are peculiar to the disease. There are no distinctive primary symptoms of diphtheria—those which are often described as such being simply common to the onset of various catarrhal throat affections. But it is stated, *per contra*, by excellent authorities, that death or paralysis has resulted from the primary poison of diphtheria in cases in which no membrane has been present. It is very easy to be deceived on this point. I have not infrequently seen cases in which the constitutional symptoms of diphtheria were evident, but on careful examination no membrane was visible. Such cases will be mentioned in the present report. In all such instances, however, membrane has been proved to exist in some concealed position. Again, it is well known that epidemics of diphtheria and of scarlatina are frequently associated. How naturally under such circumstances might a death from malignant scarlatina without eruption be erroneously attributed to diphtheria! The fundamental laws of disease, like the other laws of nature, are uniform. Shall the evidence of a hundred concurring positive observations be outweighed by that of a negative one, the conclu-

* Read before the New York Academy of Medicine, March 4, 1880.

ave proof of which is, in the nature of things, well nigh impossible?

Second, because the gravity of the constitutional symptoms is generally proportionate to the extent and depth of the membranous affection.

Third, because the employment of proper local and constant treatment does, in many cases, promptly subdue or quite dispel constitutional symptoms previously existing, or, if early employed, prevent either wholly or in great measure their occurrence. This is notably true of the symptom albuminuria, which has so often been adduced as especially characteristic of diphtheria, and an evidence of its primarily constitutional nature. The laws of its relation to diphtheria being properly understood, it goes over with strong reinforcement to the opposite view.

Fourth and finally, because proper local disinfectant treatment is beyond all comparison the most effective of the means at our command for successfully combating the disease. The further corroboration of this statement is the principal object of the present paper.

Having, from these clinical considerations, with suggestions from various sources in medical literature, arrived at this pathological view, and the logically resultant therapeutical method which I have since employed, I received great and delightful confirmation in both, with much additional instruction, from perusing the most admirable and valuable monograph* of Dr Jacobi. This was a year before my first report was written.

DIAGNOSIS.

My diagnosis of diphtheria has always been based on the presence of membranous exudation, which I believe to be the one pathognomonic sign of the disease. True membranous exudation in the fauces and pharynx is never altogether superficial to the mucous membrane, though it may be so in the trachea and bronchi. In this observation I am confirmed by Virchow, who adds that there is therefore no croupous angina or pharyngitis. The depth to which the exudative process may penetrate the epithelial layers, however, varies greatly in different cases, and on this more than anything else depends the gravity of the constitutional affection. This diversity has been made by many the basis of a pathological division, the more superficial deposit being called croupous, and that only in which the deeper epithelial layers or the sub-epithelial tissues are involved, as diphtheritic. Such a distinction, however, ignores the fact, which is generally admitted, that the exudation in both forms is essentially identical, and the other more conclusive one, that the two forms are constantly seen together, not only in groups of associated cases, but in the same case.

Even so excellent an authority as Wagner, in his valuable article on the disease in the sixth volume of Ziemssen's Cyclopædia, while he expressly admits that these forms are but varieties of one main affection, yet violates etymology by employing the misleading nomenclature of croupous and croupous-diphtheritic. The proper classification is into mild and grave, or shallow and deep.

But the important question remains, How is diphtheritic exudation in its early stage or its milder forms to be distinguished from certain other appearances which often closely resemble it, but pathologically bear no relation to it?

I answer that in ordinary pharyngitis we often see whitish patches of pultaceous follicular secretion, or smearings of white tenacious mucus, or ulcers of various kinds, covered over with or surrounded by more little distances by whitish or grayish mucopus. These appearances may be very deceptive to the inexperienced eye. Their true character may be readily ascertained by brushing them with a swab, or, still better, by throwing a stream of water upon them from a syringe. In herpetic angina, the little vesicles and the resulting ulcers are easily recognized when clearly exposed to view by this method.

But by far the most frequent occasion of error in diagnosis is the very common affection known as acute catarrhal, lacunal, or follicular tonsilitis. That I can, in the limits of this paper, touch only briefly upon it causes me the less regret, as so excellent a sketch of it was recently presented to the Academy by Dr. Lefferts. In this angina there may variously be seen on the swollen tonsil or tonsils little spots or streaks of white muco-pus flowing from and surrounding the lacunal orifices, or the points of cheesy masses protruding from them, or a whitish or grayish patch of inspissated conglomerate material covering and concealing several of these orifices and the intervening mucous surface. These patches vary in size ordinarily from that of a silver three cent piece to that of a ten cent piece. They are often rather firm in texture, and may bear a striking resemblance to diphtheritic membrane; or there may be two such patches, one above the other, or, again, in occasional instances, nearly the whole surface of the tonsil is covered with a thick and firm investment of this character. If this appearance is accompanied, as it sometimes is, with grave constitutional disturbance, distress, and prostration, if there is some enlargement of cervical glands, if the throat is filled with tenacious muco-pus, perhaps rendered sanious by points of ulceration; if there is fetor of the breath; if on the uvula or the palatine arches are the whitish smearings above referred to, the practitioner who has not studied this subject carefully and well naturally supposes that he has to deal not only with a case of diphtheria, but with a grave one, and is delighted at his success in curing it in two or three days, as he is certain to do if his treatment is not more formidable than the disease.

But how shall the diagnosis be made? Not by the circumstance that the exudation is limited to the tonsil or tonsils, for that is often true in diphtheria; nor by its short duration, for that is equalled by very mild forms of diphtheria; nor by the test of infection or non-infection, for catarrhal tonsilitis is probably sometimes infectious; nor by the presence or absence of albuminuria, for reasons which are elsewhere stated. Whitish points projecting or liquids oozing from the lacunal orifices are pathognomonic. A circumstance that I believe to be of some diagnostic value is, that the single patches above referred to are usually situated on the greatest convexity of the tonsil—that is, the portion that looks toward the uvula or the other tonsil; while, on the other hand, diphtheritic membrane is rarely, if ever, limited to that position, but, when it occurs in a small patch, is rather more marginal. I can give no anatomical explanation of this circumstance except that the crypts opening upon the central portion of the tonsillar surface are the largest and deepest.

In the rarer cases in which the greater portion of the tonsil is covered, the investment may be seen to be rather coarser in texture than true diphtheritic membrane. It presents, also, the appearance of being spread superficially over the mucous membrane

* In Journal of Obstetrics, Feb., 1875.

rather than in intimate union with it; and this appearance indicates the reality, which is the most important element in the diagnosis. If a portion of it be scraped off, which can generally be easily done with a suitable instrument, the unimpaired surface of the mucous membrane beneath it is evidence of its non-diphtheritic character. Or, preferably, a smart syringing of the tonsil with warm salt water will usually at once clear up the difficulties of the diagnosis. The diphtheroid deposit will be in part at least broken up and washed away, showing its friable and superficial character, the epithelial surface appearing intact, except just about the lacunal orifices, where there is frequently some appearance of inflammatory erosion.

The diphtheroid membrane of follicular tonsillitis, if undisturbed, will disappear after two or three days. There may then be seen, in many cases, about the lacunal orifices, shallow pits or depressions, the result of the erosion just referred to, or deeper cavities appear, sometimes with precipitous and jagged edges, as if portions of tissue had been gouged out. These are probably the gaping mouths of crypts from which masses of solid accumulation have just been discharged. They are most often seen on the upper and inner portion of the tonsillar surface. It is, doubtless, mainly due to these common appearances, that the term ulcerative sore-throat has come into such general use. They mark the termination of the acute stage of follicular tonsillitis, and confirm the diagnosis, as they do not, according to my observation, follow those mild forms of tonsillar diphtheria which are of equally short duration.

It should be added, that catarrhal tonsillitis occurs epidemically and endemically. My former assistants and I have many records of its affecting, while thus prevalent, nearly all the members of a family, and several families in a house, and the inmates of various houses in a neighborhood. May not this fact explain some of the wonderful therapeutical triumphs in epidemics of so called diphtheria of which we hear and read, in which cases have been treated by the hundred without a single death?

For the purpose of inspecting the throat, the child should be placed directly in front of a window, or a good artificial light. Its hands must often be held by one person, and its head by another. Many an error in medical practice, and in medical literature, has resulted from negligence or incompetence in throat examination.

TREATMENT.

In the treatment of diphtheria by methods of local disinfection, the danger to be most sedulously avoided is irritation. It is this which has again and again brought these methods into deserved disrepute.

Swallowing a little water at frequent intervals would doubtless be of some utility in helping to remove foul secretions from the throat. I have instead employed, in most cases, in alternation and usually at half-hour intervals, teaspoonful doses of the following pleasant mixtures: 1st, two scruples of chlorate of potassa, with half a fluid ounce of glycerine and two ounces and a half of lime-water; 2d, one fluid drachm of the tincture of the chloride of iron, with an ounce each of glycerine and water. I have omitted the use of the latter mixture, in some cases, with advantage. The tincture of iron has apparently a valuable constitutional, as well as local, effect in some cases; in others it has neither, and in some it has an injuriously irritant action even in mild dilution. It is far from being a specific for the disease.

I have also had the throat sprayed very frequently when practicable, by means of a hand-atomizer, with a mixture of ten minims of carbolic acid in four ounces of lime-water.

It is not worth while to defend the importance of these simple formulæ against those who would sneer at such details. I will mention, however, that I have in more than one case, either in my own practice or in consultation, seen very bad results from slight deviations from them, through the error of the prescriber or of the apothecary, which had the effect of making them less efficient, less pleasant, or more irritating. The recognition of the true principle in the treatment of diphtheria is nearly as ancient as the description of the disease. That it has not long ago been universally adopted and utilized by the profession to the saving of many thousands of lives, is because its discovery was not accompanied with that of the details necessary to its successful application.

Finally, but in many bad cases first in importance, I have washed the affected surfaces, at suitable intervals, by means of a syringe. The instrument employed has been the Roosa hard-rubber ear-syringe; the liquid, a weak tepid solution of common salt. It should be thrown through the open mouth into the throat, or through the nostrils into the nasal passages and the pharynx, and continued until the foul and poisonous secretions are thoroughly washed away and fetor is corrected. It is essential that this be done *secundum artem*. The method was described in my previous paper.

In the treatment of young children, I have found it very important to avoid the use of any unpleasant medicine, such as quinine, cubebs, etc.

Stimulants may be useful in the later stage of protracted cases, and in convalescence. Given early and freely, they too often prove not an antidote, but an auxiliary poison to that of the disease. Instead of sustaining they help to overwhelm. Such, at least, has been the teaching of my experience formerly in their employment, and latterly in their more general disuse. The large majority of cases in the present series, as in those that I have previously reported, have been treated absolutely without them. If there has been agreement in the profession on any one point in the treatment of diphtheria, it has been in the early and free use of alcoholic stimulants, which has indeed been advocated by some as a specific. Have the general results of this practice been so brilliant that those of a different course may not be experimentally tested?

Proper nutrition is of the greatest importance. Milk has ordinarily been my main reliance. It should be given freely and often—even by force, if necessary; and rectal alimentation, when indicated, should by no means be omitted.

In the relation of the following cases details are given of a few only which illustrate some important lesson, and such brief description only of others as is necessary to show the actual types of the disease that have been dealt with. [The reader who may lack the time or patience requisite for their perusal is referred to the subsequent *résumé* of their most important features.]

The first six cases occurred in one family. They all proved easily controllable, and three were extremely mild. Their interest, therefore, is rather diagnostic and pathological than therapeutical. Their history is as follows:

Case I.—John Dagnell, aged 4, visited at 332 East Thirty first street, January 7, 1877. He had been taken two days before to Bellevue Dispensary, where his case had been diagnosed as diphtheria. A liquid had been prescribed which his mother was to apply to his throat with a brush. I found him with high fever and cachectic aspect; refusing nourishment; tonsils much swollen, and membrane on the right one; cervical adenitis and purulent nasal discharge. He was evidently doing badly. Under my treatment improvement was rapid. The next day the appearance of his countenance was comparatively healthy, and he was taking nourishment well. On January 11th, membrane had disappeared, and nasal discharge had ceased.

Case II.—Bernard, his twin brother; January 12th. A similar case of tonsillar and nasal diphtheria. Seen by Dr White. Duration, six days. Urine tested on fourth day; no albumen.

Case III.—Joseph, aged 2; January 14th. Well-marked diphtheritic membrane on lower anterior aspect of right tonsil. Seen by Dr. White. Duration, two days.

Case IV.—Thomas, aged 9; January 15th. Taken ill that morning. Tonsils inflamed, and on the right one two transverse streaks or bands of membrane. These streaks remained unchanged though vigorously brushed with a swab for some minutes in the presence of Dr. Harriman, now of Manchester, N. H. At length, by persistent scraping with the point of my forceps, I succeeded in detaching some small bits or tufts which had only a feeble cohesion, leaving a roughened and raw-looking surface. This substance was examined microscopically by Dr. Satterthwaite, and found to be "an amorphous substance containing myriads of rod-shaped bacteria, and a limited number of pus-corpuscles and epithelial scales."

Case V.—Ann, the mother, aged 30; January 17th. Taken ill that morning. Thin membrane covering the lower posterior surface of right tonsil.

January 18th, a similar patch also on left one. Removed some of the latter with forceps after persistent scraping for ten minutes, leaving a raw-looking surface, and submitted it to Dr. Satterthwaite, who found it to consist of a "glutinous substance in which the fibrillation is very faintly marked. There are, however, many layers of flat epithelial elements, and with them a large amount of pus. Rod-shaped bacteria are numerous as usual." On the 20th, membrane had disappeared.

Case VI.—Ellen, a nursing infant, aged 11 months; January 23d. Taken ill the previous night. On the lower posterior aspect of each tonsil is a well-marked patch of membrane. Next day I detached a bit of this with forceps, leaving a raw and bleeding surface. Dr. Satterthwaite gives the following report of this specimen: "Microscopically the deposit is seen to consist of pretty well-marked fibrillated tissue, throughout which are numerous pus and epithelial corpuscles, bacteria of rod-form and leptothrix filaments. There is also some blood."

January 28th.—Membrane has disappeared.

On February 10th following I was called to see Bernard, the second of the above series, and found him suffering from regurgitation of liquids through the nose, inarticulate and nasal speech, and insensibility of palate. Dr. Swezey, physician to the class of nervous diseases at the dispensary, confirmed my diagnosis of faucial diphtheritic paralysis.

The diagnosis of diphtheria in the mildest of the above cases seems to be established by the completely demonstrated character of some of the cases, by the occurrence of all in a continuous series, and by exclusion. In neither of them was there any indication of follicular inflammation nor any form of ulceration. To save repetition I will now add that this is true of every case mentioned in this report. The microscopic examinations were in the first two instances of exceptionally slight and imperfectly organized membranous deposit on the first day, and probably within a few hours of its occurrence. It is to be noted that this comparatively superficial diphtheritic deposit conformed in its relation to the mucous membrane to the law above laid down.

Case VII.—Rose McCaffry, aged 11 months, 340 East Thirty first street; January 13th, third day of the disease. Membrane on both tonsils; nasal discharge with excoriation of nostrils and upper lip; fever, adenitis; evident diphtheritic toxæmia; refuses the breast. Seen by Dr. White. Cured in four days. Three weeks later was attacked with convergent strabismus of both eyes, which was also seen by Dr White, and which persisted for several months.

Case VIII.—A fatal case. These will be subsequently described.

Case IX.—Mary McAuliffe, aged 8, 435 First avenue, March 12th, second day of the disease. Sleeplessness, vomiting, distress, and marked diphtheritic pallor. Swelling of submaxillary glands. A patch of membrane on the soft palate, extending down over the right anterior faucial pillar. Temperature, 102°.

March 14th.—Urine examined, no trace of albumen.

March 17th.—Discharged cured the sixth day of treatment. Seen twice by Dr. Smith, and daily by Dr. A. E. Prince, now of Grand Rapids, Mich.

Case X.—The following case, presenting features of especial interest, will be related in extenso: William Foster, aged 3, 489 First avenue; March 17th. Had been feverish and vomited all night. Faucial and external swelling. On posterior side of left tonsil a patch of membrane. March 18th.—General condition improved; had slept some, and had taken food and drink pretty well. March 19th.—There had been a sudden change to cold and windy weather. Found the child playing on the floor in a cold room. Throat more swollen and both tonsils covered with membrane. Temperature, 101¾°. March 20th.—Still worse. Membrane had extended over the posterior wall of the pharynx and the back part of the tongue. Throat full of a viscid secretion. March 21st.—Several pieces of membrane have been coughed up, and none remains in the throat except the original patch on the posterior side of the left tonsil, which is particularly firm and thick. March 22d. Condition of the throat the same. Urine for the first time scanty, and the countenance has that heavy and puffy appearance that suggests uræmic poisoning. The urine is found to be heavily loaded with albumen. Indisposition to take nourishment, and occasional vomiting. Dry cups were applied over the kidneys, and, in addition to the other remedies, infusion of digitalis and citrate of potassa were prescribed.

March 23d and 24th.—No change in the symptoms, the thick membrane persisting on the left tonsil, and the urine continuing scanty and heavily loaded with albumen.

March 25th.—Membrane has disappeared. Urine much increased in quantity and contains but little albumen. Vomiting has ceased and the case is considered convalescent.

March 26th.—Much worse. Membrane again on left tonsil. Urine again scanty and heavily albuminous. Vomiting began in the night, and frequent all day. Nourishment refused. Child pale, weak, irritable, drowsy, vomiting frequently, and refusing nourishment. Prognosis bad. I now learned that the child, who had no mother, had been entrusted at night to an aged grandmother, who had neglected to give his medicines and milk as directed, which was doubtless, in part at least, the cause of this alarming change.

I now decided to discontinue all other medication and to combat the constitutional disease entirely by the usual anti-diphtheritic measures, which were from this time faithfully carried out both by day and night. Warm poultices were directed to be kept over the abdomen and lumbar region.

March 27th.—Somewhat stronger and brighter. Vomits only seldom, and retains some nourishment.

March 28th.—Much improved. No vomiting; takes milk freely. Urine more abundant, but still somewhat albuminous. Membrane on left tonsil very dense, firm, and thick.

This condition continued unchanged for six days more. At length the obstinate patch of membrane disappeared. The next day the albumen in the urine had greatly diminished, and on the following day was scarcely perceptible. Convalescence was this time permanent. This case, which is of no very unusual type, yet presents some features which deserve to be distinctly noted: First, the very common one of the occurrence of rather extensive membranous exudation, all of which was comparatively superficial, or, as some prefer to call it, croupous, and disappeared under treatment in two or three days, with the exception of one patch—that on the posterior side of the left tonsil—which was very deep and unyielding, the latter having persisted for seventeen days in two successive deposits of eight and nine days' duration. Second, the occurrence of albuminuria after exposure to cold about the fifth day of the first deposit; its marked diminution after the detachment of the membrane; its return in aggravated degree after the formation of the second; its diminution under faithful disinfectant treatment, and its prompt cessation after the final disappearance of the membrane. Third, this case illustrates the difficulty and the importance of knowing that directions are faithfully carried out—a difficulty not always confined to dispensary practice. Fourth, the importance of having sufficiently definite and clear convictions to persist in a proper line of treatment, even when a case is progressing unfavorably, and of remembering that the stomach of a child whose vital forces are prostrated with diphtheritic poison, is not a suitable receptacle for a varied assortment of powerful and nauseating drugs.

This case was seen by Dr. White, three times by Dr. Smith, and daily with valuable assistance in treatment by Dr. Prince

About ten days after his recovery, this child was attacked with paralysis, both of the fauces and the lower limbs, which disappeared without special treatment in five or six weeks.

Case XII.—Thomas Malony, aged 7, 506 First avenue; September 19th. In spite of treatment this case grew worse, and on the 21st, when seen with me by Dr. Smith, presented a swollen and œdematous throat, left tonsil much enlarged and covered with membrane, cervical glands on that side enlarged, hard and tender, high fever, and marked evidences of diphtheritic toxæmia. So plainly was the case one of bad tendency, that Dr. Smith remarked that it would be a good one to test the efficacy of my treatment.

Four days later he again saw the case with me. Membrane had disappeared, faucial swelling had diminished, adenitis was scarcely perceptible, pulse and temperature were nearly normal, though pallor still remained. Duration of membranous affection under treatment, six days. The urine was twice examined and exhibited no trace of albumen.

Case XIII.—Mary Callahan, aged 2½, 340 East Twenty-sixth street; September 24th, third day of illness. Every attempt to swallow at once followed by vomiting. Profuse purulent discharge from nostrils, producing angry inflammation of upper lip. Throat red and much swollen. No membrane visible.

September 25th.—A band of membrane now encircles the uvula, which is doubtless a continuation from a previously existing deposit on the posterior side of the soft palate. High fever and marked cachexia.

I at once commenced syringing the throat through the mouth and the nasal passages twice daily, and directed the two mixtures and milk and lime-water to be given by force. The case was seen by Dr. Smith.

September 28th.—Vomiting has ceased, and nasal discharge diminished. Uvula still coated with membrane. Milk and medicines taken freely. Pieces of membrane washed from behind the palate by syringing.

September 30th. Nasal discharge has nearly ceased, and membrane on uvula diminished. General condition good. Thinking the other remedies would now be sufficient, I took away my syringe.

The second day afterward (October 2d), I found the case much worse than ever. The child was feverish, pale, and weak; had not slept, refused nourishment, membrane on uvula had increased, and nasal discharge was again profuse. Syringing was resumed.

October 3d.—Urine tested; no albumen.

October 8th.—Membrane has disappeared and nasal discharge has ceased. Duration of disease under treatment, fourteen days.

Case XIV.—Edward Barr, aged 5, 350 East Thirty-second street; September 29th, fourth day of illness. Severe tonsillar diphtheria, with implication of the posterior nares. The case had been seen the day before by a respectable physician, who had prescribed the too common combination of iron, quinine, and glycerine. This the child, who was neither a lover of bitter things nor yet a Stoic philosopher, had, after once tasting, refused to take. Dr. Smith probably remembers how much time and how much moral suasion were expended before the little patient could be induced to taste the medicines which I had prescribed. Having once tasted them, however, every difficulty at once vanished. He was discharged cured four days later. Urine tested on fourth day; no albumen.

Case XV.—Kate Madden, aged 5, 232 East Twenty-ninth street; October 22d, third day of illness. A very grave case; high fever, pallor, cervical adenitis, intense pharyngitis, with large patch of membrane on each tonsil. Seen by Dr. White.

Oct. 23d.—Profuse purulent nasal discharge; syringing twice daily. 24th.—Seen by Dr. Smith.

Oct. 25th.—Membrane has disappeared from tonsils, but covers left faucial pillar.

Oct. 27th.—This has disappeared. Patch on right pillar. Great general faucial inflammation. Moaning and delirium at night; nose-bleed frequently. Urine tested; no albumen.

Oct. 29th.—Only small spots in the throat, but a

large patch of membrane occupies centre of the tongue.

Oct. 31st.—Membrane has disappeared. Some nasal discharge continues. Marked pallor and extreme feebleness.

Nov. 3d.—Discharged cured; thirteenth day of treatment.

Cases XVI., XVII., and XVIII.—Henry, Antony, and James Sargahan, aged 6 years, 4 years, and 10 months, 422 East Twenty-fifth street, November 17th, 22d, and 23d. Three cases of medium severity, with membrane on both tonsils in first and third; on right tonsil and faucial arch in second. The first and second seen by Dr. Smith, the third by Dr. White. Duration under treatment, three days, four days, and six days. Urine tested in the first two; no albumen.

Case XIX.—Carrie Fitzpatrick, aged 2½, 310 East Thirty-first street, January 14, 1878, third day of illness. Much faucial inflammation and glandular swelling, but no membrane visible. Profuse purulent nasal discharge, and throat filled with similar material. Marked diphtheritic pallor and depression. Diagnosis of probable membrane posteriorly to the soft palate.

Jan. 15th.—This diagnosis confirmed by the appearance of membrane on the posterior side of the uvula. The usual remedies employed, including syringing twice daily.

Jan. 16th.—Membrane also on posterior aspect of both tonsils. Seen by Dr. White.

Jan. 18th.—Improved. Membrane and nasal discharge diminished. Seen by Dr. Smith.

Jan. 19th.—Discharged cured, having been under treatment five days.

Case XXI.—Sarah Hawley, aged 5, 590 Second avenue; February 11th. A severe case, with membrane on both tonsils and uvula, faucial swelling, and much cervical adenitis. Urine tested on fourth day; no albumen. Duration, seven days. Seen by Dr. Smith and daily by Dr. O. B. Douglas.

Case XXII.—A gangrenous case. Edward Scully, aged 5, 338 East Fortieth street; February 19th, eighth day of illness. The history given by the parents was that he had been attacked a week before with sore throat and much swelling, with white patches in his throat. He had been treated by a homœopathic physician, who had steamed his throat. He had continued to grow worse. Much glandular swelling about the neck, and great faucial tumefaction. Some membrane on uvula and left faucial arch, but the surface of the right tonsil and of the posterior wall of the pharynx occupied by gangrenous inflammation and sloughing with most offensive odor. Foul purulent discharge from nose. Extreme pallor and weakness. Swallowing extremely difficult.

Although recovery was considered impossible, treatment was commenced and faithfully continued; the internal remedies, spray, and throat and nasal syringing, being assiduously employed.

Feb. 21st.—Some improvement, but patient is very weak. Swallows with the greatest difficulty. Masses of black, offensive slough have been detached from his throat by direct syringing.

Feb. 23d.—Nasal discharge has nearly ceased. Membrane persists on uvula. Gangrenous material nearly removed from throat, leaving raw and painful surfaces. Swallowing is a most distressing effort; no sleep. Alarming weakness and prostration. Urine tested; no albumen.

Feb. 26th.—Condition of throat improved, but increased dysphagia, with continued sleeplessness and weakness.

Feb. 28th.—Throat quite clean. Much evident loss of substance, but the granulating surfaces are healthy. Takes liquid nourishment freely and sleeps well. Duration of disease, seventeen days, under my treatment nine days.

This case was seen twice by Dr Smith, daily by Dr O. B. Douglas, and also at times by several other physicians. It is probable that few cases so unfavorable as this have ever recovered.

Case XXIII.—Will Shaw, aged 1 year and 10 months, 491 First avenue, March 6th. A severe case. Cervical adenitis, membrane on both tonsils and uvula, nasal implication, and laryngeal croup, which persisted for ten days. Treatment the usual remedies, with syringing twice daily. Seen by Dr Smith, and daily by Dr. Douglas.

Case XXIV.—Delia Joyce, aged 5, 319 East Thirty-ninth street, March 8th. Membrane covering both tonsils and uvula; cervical adenitis and evident toxæmia. Cured in five days. Urine tested on third day; no albumen. Seen by Dr. Smith and Dr. Douglas.

Case XXV.—Matilda Geis, aged 3½, 382 Third avenue; April 18th, third day of illness. A most malignant and toxious case. Great faucial and external glandular swelling. Temperature, 104°. Extreme prostration. Membrane covering both tonsils and encircling uvula. Purulent fluid filling the throat and flowing from the nostrils. Large pieces of thick membrane were repeatedly washed by syringing from the post-palatal region. Persistent membrane on tongue and lips. In spite of an unfavorable prognosis, treatment, including syringing twice daily, was kept up for three weeks. During the last week quinine, brandy, and beef-juice were freely administered. Discharged cured on the twenty-second day, but continued in a critically feeble condition for several months. Seen by Dr. Smith and daily by Dr. Douglas.

Case XXVI.—Thomas Duffy, aged 4, 230 East Twenty-ninth street; June 26th. Tonsillar diphtheria of medium severity. The membrane, having exfoliated after four days, was replaced on both tonsils by a second formation, which persisted for four days more. Seen by Drs. White and Douglas. Urine tested on the fourth day; no albumen.

Case XXVIII.—John O'Brien, aged 9 months, 590 Third avenue; August 5th. A very severe and tedious case. Membrane on both tonsils, uvula, and gums. Much cervical adenitis and nasal implication. Syringing twice daily. Discharged cured on twelfth day of treatment. Seen by Dr. White and daily by Dr. Douglas.

Case XXIX.—Jane Reynolds, aged 3, 340 East Thirty-sixth street; Sept. 11th. A most malignant and obstinate case. Membrane covering soft palate, uvula, and tonsils. Much faucial and external swelling; nasal implication. A piece of firm membrane an inch long, and a quarter of an inch thick, washed from the post-palatal region by syringing, and others nearly as large on subsequent occasions. Membrane was removed by treatment, only to be renewed again. That it was only the persistent local treatment that saved the case from a fatal issue was proved by the fact that on two occasions, when it was intermitted for a single night, the condition of the patient had become almost hopeless, with increased local disease, high fever, and the usual evidences of severe constitutional infection. On the renewal of thorough treatment these symptoms would

abate. The disease persisted until Oct. 7th, a duration of twenty-seven days. This case was seen by Dr. White, and daily, with valuable assistance in treatment, by Drs. Douglas and F. C. Riley.

Case XXXI.—Patrick Campbell, aged 6, 583 First avenue; Oct. 27th. Tonsillar diphtheria of medium severity. Duration, six days. Seen by Dr. Smith and Dr. Douglas.

Case XXXII.—Carrie Wardleigh, aged 17, 523 First avenue; Nov. 14th. Distinctive membrane on both tonsils. Duration, four days. Seen by Dr. Smith.

Case XXXIII.—Mary Thompson, aged 12, 233 East Thirty-third street; Nov. 28th, third day. A gangrenous case of the worst type. Its features and history are so similar to those of case twenty-two, which it fully equalled in severity, that details may be omitted. Urine examined on the sixth day; no albumen. On Dec. 11th, the thirteenth day of treatment, diphtheritic disease had disappeared, and gangrenous destruction had been replaced by healthy granulation. Considerable loss of tissue was evident. Seen by Dr. Darken, twice by Dr. Smith, and daily by Dr. Douglas. Faucial, laryngeal, and ocular paralysis followed.

Case XXXIV.—Bridget Heffern, aged 25, 315 East Twenty-ninth street; Dec. 16th. A grave case. Membrane on posterior aspect of both tonsils; subsequently on right posterior pillar, and later, serious laryngeal implication set in, with aphonia and dyspnœa. Duration under treatment, fifteen days. Seen by Dr. Smith, and daily by Dr. Douglas.

Case XXXV.—Nellie Sheridan, aged 8, 338 East Thirty-fourth street; Dec. 20th. A well-marked tonsillar case, of medium severity. Duration seven days. Seen by Dr. Smith, and daily by Dr. Douglas.

Case XXXVI.—Will Fitzgerald, aged 1, 333 East Thirty-fifth street; Dec. 27th. Well-marked tonsillar and nasal diphtheria. Duration, under treatment, five days. Attested only by Dr. Douglas, who saw it daily, as Dr. Smith, though repeatedly requested to visit it, did not find leisure to do so.

Case XXXVIII.—This case presents the rather curious history of scarlatina without eruption supervening upon pre-existing diphtheria—the reverse of the usual order; the resulting disease being one of extraordinary severity.

Thomas Touhay, aged 6, 311 East Thirty-seventh street; February 3, 1879. Had had a cold for two weeks, and sore throat for four days. Membranous patches on the posterior side of both tonsils, and on the post-pharyngeal wall. Throat and nares full of most offensive secretion, and syringing brought from the posterior nares small masses of gangrenous slough. The usual evidences of diphtheritic toxæmia. No symptom of scarlatina.

On the 6th, a younger brother was attacked with malignant scarlatina, and died on the 7th. On that day a sudden and violent rise of temperature in the patient, with increased faucial redness, showed the effect of scarlatinal poison. There was, however, at no time any eruption, nor the strawberry tongue. The child rapidly sank into a profound typhoid condition. The urine and fæces were passed unconsciously for twelve days. The temperature in the axilla was as follows: On the 7th, 105.2°; 8th, morning, 105.2°; evening, 104.5°; pulse weak, rapid, and intermittent; 9th, morning, 105°, evening, 104.5°; 10th, 104.8°; 11th, 103¼°, tongue swollen, otorrhœa; 12th, 101¼°. During this period much foul material, with occasional pieces of membrane, was washed by syringing, morning and evening, from the post-palatal region. During this period, Dr. F. C. Riley, to whom the treatment of the case was mainly entrusted, asked me if such remedies as digitalis, quinine, and brandy, were not plainly indicated. I replied that our patient was almost certain to die, but that we would probably give him his best chance by locally combating diphtheria and septicæmia, supplying nourishment, and, for the rest, trusting with the least possible medication to the reserve forces of nature. Accordingly, our disinfectant measures were persevered with, and milk was given frequently by compulsion, with an occasional teaspoonful of beef-juice. To our surprise we continued to find him alive each morning, though in a critically low condition, until the 20th, a period of fourteen days, when diphtheritic disease had disappeared and convalescence began. The child owes his life to Dr. Riley's faithfulness and perseverance, and also, as I believe, to our disregard of indications. This case was seen by Dr. Smith.

Case XXXIX.—Ann Kennedy, aged 10, 338 East Thirty-third street; March 18th. A very severe case. Much faucial and glandular swelling, foul gangrenous odor, membrane on both tonsils and covering the anterior pillars, and every evidence of diptheritic toxæmia. Mother out at work, and only an aged and imbecile grandmother present. Calling again in the afternoon, I found the mother at home. Left an atomizer, having showed her how to use it, and obtained a promise from her to stay at home and take care of her child.

March 19th.—Found the mother again absent, and the father at home, dead-drunk—he and the imbecile grandmother being the only nurses.

March 20th.—Mother again absent. A stupid neighbor, to whom the care of the child had been entrusted, had been operating in the throat, on her own responsibility, with a swab. Patient in every way worse. I now made arrangements with my assistants, Drs. Riley and Hoag, to henceforth insure faithful treatment by very frequent visits, both by day and night.

March 21st.—Somewhat better. Urine tested; no albumen. Improvement was now continuous, the last trace of membrane being seen on March 31st, the fourteenth day of treatment. This case was seen by Dr. Smith.

That the difficulty in securing efficient nursing was no greater in this case than in a number of others, of which I spare the details, will be readily believed by those who know the peculiarities of dispensary patients. Nor was it always possible to so fully obviate it by personal attendance as in this instance. This disadvantage should in fairness be taken into consideration in estimating the results of treatment.

Case XL.—Lizzie Howard, aged 14 months, 502 Second avenue; September 20th. Throat generally swollen. The uvula, which was several times its normal size, had a thimble-like coating of firmly organized and moderately thick membrane. Occasional vomiting. Swallowing evidently painful.

In order to avoid irritation I prescribed only the chlorate of potassa mixture, requiring this and milk and lime-water to be given frequently by force.

The last trace of membrane was seen on the 25th, the sixth day of treatment. This case was seen by Dr. Smith.

Of the forty cases included in this report, six terminated fatally, viz.:

Case VIII.—Ann George, aged 2, 339 East Twenty-

fifth (sixth) February 16, 1877. Severe croupy symptoms. Membrane on posterior aspect of tonsils.

February 17th.—Extreme laryngeal obstruction. Tracheotomy performed by Dr. White. The patient lived fifty-three hours after the operation. The trachea below the wound was lined with partially organized membrane, which lay loosely on the mucous surface.

Case X.—Thomas Lee, aged 10 months, 189 First avenue; March 12, 1877, third day of the disease. Extensive facial diphtheria, with high fever. Child sleepless and refuses to take.

March 13th. Greatly improved under treatment. Nurses and sleeps. This improvement continued until night, when dyspnœa set in, evidently from laryngeal obstruction, which increased rapidly, and death from asphyxia ensued on the evening of the 14th, tracheotomy having been refused. Seen by Dr. Smith and Dr. Prince.

Case XX.—Mary McGowan, aged 1 year and 6 months, 520 Second avenue; February 9, 1878, third day. A sickly, ill-nourished child of strumous diathesis. Has an unhealed sore on her hand of four months' standing. Membrane on both tonsils, uvula, and velum, with much swelling, and nose so much obstructed that efficient syringing is impossible. Marked diphtheritic toxæmia. Prognosis bad.

February 11th.—Profuse nose-bleed. The parents having become discouraged, neglected the regular use of the remedies.

February 16th.—The child died from septicæmia and exhaustion. The unfavorable circumstances in this case were, first, the advanced stage of the disease when treatment was commenced; second, the age; third, exceptional inefficiency in the nursing; and fourth, the low vitality of the patient. The case was seen by Dr. Smith and Dr. Douglas. Stimulants were in this instance freely administered from the first.

Case XXVII.—Robert Brown, aged 3, 308 East Twenty-sixth street; first seen July 8, 1878, the fifth day of illness. Drs. White and Smith both being out of town, Dr. Herrick kindly saw the case with me. It was then in a hopeless and almost moribund condition from extensive faucial deposit, toxæmia, and laryngeal croup. Tracheotomy was refused, and death occurred from asphyxia on the following day—less than twenty hours after the case was first seen. It will, of course, be excluded from the list of those in which treatment could be in any degree tested.

Case XXX.—Ann Daly, aged 7½, 312 East Thirty-eighth street; seen September 27, 1878. This case, as was stated by the parents, after having been under the treatment of a physician for a week or more, had been abandoned by him. It had then come under the charitable notice of Dr. W. O. Moore, who had referred it to the dispensary for treatment. It was visited at evening by Dr. F. C. Riley. The atomizer he prescribed was not even procured. I only learned of the case on the following day so as to see it about noon. The patient was then moribund from laryngeal croup, and died from asphyxia a few hours later, tracheotomy having been refused. This case also will be excluded from the list of those in which treatment could be in any degree tested.

Case XXXVII.—Kate Rooney, aged 3, 314 East Thirty-ninth street; January 3, 1879. Laryngeal diphtheria, with extensive faucial deposit. The exceptional perversity and negligence of the parents rendered efficient treatment impossible. The child died from asphyxia on January 7th. This case was seen daily by Dr. Riley.

RESULT OF CASES, WITH REMARKS.

Out of these 40 cases, then, *seen* in dispensary visitation, there were 6 deaths, but out of 38 cases *treated* with such efficiency as was practicable under most unfavorable circumstances there were 4 deaths—or a little over 10 per cent.

The statistics which I have previously published, of which the present series has been a continuation, and was intended to be a test, were as follows. In 1875, out of 124 cases visited in the same district, 20 died; but out of 98 treated, 10 died; and in 1876, out of 87 cases visited there were 5 deaths, but out of 32 treated there were 3 deaths—about the same percentage in each series.

But a further classification of the present series will doubtless add to the instruction which may be derived from them.

Of the 38 cases treated, 6 were one year old or under, 5 from one to two, 5 from two to three, or 16 of three years or under—an unusually large proportion, and as is universally conceded, and for obvious reasons, an unfavorable circumstance. This portion of the cases included all of the fatal cases—the ages in these being respectively ten months, eighteen months, two years, and three years.

The gravity under treatment of the thirty-four cases that recovered may be fairly stated as follows: Very mild, three (Nos. 3, 4, and 5); mild or moderately severe, fifteen (Nos. 1, 2, 6, 7, 14, 16, 17, 18, 24, 26, 31, 32, 35, 36, and 40); decidedly severe, five (Nos. 9, 12, 21, 23, and 29); extremely severe, including three gangrenous ones, eleven (Nos. 11, 13, 15, 22, 25, 28, 29, 33, 34, 38, and 39).

The location of diphtheritic exudation in the thirty-eight cases treated was as follows: tonsils only, 11; tonsils and velum, 3; tonsils and nares, 4; tonsils, soft palate, and nares, 8; tonsils and tongue, 1; tonsils, nares, uvula, and gums, 1; tonsils, nares, soft palate, and tongue, 1; tonsils, nares, soft palate, tongue, and lips, 1; uvula, 1; velum, 1; uvula and nares, 1; tonsils and larynx, 1, tonsils, soft palate, and larynx, 4.

Of the five in which the larynx was involved, two recovered and three died. Implication of the larynx is by far the most unfavorable circumstance that ordinarily occurs in diphtheria. It is so for obvious reasons, one of which is that the larynx is, of all the localities that are liable to be affected, the one to which it is most difficult to efficiently apply disinfectant treatment. In my previous paper I expressed the belief, supported by cases, that the very frequent use of the spray of carbolic acid and lime-water is one of the most reliable means for accomplishing that object, and that it not only sometimes cures, but tends to prevent laryngeal diphtheria. In the three fatal laryngeal cases in the present series the patients were too young to permit this means to be employed. The principle of the supreme importance of local disinfectant treatment is no less strikingly confirmed in its limitations and failures than in its successes—its failures being those cases in which it cannot be or is not efficiently applied.

In laryngeal cases in which the spray cannot be employed, the weight of published evidence is doubtless in favor of the utility of the treatment with the steam of lime-water, though it should be remembered that the cases of its use that are reported are usually those that terminate favorably rather than the larger number in which it fails, and though, moreover, there are certainly grave theoretical objections to it.

Setting aside in the present statistics the three

fatal laryngeal cases, there remain thirty-five cases, an unusually large proportion of which were of great severity, with only one fatal result, and that in a sickly child of one and a half years under particularly inefficient nursing. And this is but a repetition of my previously published experience through a series of years in much larger numbers of cases.

What, then, should be the prognosis in diphtheria? I answer that the presence of laryngeal implication must always occasion grave anxiety, especially in the cases of very young children. The same is true of exceptionally malignant faucial diphtheria in occasional instances of very young children of bad powers of resistance. With these exceptions and but few others, I do not hesitate to assert, realizing the full solemnity and responsibility of the assertion, that the disease, as a rule, can be and should be cured, and that the physician who fails to cure it should anxiously question the soundness of his therapeutical methods, or the skill, the judgment, or the faithfulness with which they have been applied.

The duration under treatment of membranous disease in the thirty-four cases that recovered was as follows: 2 of two days, 2 of three days, 4 of four days, 5 of five days, 6 of six days, 2 of seven days, 1 of eight days, 1 of ten days, 1 of twelve days, 2 of thirteen days, 3 of fourteen days, 1 of fifteen days, 2 of seventeen days, 1 of twenty-two days, 1 of twenty-seven days. This is of importance, not merely as showing the grave and persistent type of many of these cases, but as illustrating just what has been accomplished by treatment. In the milder cases the comparatively superficial membranous exudation has been dispelled and the duration of the disease shortened, but in those of deeper and severer grade the amount of membrane has been diminished by the early removal of the more superficial portions, the deeper patches persisting or being repeatedly renewed. At the same time enough of the locally produced poison in the foul secretions of the throat and nasal passages has been either neutralized or washed away to prevent fatal septicæmia, the patient being thus kept alive until the membranous affection has finally yielded. And this suggests the inquiry, would it be generally an advantage if we possessed an innocuous solvent by means of which we could at once remove deep and firmly adherent membrane? I believe not. Such membrane is probably a desirable protection until such time as it exfoliates by natural processes, when there has been sufficient tissue-repair beneath it to render its presence no longer necessary. It is true that while it remains *in situ* its under surface is a laboratory for the production and retention of septic poison. But there seems to be possible sufficient transudation of fluids through it, so that by the frequent application of disinfectants to its surface this evil is partially obviated. I am led to this conclusion by the fact to which I have already referred, that there is often, after the commencement of disinfectant treatment, a prompt and striking improvement in the symptoms that depend on toxæmia, though the membrane may remain undiminished. Though the temptation to effect the early removal of such membrane by forcible avulsion or chemical destruction is great, it is therefore a temptation which should usually be resisted. *Ne quid nimis* is a golden rule in the treatment of diphtheria.

In fifteen of the thirty-four cases which recovered, throat and nasal syringing was employed. No one who watched the progress of these cases could have doubted that but for this procedure most of them must have terminated fatally. Nasal implication has been pronounced by eminent authorities one of the most unfavorable circumstances in diphtheria, but by the timely and proper use of this therapeutical measure it is robbed of its terrors. I repeat with emphasis its *proper* use—for I have known it to be very badly done even by physicians, and when it is inefficiently or bunglingly practised, or is overdone, it may be not only useless but injurious. It is not only in removing foul accumulations from the nasal passages that it is useful. The action of common salt in producing exosmosis and causing free secretion from mucous surfaces is well known, and in this way it has proved of great service in relieving congestion, promoting disinfection, and expediting the detachment of membrane in bad forms of pharyngeal diphtheria. The superiority of this mode of applying it over that of gargling is beyond comparison.

The urine was tested for albumen in fourteen of the foregoing cases, including a fair proportion of the most severe—always when the disease had continued for some days, and usually when it was at its height. That it was not tested in all was simply because some of the patients were so very young, and from negligence in other cases. In only one (No. 11) was any trace of albumen found.

The occurrence of albuminuria is rather the exception than the rule in cases of diphtheria which are properly treated.

Success, such as I have described, in the treatment of diphtheria will never be attained even with the nominal employment of these methods by merely issuing directions in one or two brief visits daily, but can only be the reward of the closest, the most determined, and the most intelligent attention to every detail, with a dexterity in manipulation and adaptation of means to each particular case that can only be the result of experience. It must be seen that the child takes his medicines and his nourishment. He must, if possible, be taught to permit the use of the spray. While gentle persuasion is sufficient in most instances, stern determination or actual force is now and then required. The issue in many a case depends on tact and efficiency in this particular. It is equally necessary that the parents or nurses be not only instructed but trained in each practical detail, and inspired with the faith and zeal that will insure the absolute carrying out of every direction, through the anxious and weary days and nights of a perhaps tedious and discouraging illness. If the treatment of bad forms of this disease makes unusual demands on the vigilance and energies of the physician, there is scarcely another in which he can so often be compensated with the supreme satisfaction of having unquestionably been the instrument of saving life.

I might reinforce the conclusions drawn from this series of cases, with the lessons of a few treated during the same period in my private practice, and of a larger number seen in consultation, and with the concurrent testimony of numerous interesting and instructive letters which I have received from physicians in all parts of the country, who have tested this method of treatment; but the proper limitations of time have already been exceeded.

That I have now twice presumed to ask the attention and occupy the time of the Academy on this topic, has been in obedience to such considerations as were recently so eloquently urged upon us by our honored President in speaking of the obligations of those holding positions in public institutions to the profession at large. Having, in the course of my duties as out-door dispensary visitant, enjoyed rather

exceptional opportunities of clinically studying this subject, I have endeavored and to the best of my ability placed the result of that study before the profession, with no worse wish than that so much of it only as is true may meet with acceptance, and that it may prove of service to some.

ETHYLIZATION:

THE ANÆSTHETIC USE OF THE BROMIDE OF ETHYL.

BY R. J. LEVIS, M.D.,

SURGEON TO THE PENNSYLVANIA HOSPITAL AND TO THE JEFFERSON MEDICAL HOSPITAL, PHILADELPHIA.

MY observations of the anæsthetic action of the bromide of ethyl, which commenced nearly one year ago, have been directed to its physiological action in the human subject, to its practical application in the relief of human suffering, and to its value as compared with other anæsthetics. Every administration has been carefully watched and studied, and records of its phenomena have been made as they were observed. From such basis of experience, I present some facts which may at least help toward a proper estimate and appreciation of its therapeutic value.

Since the publication of my recent articles on the subject in the *Philadelphia Medical Times*, my continued observations have been generally confirmatory of the statements then made. I now summarize the deductions from my entire experience in the anæsthetic use of the bromide of ethyl, and present my convictions in regard to its comparative value.

The terms bromide of ethyl and hydrobromic ether are arbitrarily applied by chemists, in accordance with differing chemical nomenclature; but, for distinctiveness, and without reference to chemical accuracy, I prefer the former expression. I prefer to give to the substance the generic name of ethyl, and speak of ethylizing and ethylization on the same grounds, as, by common consent, the words ether and etherization are applied to sulphuric ether.

The decided characteristics of the administration are its rapidity of action and the quickness of recovery from its impression. I have produced complete anæsthesia in cases of young children in less than one minute. The longest period required to produce the anæsthetic state in adults has not exceeded five minutes.

The ethylized patient recovers much more rapidly than is the case with chloroform or ether. Intellection and muscular co-ordination are regained very soon after the inhalation has ceased. In some instances these functions return as quickly as after the administration of the nitrous oxide gas, and frequently the patient, on awakening, is able to at once stand erect and to walk.

If the anæsthetic impression be slowly effected, a brief period of intellectual excitement, associated with muscular action or rigidity, may occasionally be manifested; but violent emotion and struggling, if they should occur, are more moderate, brief, and transient than in the early stage of the anæsthesia of ether or chloroform. The stage of excitement can generally be avoided by making a rapid impression of the anæsthetic. I have observed that persons accustomed to the habitual use of alcoholic stimulants are less readily impressible by anæsthetics generally, and with them a stage of excitement is apt to precede anæsthesia. In this class of subjects narcotics act as stimulants, and the same holds true with regard to anæsthetics.

As anæsthesia is developed the circulation generally shows evidences of moderate excitement, as indicated by some increase in the rapidity of action of the heart, and the pulse evinces greater general arterial tension. The face of the patient usually becomes brightly flushed, and, when anæsthesia is profound, the forehead and the general surface are apt to be moist with sweat. In these respects the anæsthesia differs from the ordinary pallor of countenance and the usual cheek of skin-transudation of chloroforming.

The physiological action of the bromide of ethyl does not incline to the dangers of cerebral anæmia and cardiac syncope, which sometimes occur in chloroforming, and, in my experience, no tendencies in such directions have seemed to threaten.

The respiration is slightly increased in frequency until anæsthesia becomes complete, when it assumes the characteristics of normal sleep. The decided indication of the attainment of very profound anæsthesia is the slowing of the patient's breathing, as in ordinary sleep, which becomes easy, long, and free. The irritation of the respiratory passages, which often inconveniences the inhalation of ether, does not occur in any degree with the bromide of ethyl. If brought into contact with the skin of the face, it is less irritating than chloroform.

I do not recognize any ordinary after-effects on awakening from the anæsthesia of bromide of ethyl, the patient speedily returning to his normal sensations and usual condition with but a drowsy sense continuing for a brief time. In my own person, the whole impression is more agreeable than is that of ether or chloroform; and others who have thus tried comparatively the different anæsthetics have expressed to me the same appreciation.

The liability to nausea and vomiting is less than after ether and chloroform, but is not entirely avoided. Occasionally vomiting will occur when food has been but recently taken, and I have in a few instances observed decided nausea and retching when no food was in the stomach, and merely some frothy mucus was ejected. The quick relief from the anæsthetic impression of the bromide of ethyl seems to render less likely the long continuance of the distressing nausea and vomiting which are liable to follow etherization and chloroforming. It should be borne in mind that the fully anæsthetized patient never vomits, and that the manifestation of nausea during the continuance of the inhalation is the indication for making the impression more profound. When vomiting occurs and persists after anæsthesia passes off, it can be best relieved by giving to the patient small pieces of ice to swallow, or a full draught of ice-water.

The quantity of the bromide of ethyl required to produce anæsthesia varies with individual susceptibility and with the manner of using it. Its rapid evaporation causes much loss by diffusion in the atmosphere, but this waste may, with a view to economy, be to some extent avoided. I am in the habit of administering it by pouring two or three fluid drachms on several folds of woven lint, or on a small, soft linen handkerchief, over which is pinned a napkin, folded large enough to cover the entire face of the patient. Anæsthesia is, in my experience, more quickly obtained without the intervention of excitement, if light is excluded, and the temptation to look about avoided, by covering the eyes with a napkin. This plan seems to me to be the simplest and the best, and I trust that the anæsthetic use of the bromide of ethyl may never become complicated

or embarrassed by any forms of the absurd contrivances called inhalers. Such apparatus implies that all individuals are, under all circumstances, to be dosed with anæsthetics in the same mechanical manner. Nothing can be gained by any mechanical device for the purpose, excepting economy in the use of the anæsthetic, and some of the numerous devices would rather tend to wastefulness. A simple napkin or piece of lint, or both together, which absorb and gradually exhale the vapor, are perfectly effective and controllable as the means of administration, and nothing more can be required. With an extremely economical object, the texture upon which the anæsthetic is poured may be covered with an impervious material, or by a napkin dampened with water.

In commencing the inhalation of the bromide of ethyl, I prefer always to make a rapid and decided impression, with the lint and napkin held closely over the nose and mouth of the patient. It is the object to attain anæsthesia without the intervention of mental and muscular excitement. In the administration of another anæsthetic—the nitrous oxide gas—we are familiar with the uncontrollable excitement liable to be produced by slowly inhaling small quantities; and we know as well what profound anæsthesia is induced by rapid and impressive doses of the gas. In the method which I prefer of administering the bromide of ethyl from a piece of folded lint and a napkin, it does not seem possible to exclude so much atmosphere as to cause danger from asphyxia. The air which, through the open texture of the material and from lateral directions, reaches the lungs, must really contain but a very small percentage of the vapor, and at every expiration it is forcibly blown away.

In my experience the entire quantity of ethyl consumed in effecting and continuing anæsthesia in any single case has varied from one fluid drachm, used in a very brief period, to eleven drachms required in maintaining anæsthesia through an operative procedure of forty minutes' duration.

After having tranquillized the patient's mind by assurances of freedom from suffering and danger, I direct him to inspire and expire, for a time, as deeply as possible. The expirations should be so complete that the residuary air is expelled from the lungs. While continuing to thus breathe deeply, the inhalation is commenced.

This preliminary drill I regard as important, and it will always facilitate the proper production of anæsthesia. Until complete anæsthesia is effected there should not be allowed a moment during which the patient does not inhale the vapor, and as the anæsthetic becomes exhausted it should be quickly replenished.

It is proper that the administrator should be able to recognize and be satisfied with the simple production of the anæsthetic state—insensibility to pain—without pushing the inhalation, as is often through ignorance or carelessness done, to a dangerously toxic condition. The best indication of complete anæsthesia is the change in the breathing of the patient to that of ordinary deep sleep. When anæsthesia becomes profound there may be a more or less snoring or puffing sound, due to relaxation of the palatine and buccal muscles. With such manifestations the administration should cease or be very moderately continued. It should be borne in mind that all anæsthetics become eventually, by continuance, depressing agents, and their administration should not be viewed as a matter of trifling responsibility, and entrusted to careless or inexperienced persons. The administrator should exclusively direct his attention to what he is entrusted with, regarding only the condition of the patient, and not observing the operative proceeding. I have witnessed an ignorant and heedless assistant resting his elbows on the chest of a patient, whose labored respiration and livid, turgid face showed threatening asphyxia, while the administrator gazed abstractedly at a surgical procedure taking place at the groin.

I cannot too much impress the greater importance of observation and reliance on the state of the respiration, rather than of the circulation, as an index of the condition of the ethylized patient.

The patient's position should, if possible, be that of dorsal recumbency, with the head slightly elevated and flexed. It is well to remember that in the sitting or erect positions there may be more danger to very feeble patients from syncope. During muscular excitement the neck should not be allowed to be forcibly curved backward, as is the tendency, producing tension on the ante-tracheal muscles and impeding venous return. The chest and abdomen should be free from the mechanical restraint of tight clothing, so that full and deep inspiration may not be impeded. If it should be necessary to have the patient in the prone position, the administration requires watchfulness lest respiration should, by pressure, become embarrassed.

When practicable, the taking of solid food should be avoided by a patient for four hours, and liquid food for three hours before the administration. If the patient's condition should be feeble, alcoholic stimulants or ammonia may in advance be given. When, in an emergency, anæsthesia must be induced very soon after a meal, the act of vomiting should be carefully watched, and the patient's trunk so held that ejected substances may not gravitate into the larynx. Should such an accident occur and threaten life, the complete inversion of the trunk should be energetically made, and forced expiration aided by successive and rapidly alternating compression of the chest.

No fatal case referable to the action of the bromide of ethyl has occurred, nor even in the now large number of administrations, as far as I am aware, have there been any dangerous or threatening symptoms; yet, just as in what ought to be the almost invariably safe administration of sulphuric ether, death may occur, but it will, most probably, be in cases in which, if proper care had been observed, the fatal result would have been avoided. Its action does not seem insidious or uncertain; but, judging from the careless and bungling manner in which other anæsthetics are sometimes administered by incompetent persons, I think that so agreeable and unirritating an agent as the bromide of ethyl is liable to be ignorantly, heedlessly, and inordinately used, and its usual harmless and beneficent anæsthesia pushed to toxic conditions, and even death.

Should respiration become embarrassed, as evinced by pallor or lividity of the face, the free access of fresh air, aided by fanning, should be allowed, and the fauces cleared of mucus. The tongue should be forcibly drawn forward by seizing it with the fingers covered by a napkin, to prevent its slipping, or it may be necessary to lift it from the fauces with a tenaculum or the artery forceps. Cold water should be dashed on the face and chest. If the pulse should show signs of failing, or symptoms of cerebral anæmia appear to threaten, the head of the patient should be rendered pendent below the general level of

the body, and the vapor of ammonia should be inhaled.

In the major operations of surgery, occupying but a very brief time, and of but momentary pain, it is sufficient evidence of the production of anæsthesia when the patient does not respond to a sudden call by the voice. The more profound state of anæsthesia is evinced by insensibility of the surface of the conjunctiva to the touch of the finger, and by change in the breathing of the patient to that of normal, deep sleep. The occurrence, during full anæsthesia, of dilatation of the pupils and of general sweating, are frequent, but not invariable phenomena of ethylization.

The bromide of ethyl, as most recently produced by our best chemists, differs materially in some of its sensible properties from that which has generally been described by chemical writers, and from that which I first had the opportunity of using.

Its odor is characteristic, but is less decided than that of ether or chloroform, and to most persons it is more agreeable. The article I now use leaves less evidence on the breath of the patient, and is soon dissipated from the apartment, and the odor does not remain, as does that of ether, on the clothing of the operator and his assistants.

The bromide of ethyl is said to be liable to chemical change by prolonged exposure to light, but I have kept daily, for about a month, exposed to direct sunlight, a specimen made by Wyeth & Bro., of this city, and can perceive no evidence of change in either its ordinary properties or its anæsthetic action.

The bromide of ethyl may always be used without danger, in the closest proximity to lights and to the actual cautery, as its vapor is not inflammable. If a few drops be poured into a tumbler, or other deep vessel, a lighted taper or a match is at once extinguished if immersed in the vapor.

I have used the bromide of ethyl in the surgery of two large general hospitals and in private surgical practice, under the most varied circumstances which could be required to test the merits of an anæsthetic. In my use of it in the most abnormal conditions of debility and shock of injury, in capital operations, through protracted periods of administration, in patients from early infancy to extreme old age, it has always been satisfactory and free from manifestations of danger. I express my conviction that it is practically the best anæsthetic known to the profession.

Writing Prescriptions in English.—The Legislature of California has passed a law compelling physicians to write their prescriptions in English, if so desired by the patient. This is a ridiculous law, and will, of course, be practically a dead letter.

Antiseptics in Ozæna.—There is an item of treatment and a tender morsel of cool comfort in the following communication to the *British Medical Journal* made by Lennox Browne: "I have, for a very long time, abstained from prescribing *carbolic acid* as a gargle or nasal douche; not only, however, on account of its danger, but also, because of its taste and *odor*, which are, to many persons, most objectionable." "In all cases of ozæna, of whatever kind, it is important to keep the passages as moist as possible, so as to prevent reincrustation between the periods of using the douche; and, for this purpose the interior of the nostrils should be well anointed with vaseline, containing about five grains of *iodoform* to the ounce."

FORMATION OF AN EYELID

BY TRANSFER OF LARGE PIECE OF SKIN, WITHOUT PEDICLE.

By HENRY D. NOYES, M.D.,

NEW YORK.

[Communicated to the New York Academy of Medicine March 4, 1880.]

The matter which I bring to the notice of the Academy is one of interest in surgical pathology. It is an instance of the performance of an operation first introduced into surgery in Glasgow, in the summer of 1876, by Mr. J. E. Wolfe. The case in which he operated was reported in the *Medical Times and Gazette* for June 3, 1876. In that communication Mr. Wolfe reported two cases of success, and a brief summary of the article is to this effect: In a man, for whom, upon one eyelid, he had performed the usual operation of skin grafting introduced by Reverdin, he afterward performed an operation in which he took large pieces of skin and formed a lower eyelid. He took a piece of skin, divided it into three pieces, the whole being two inches long by one inch in diameter, and the result was the formation of a satisfactory eyelid, and after the lapse of eight months it was found that no undue contraction had occurred. Not long after he had occasion to treat a second subject in the same way. A piece of less size was used, and this likewise turned out a success. These operations by Mr. Wolfe did not appear to attract much attention; but the report fell under the notice of Dr. Wadsworth, of Boston, who, having a case in which he thought it justifiable, he performed a similar operation, and reported it in the Boston *Medical and Surgical Journal* for December, 1876. In his case very much the same steps which were instituted by Wolfe were repeated, with this difference, that he took a single piece of skin, which measured two and a half inches in length by one and a quarter inch in its greatest width. His patient was in excellent health, and four months after the operation showed a satisfactory eyelid.

Other reported cases are to be found in the *Archives of Ophthalmology*, vol. viii., No. 1, p. 94, by Dr. Aub, of Cincinnati—two cases; also in *Klinische Monatsblatter fur Augenheilkunde*, vol. xvii., June, 1879, p. 213, by Zehender—three cases. Both cases reported by Aub were successful—one having been done by Dr. Corson and one by himself; and of Zehender's cases two were failures, and the third was a partial success. Dr. Zehender alludes to another case in which the operation was performed by Wharton Jones, an English surgeon, and although he gives an unsatisfactory account of it, one is led to infer from the reading that the operation was a success. These constitute all the published cases with which I am acquainted, and make a total of eight. I have heard of three other cases, none of which have been published. Dr. Reeve, of Montreal, did operations upon different eyelids of the same person, and they resulted in success. In another case the operation, I have understood, has been successfully performed by Dr. Abbott, of Buffalo.

The patient whom I propose to present this evening is not the first upon whom I have operated in this manner. I have undertaken it in four instances. Two of the four operations were performed under very unsatisfactory circumstances. The first patient was a woman, who had a small extent of cicatricial contraction of the upper eyelid, causing a moderate deformity; and while wishing to relieve her of the

deformity, I did not care to make a flap operation, which would involve some supplementary deformity. I therefore dissected out a piece of skin, with great care, from the arm, thinned it down with considerable vigor, adjusted it, and carefully secured it by means of stitches. I did not fasten it down by collodion, or by gold-beater's skin, nor did I stitch the eyelids to each other. The piece of skin sloughed, and the operation was a failure.

The second case was one in which I had had occasion to remove considerable tissue about the inner angle of the eye for the cure of an epithelioma. I removed nearly all of the lower lid, and nearly one-half of the upper lid. I was able to find tissue sufficient to provide flaps with which to fill up all the vacancy, except the gap that remained after removing the portion of the upper eyelid. I thought it a fair opportunity to try this method. I took a piece of skin from the arm, introduced it into the opening, and attached it with sutures, and took no further measures to secure immobility. Inasmuch as I had been obliged to use the actual cautery, in order to destroy some of the epithelial disease which penetrated into the orbit, I felt justified in ascribing the sloughing, which took place after the plastic operation, to the suppuration thus produced, but probably that was not the only factor. This case, then, proved a failure.

The third case came under observation within the last six months, and was in the person of a man who had an extensive epithelial ulceration about the left temple, which invaded the external commissure, and, destroying a considerable portion of the upper part of the lids, had lately caused ulceration of the cornea (1) and produced a sudden development of cataract. The man was suffering extreme pain. The amount of excision practised in order to remove the diseased tissues was large, and I was obliged to enucleate the eye. My purpose was to thoroughly seal up the orbit so that there should be no unpleasant discharge from it, hoping that by so doing the patient would suffer the least possible annoyance. He was a man advanced in years, the tissues were rigid, the skin was tight, and it was absolutely impossible to effect complete closure of the skin-wounds, even by the most thorough undermining and sliding the skin. In order to assist in closing the gaps, I brought down a flap from the forehead, in the ordinary manner. In turning down the flap, which had a wide pedicle from a vertical to a horizontal position, there necessarily occurs a deep wrinkle at the inside angle of the pedicle, and, in order to make the flap fit well, I was obliged to cut out a considerable piece of skin. It then occurred to me that the piece of skin removed could be used in patching the deficiency I was making in the forehead. The piece was triangular in shape, and measured about an inch and a quarter upon each side. It was accordingly put in position without sutures, was covered with collodion, as was also the raw surface which remained uncovered by the patch. That fragment of skin served to furnish a basis for granulation tissue. It did not slough throughout its thickness, but its entire epidermal surface sloughed, and the deeper tissue survived. That was the first case in which I secured any success in any attempt to imitate Wolfe's operation.

The last case is that of the boy whom I present to your inspection, Alfred Campbell, aged ten years, who first came under observation four years ago. He had been burned with kerosene. The burn extending over the upper part of the face upon the scalp, involved the entire forehead, reached down upon the cheeks and sides of the neck, and caused a shocking ectropion of both upper eyelids. Four years ago I operated for the rectification of the ectropion of the right eye. Inasmuch as sufficiently sound skin from the forehead could not be obtained, I made a flap from skin taken from the naso-buccal furrow, and the lid formed served a very good purpose. In December last the boy was taken into the Eye and Ear Infirmary in order that the ectropion of the left eye might be corrected. The deformity was not extensive; nevertheless, was sufficiently so to be annoying to himself and disagreeable to his companions, and I felt justified in attempting an operation for his relief. Having in the first operation used up all the available material upon the face with which to construct an eyelid, I thought that if any case was suitable for Wolfe's operation, this must belong to that category. I therefore dissected down the everted upper lid to the necessary degree, and when the wound was formed it measured an inch and a half in length by an inch in breadth, and to fill this space I dissected a piece of skin from over the ribs about 2½ inches in length by 1¼ inch in breadth, or, in exact measurement, 66 mm. long and 33 mm. wide, and of a semi-elliptical shape.

Some importance is to be attached to the manner in which the skin is removed. It is to be taken up entirely free from subcutaneous connective tissue and fat. When I began my dissection I found no little difficulty in removing the piece in that manner, but finally succeeded, and when taken up it looked very much like a piece of white kid-glove. The moment it was separate from its position it shrank to about two-thirds of its previous superficies. It was immediately placed in warm water for the double purpose of washing it off and preserving its temperature, and the wound being dried by means of bits of muslin, it was laid on and found to fit exactly, with the exception of the outer angle, where a small space still remained uncovered. I did not tuck the border under the edges of the wound, as was the fact in Mr. Wolfe's operations, but simply laid the piece upon the surface. Gold-beater's skin was placed over it, and collodion was carefully applied over the gold-beater's skin and the surrounding parts, and then the two eyelids were stitched fast to each other by three sutures passing between their edges. This was for the purpose of securing absolute immobility. A wad of cotton was then placed over the whole and secured by a bandage covering both eyes. The bandage was removed after a few days, but the gold-beater's skin and collodion dressing remained in place from December 12th, the day of the operation, until January 2d. During that time the parts remained entirely undisturbed. There was absolutely no suppuration, except what came from the conjunctival sac. There was no suppuration from beneath the flap, no pain, no swelling.

When the dressing was removed, by paring away the edges first, the edge of the flap was found presenting the appearance of normal skin, and I flattered myself that I had secured the vitality of the whole of the transplanted piece. But later it was found that the epidermis had sloughed from the centre of the flap. Granulation ensued on this surface, and finally the whole was covered with normal epidermis.

While success has followed this performance, it must be remembered very distinctly that the amount of shrinkage which occurs in skin thus treated is something extraordinary. The reduction in the size of this piece of skin has been not less than one-fourth

of the superficies of the whole, but it has resulted in giving a supple movable, and sufficient covering for the eye. The diagram shows the outline of the piece when removed, and the inner tracing the size it had seven weeks after the operation. The skin has but little sensibility; it has a pale yellow tint, and is only slightly stiffened, and he can now cover that

eye better than he can the other. The photographs represent the appearance as he looks downward and forward.

The interest attaching to this case is that which is something beyond the ordinary experience in surgical operations and pathology. It will seen by the statistics given that a number of cases have proved failures. In some of these instances failure is sufficiently accounted for, either by unfavorable local circumstances belonging to the operation, such as complication by other wounds, etc., and to unhealthy conditions of the patient. At the same time, if, out of fifteen cases with which I am personally acquainted, ten have proved successes, it is something very remarkable. While this operation is not likely to supplant the ordinary methods of plastic surgery in which a flap shall still retain its connection with the surrounding parts by means of a pedicle, it shows that the operation of skin-grafting may be employed upon a larger scale than has hitherto been regarded possible.

The following seem to be important factors in the success of the operation:

First. The piece of skin used must be dissected so as to be entirely free from subcutaneous connective tissue and fat.

Second. The piece of skin should not be secured in position by means of sutures, but by coaptation with gold-beater's skin, or such means as maintain absolute immobility during the entire process of union.

Third. There must be expected an extraordinary contraction when the piece of skin is separated from its surroundings.

An Epidemic in Virginia.—A disease which is called black measles has been prevailing extensively in Petersburg, Va., and the counties adjacent. It has of late caused a number of sudden deaths.

Progress of Medical Science.

Gangrene of the Lung treated by Incision. The high rate of mortality in gangrene of the lung suggests the possibility of relieving the condition by means of operative measures; and that by incision, which has been recently spoken of, seems to possess many advantages. Mr. S. C. Smith, of Halifax, England, cites the following as an example of this mode of treatment. A gentleman, sixty years of age, was attacked with pneumonia of the right side. It gradually grew worse, and developed gangrene of the lung. The matter expectorated was of two kinds: at one time thick, tenacious, and muco-purulent, but frequently thin, gray, and offensive fluid, which appeared to gush up into the throat, and was spit out in large quantities. This continuing, and there evidently being a large cavity in the middle lobe of the right lung, it was decided to relieve that organ by making an opening for the exit of pus. An aspirator-needle was accordingly inserted near the angle of the scapula to the depth of about three or four inches. No fluid escaped, but very bad-smelling air was drawn through the tube, a candle held opposite the canula caused the flame to blow to and fro during respiration, showing that a cavity had been reached. The canula being used as a director, a knife was inserted between the ribs, and by its side a pair of dressing-forceps was introduced, by means of which an opening could be made large enough to introduce a strong india-rubber tube, through which carbolic acid lotion was injected; this induced coughing, and about half a pint of fetid, grayish pus was ejected. The tube was left in, and the wound covered by a large pad of a dozen folds of coarse muslin wrung out of a solution of carbolic acid, which was ordered to be changed every three hours. For six days the expectoration was diminished, the fetor was less, and on the whole there was decided improvement. The discharge from the wound was offensive, although the cavity was washed out daily by means of a syphon; the water which escaped at these times was but little stained, so that the offensive odor was due rather to the sloughy condition within the lung than to a decomposition of pus. He had a relapse, and gradually sank and died. S. suggests this mode of treatment in cases where the bronchi are blocked up to such an extent as to prevent the free exit of pus, and when the patient is rapidly sinking, in order to give him the only chance of recovery that remains. —*Lancet*, Jan. 17, 1880.

Nerve-stretching in Tabes Dorsalis.—Dr Langenbuch, of Berlin, reports a case in which nerve-stretching relieved completely the shooting pains of tabes dorsalis, and at the same time exerted a remarkable influence on the other symptoms of the disease. The patient, a merchant, forty years of age, had suffered for several months from the affection, all the characteristic symptoms of which were well marked. The pains were very intense, and were but slightly relieved by sedatives. The left sciatic nerve was operated on first, as the pains were most severe on that side. When the nerve was laid bare, it was found to be somewhat swollen and of a reddish color; it was forcibly stretched and the wound was then closed with sutures and dressed antiseptically. When the patient recovered from the narcosis, he stated that the pain had entirely ceased in the parts supplied by the stretched nerve. The motor and

sensory paralysis resulting from the operation disappeared in a few days, but the pains did not return. The wound was healed, and twelve days after the first operation both the crural nerve and the right sciatic were stretched in one séance. The three wounds healed in a few days under antiseptic dressings. The effects of the second operation were similar to those of the first. All the pains ceased immediately and permanently, and the paralysis of motion and sensation lasted only a few days. When the patient made his first attempts at walking after the operation, he declared that he was again able to tell what there was under his feet. He rapidly regained the power of walking, and it was then unexpectedly discovered that the ataxic symptoms had also completely disappeared. As soon as he was able to walk tolerably well, he left the hospital, but soon afterward entered another hospital. Dr. Langenbuch sought him out there, and found him free from all ataxic symptoms and disturbances of sensation in the legs. He was able to walk about without a stick, and complained only of weakness and pains in the arms. Dr. Langenbuch thinks that in this case the primary seat of the disease was in the peripheral nerves. He believes that a rigid adherence to the antiseptic treatment is of the greatest importance in these operations in the nerves.—*Berliner klin. Wochen.*, No. 48, 1879.

Atropine in Spermatorrhœa.—Dr. Stephanides, of Carlsbad, has obtained excellent results from atropine in a case of profuse spermatorrhœa, in a patient suffering at the same time from advanced progressive muscular atrophy, and from commencing bulbar paralysis. As no source of irritation of the urethra could be discovered, he ascribed the spermatorrhœa to a relaxation and dilatation of the ductus ejaculatorius, dependent upon irritation of that part of the spinal cord where the nerves controlling the preparation and discharge of the semen take their origin. The affected muscles were so weakened that they were unable to hold back the semen, which, following the law of gravity, flowed into and through the urethra. As, moreover, the flow of semen was constant, it seemed fair to assume that the patient secreted more semen than a healthy man would; this phenomenon is analogous to the increased secretion of saliva occurring in progressive bulbar paralysis. Dr. Stephanides thought that under these circumstances the use of atropine, which is known to control the so-called paralytic salivation, as well as hyperhidrosis, was indicated, rather than the bromide of potassium. He accordingly ordered the patient to take every evening one drop of a solution of 8 ctgrm. of atropine in 8 grm. of distilled water (gr. 1½ – ʒ ij.). Under this treatment the spermatorrhœa ceased entirely in three days, but the remedy was continued for a few days longer, until dilatation of the pupils and irritation of the throat was produced. The spermatorrhœa made its appearance again in about two weeks, but again yielded at once to atropine administered in the same way.—*Schmidt's Jahrbücher*, No. 8, 1879.

Apomorphia in Croup and Acute Laryngitis.—The internal administration of apomorphia has been highly recommended by several German authorities in the treatment of croup, pseudo-croup, and capillary bronchitis. Dr. Smidowitsch, of Tula, reports four cases of croup and acute laryngitis, in which he employed the drug in this way, with very good results. In all these cases very large doses were given. In the case of a boy, 1½ year old, who was suffering from a severe attack of croup, from 6 to 7 ctgm. were given daily, for five days, while toward the end of the disease a dose of 4 mgm. could no longer be tolerated. The same patient suffered two and a half years afterward from a second attack of croup, in which croup-membranes were coughed up. This second attack also terminated favorably under the use of apomorphia, a teaspoonful to a teaspoonful and a half of a one per cent. solution of the drug being administered every hour. The second case reported by Dr. Smidowitsch was also one of croup, while the remaining two were cases of pseudo-croup, or acute laryngitis, with very tough expectoration. All these cases terminated favorably.—*Schmidt's Jahrbücher*, No. 8, 1879.

Antiseptic Treatment of Head Injuries.—Since 1860 Prof. J. A. Estlander has treated 341 cases of injuries to the head, not including those of the face. Previous to 1870 the old methods were followed; since that time Lister's antiseptic treatment has been in use. To render the results of these two epochs more evident, he has divided his cases into three groups: 1. Simple wounds of the integument. 2. Similar wounds with denudation of the cranium. 3. Such as were complicated with fracture of the cranium and lesions of the encephalon. He has omitted the cases where other affections caused sudden death and no treatment of the wounds could exert any influence. From this comparison it would appear that previous to 1870 simple wounds afforded less favorable results than those treated by the antiseptic method, but the difference is not very great. The wounds with denudation of the cranium, on the contrary, gave much more favorable results by Lister's method. By the latter the mortality fell to 1.5 per cent., whereas by the old methods it was 24 per cent. The author considers that this complication should no longer be viewed in the serious light which prevailed previous to the adoption of the new method. The difference is still greater in the third category, for, before 1870, he lost three-fourths of the cases which presented lesions of the bones of the cranium and of the brain, while by the antiseptic treatment he has saved five-sixths of them. This is still more remarkable, as the fractures of the base, where the antiseptic treatment cannot be placed in question, have furnished the same results during the two periods. It is true that the diagnosis of this lesion may have been occasionally doubtful, where death did not result, but the diagnosis has always been based on the same signs, and the errors it is fair to suppose have been equal. Several cases are related in detail to illustrate this method of treatment.—*Nordiskt Medicinskt Arkiv*, Vol. XI., No. 3.

Perforation of a Hydrocephalus through the Spinal Canal.—Magnus reports the case of a strong and healthy primipara with a breech and foot presentation. The foot was brought down, and the delivery continued till the breast had passed down so low as to permit of the disengagement of the arms. After numerous unsuccessful attempts to complete the delivery with forceps and cephalotribe, and the perforation of the hydrocephalic head, which still remained high in the pelvis, the author determined to open the spinal canal and pass an elastic catheter up through the latter as far as the brain, and thus evacuate the fluid. This attempt was crowned with success.—*Nordiskt Medicinskt Arkiv*, Bd. XI., No. 6.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, March 27, 1880.

REMARKS ON DIPHTHERIA.

At this time, when diphtheria is prevailing in various parts of the country, and is assuming an epidemic and malignant type, any points bearing upon the diagnosis or treatment of the disease are of great interest to the profession. In this view it is safe to assume that the paper in the present issue by Dr. Billington, and the discussion upon it before the New York Academy of Medicine, will be very welcome to our readers.

Although it cannot be claimed that it contains anything strikingly original, it is, nevertheless, a very valuable contribution to the diagnosis and treatment of this dreadful disease. It is always well to compare notes and take a reckoning of progress made. Even if the latter is only such as extra experience has afforded in verifying old ideas, the results to the practical man are of the greatest possible value. So much has been written concerning the nature of diphtheria, and so many different methods of treatment have been advocated, that it would be exceedingly difficult, in presenting the subject in any detail, not to travel over ground already well beaten and track-worn.

Thus it is that our author comes to us with no startling announcement that a new specific has been discovered for the disease, but simply with the statement that additional experience has confirmed the views expressed by him four years ago. It will be recollected by the majority of our readers that these views were quite positive in the direction of the curability of the disease, even in many of its most malignant forms. The remedies used were those which had already enjoyed a good reputation, but their combination and methods of application were somewhat original. Substantially the same line of practice has been followed, and the good results which have been obtained will serve to make not a few converts to the doctrine upon which the treatment has been based.

The real interest to the paper will centre upon its practical character in the methods of treatment advised, and upon the faithful manner in which the cases have been reported. There can be no doubt that such cases were those of genuine diphtheria. A great many circumstances must be taken into account in summing up results—the character of the symptoms, malignancy of the type of the disease, and the variety and character of the remedies used. But, making all necessary allowances, it is impossible to resist the conviction that the remedies employed had a great deal to do with the results.

Perhaps, however, the greatest element of success is the faithful and persistent attention to details. In no disease is it more important to watch for bad symptoms and to fight them promptly and persistently when they show themselves. The attention to apparently trivial matters may often turn the tide of battle in favor of the patient. This point is strongly made by Dr. Jacobi, and will doubtless carry its due weight with all who are called upon to watch and to fight with desperate cases. It is not difficult to believe that the success of the cases related in the paper is more due to the manner of using the remedies than the remedies themselves. Such a belief will help, perhaps, to reconcile the difference in results which have obtained with other practitioners who have used the same ingredients, and will doubtless encourage them to insist more strongly than ever upon every detail of treatment as laid down.

The importance of an early recognition of nasal diphtheria, and the necessity for prompt and persistent syringing of the nares, is strongly urged, not only by the author, but by those who discussed the paper. No practitioner who has given the method a trial in an apparently hopeless case, will be willing to omit it in any subsequent and similar experiences he may have. In no instance will any single procedure give him more gratifying results. But like all other delicate manipulations, a certain amount of manual skill is quite necessary to do it properly.

The apparent contradictory propositions of the author that the diphtheritic membrane, although the source of the poison, can be allowed to remain for a time upon a given part without danger, can hardly be reconciled with the assertion that the superficial parts of the membrane are the only sources of infection. The explanation that the poison simply passes through the deeper portions of the membrane as through a filter, merely to be discharged upon the surface, is ingenious, but is hardly in accordance with pathological laws. It is very proper to consider the presence of these membranes always dangerous, and to get rid of them as soon as possible without producing undue irritation.

Even if there is no positive danger of direct ab-

sorption of the poison from the spot infected, as when the membrane is limited to the tonsils, there is a risk of the diphtheritic secretions contaminating the neighboring tissues, notably those of the posterior nares, and thus establishing a direct communication with the neighboring lymphatics.

It is proper to state that the author of the paper does not claim any originality in regard to the purely local origin of the disease. In fact several other distinguished observers have advocated that view long ago, and have published many striking facts in support of it. He is a strong advocate for the doctrine, and is at times too positive in his statements. We venture this opinion with the full appreciation of the force of the author's arguments to prove his position. The assertion that membrane is always present, whether the observer succeeds in finding it or not, will not be accepted by a large number of the profession. Nor will the probability be always admitted that in the so-called non-membranous diphtheria, the practitioner has in reality to deal with a case of malignant non-eruptive scarlet fever. Non-membranous diphtheria is a very exceptional occurrence, but its actual existence has been clearly proven by several competent observers. A knowledge of this fact may at some time or other be of great service to the practitioner, and may help him to explain the possibilities of general blood-poisoning from the start, entirely independent of membrane in the throat.

It is not, however, our purpose to do more than draw the attention of our readers to some of the more interesting points in the paper, and with this introduction we leave them to study the subject in all its interesting details.

THE BENZOATE OF SODIUM IN PHTHISIS.

Within the past six months considerable attention has been directed to the benzoate of sodium as a remedy for phthisis. Although the profession naturally looks with distrust upon any agent said to have a curative agency in tubercular disease, the strong advocacy of the claims of the salt in question by several leading men has invited serious discussion. From time to time we have noticed the reports, mainly from foreign sources, concerning the so-called efficacy of this drug. As might have been expected, the account of the results obtained are somewhat exaggerated and conflicting. The very hope that phthisis can be cured by a single remedy is enough to pardon the enthusiasm which has been infused into the discussion of the subject. It is hard to believe that the salt has any special effect upon the disease. We cannot afford, however, to ignore the statements of men who have good reputations, who are competent observers and conscientious practitioners.

Benzoate of sodium is not, however, a new salt. Although its reputation in connection with the treatment of phthisis transcends that for other diseases, it has long been known as a drug of considerable therapeutic value.

Among the first to call attention to it as a valuable article of the materia medica was Graham Brown (Archiv für exper. Path., vol. viii., p. 140), who found that it destroyed in diphtheritic fluids the power of communicating contagion.

Klebs (Prag. med. Woch., iv., No. 385) claims that the benzoate of soda is the best known antimycotic remedy for all infectious maladies, and has proved more efficacious as such than either quinine or salicylate of soda. It is not, according to his observations, a febrifuge. The average dose employed was two to five drachms per day. He finds it especially applicable to cases in which the blood-pressure is abnormally low. Valvular diseases of the heart, however, contraindicate its use. Inoculations with diphtheritic or tubercular material produce no effect, when followed by hypodermic injection of the benzoate. Finally, its administration on two consecutive days is said to have checked the progress of erysipelas.

Schüller (Deutsch. med. Woch., 1878, No. 11), observes the rapid fall of high temperatures, together with amelioration of local symptoms, in diseases following traumatism. Scrofulous affections of the joints are also said to be greatly benefited. He administers the drug in doses varying from two drachms and a half to six drachms.

Senator has reported twenty cases of acute, and twelve of subacute articular rheumatism, in which the benzoate was employed. In the acute cases excellent results were obtained, even when salicylated soda had proved useless.

Letzerich (Berlin. klin. Woch., 1879, No. 7) recorded twenty-seven cases of diphtheritis treated by this method. With only one exception, the success was complete. The drug was exhibited both internally and by local application.

Hoffmann (Berlin. klin. Woch., 1879, No. 11) has treated successfully twelve cases of diphtheritis, one case of erysipelas, and three of albuminuria. With regard to the cases of nephritis, the good results were ascribed to the increased elimination of nitrogen. This fact was previously noticed by Fürbinger (Deut. Arch. f. klin. Med., vol. xxi., p. 486), and Gäthgens (Ueber d. Stoffwechsel eines Diabetiker's, Dorpat, 1866).

On the 15th of September, 1879, Kroczak reported three cases of advanced phthisis treated with marked success by inhalations of a five per cent. solution of sodium benzoate. His article appeared in No. 37 of the Vienna *Medical Press*, and gave rise to much sensational newspaper comment. This appears to be the first mention made of the efficacy of this drug in the treatment of lung diseases.

Then followed Rokitansky (Wien. med. Presse, Oct.

18, 1879, with a report of cases in which the remedy was used. Finally, Klebs (Allg. Wien. med. Zeit., No. 1, 1880) afterward recommended the sodium benzoate, and benzoate of magnesium in phthisis. This author also extended the range of applicability of these drugs to other pathological conditions of the lungs. The treatment consisted of conjoined local and internal administration.

Guttman (Berl. klin Woch., No. 49, 1879) refers to thirty-one cases of phthisis where the benzoates had proved unavailing, and Wenzel reports, in the same number of that journal, ten other cases with a similar negative result.

Rosenfeld (Med. Corr. Blatt, Jan. 9, 1880) observed injurious effects of these inhalations, and warns practitioners against entertaining sanguine expectations of their general usefulness.

Prof. Halla (Deut. med. Woch. 1880, No. 7) also failed to obtain satisfactory results. He tested the efficacy of the drug in a large number of cases, always paying strict attention to the measures of precaution enjoined by Klebs. The results were invariably disappointing.

At Innsbruck a special committee of competent medical men was appointed for the purpose of investigating this subject. The report of this committee was quite unfavorable to the general utility of these inhalations in phthisis.

From these brief abstracts of the most important publications on this subject we are unable to deduce any convincing proof of the real value of this, the latest anti-phthisical remedy. Still, it is quite evident that the benzoates had an extended trial.

If experience realizes a tithe of the expectations which are entertained of its curative properties in phthisis, the profession can take courage in still fighting against the odds in this disease, and taking the chances for success, desperate as they are.

LEGISLATION ON THE SUBJECT OF COLOR-BLINDNESS.

THERE are at present no laws in this country compelling examinations for color-blindness; Dr. B. Joy Jeffries is, however, endeavoring to initiate legislation on the subject in Massachusetts, as well as in the national legislature. The railroad commissioners of that State have unfortunately reported that they do not think legislation is needed in the matter, but that private interest will be strong enough to cause the examinations to be made before long. They also recommend that the examinations be made by laymen, and consider such to be sufficiently expert. Against both these positions Dr. Jeffries has argued very strongly, and has shown that he has all the authorities of Europe on his side and against the commissioners. Dr. Jeffries would introduce an examination to test the visual acuteness and the sense of form. The examinations are to be repeated at annual or biennial intervals, and would be made by a regularly appointed medical officer. The matter still remains unsettled.

VACCINATION IN ENGLAND.

THE agitation in England upon the subject of compulsory and animal vaccination, has, at last, ended in a tolerably satisfactory manner. The investigations by the parliamentary committee have led to the following conclusions:

1. That the present system of compulsory vaccination is efficient and necessary, and should be continued.

2. That there is a remote possibility of inoculating syphilis with humanized lymph; but that, nevertheless, the old system of arm to arm vaccination is a good one, and should, as a rule, be adhered to.

3. That vaccination with calf-lymph gives also an efficient protection against small-pox, and that humanized lymph ought to be rejuvenated at regular intervals by the use of calf lymph.

4. That the public vaccinators ought to have a supply of calf lymph for the above purpose, and also for use upon those persons who object to the humanized lymph.

Experiments are to be undertaken to test the absolute and comparative value of calf-lymph as a protective against small-pox.

THE REGULATION OF MEDICAL PRACTICE IN MASSACHUSETTS.

THE bill to regulate medical practice in Massachusetts has received the endorsement of the majority of the medical profession in that State. The legislature is also favorable to it, and the prospect of its passage is very good. By its provisions every person who proposes to practise medicine in the State must pass an examination before a board of censors. This board is to be composed of representatives of the Massachusetts State Medical Society, the Homœopathic, and the Eclectic Medical Societies. The representation will be in proportion to the membership of the societies, and this will give a majority of the board to the regular profession.

Opposition to the bill comes from two sources, on the one hand, all the quacks, and, on the other, a few of the more conservative of the regular profession. These latter claim that the law will create an examining board whose standard of examination is likely to be low—certainly not so high as that of the Harvard Medical School; the bill, therefore, is, they say, an encouragement to cheap medical colleges. It also assumes, to a certain extent, that the regular profession constitutes a particular school of practice like the Homœopaths. And one of the results already of the present agitation is the proposition to have Homœopaths on the staff of the Boston City Hospital. It

is, finally, urged that the number of quacks driven away will be small, and the great benefits expected in this direction are illusory.

It is very doubtful if the sanguine hopes of ridding Massachusetts, or any other State, of quacks by law will ever be realized. The State of Illinois did something in this way, but things soon began to lapse back to the old condition. The very fact, however, that the strongest opposition to the law comes from the ranks of charlatanism and of the low and ignorant, is an evidence that it will accomplish some good. And, on the whole, we believe it will be found to have something of a purifying effect.

Reports of Societies.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 4, 1880.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

THE Academy was called to order at 8 P.M., and the minutes of the previous stated meeting were read by the Secretary, DR. E. F. WARD. The Librarian, DR. LAURENCE JOHNSON, acknowledged the reception, since the last meeting, of 279 bound, and 8 unbound volumes; 1380 medical pamphlets, and a marble bust of Dr. J. Kearney Rogers, with pedestal, the gift of Mrs. Eigenbrodt. The thanks of the Academy were extended to Mrs. Eigenbrodt for her generous donation.

The Statistical Secretary, DR. FRANCIS V. WHITE, announced the death of Dr. Henry LeBaron Hartt.

BLEPHAROPLASTY IN WHICH THE EYELID WAS FORMED BY A PIECE OF SKIN TRANSFERRED FROM THE CHEST.

DR. HENRY D. NOYES exhibited a patient upon whom he had successfully performed the above operation, and made some remarks. (See MEDICAL RECORD, this number, page 344).

The case being before the Academy for discussion, DR. HERMAN KNAPP remarked that he had always thought, in all plastic operations, blepharoplasty in particular, that sloughing was in direct proportion to the thinness of the piece of enticle used; the less enticle the more probable the sloughing. The procedure reported, however, was somewhat different from that employed in many such operations, and the facts must be accepted. There were a certain number of cases upon record in which the flap united throughout its entire extent, without the least sloughing around the edges, and he thought that the indication would be—where there was no skin upon the face or head, taking this principle into consideration—to try this procedure, and that it was legitimate. The photographs were satisfactory, yet the report was made a short time after the operation. He could well imagine that a flap which had so little substance, almost epidermal, would shrink so as to leave but little. He thought that Dr. Noyes deserved great credit for the skill manifested in his cases, certainly in the one in which there was so much deficiency in tissue.

DR. FRANK H. HAMILTON alluded to the fact that plastic surgery was an old operation, and as to its application to blepharoplasty, he was not so sure that it was an entirely recent procedure. At all events, the records of surgery supplied a considerable number of reports of plastic operations which had proved successful, and in which large portions of integument had been removed from one part of the body to another having previously been completely separated from their original attachments.

It was a tradition that Tagliacozzi was in the habit of securing tissue for an artificial nose by first inflaming the integument of the nates, whipping it until it was thoroughly reddened, exciting a certain degree of erythema, and then removing the skin and applying it to the nasal appendage. He thought, however, that a good deal that was upon record concerning anaplasty was not well established.

But to the same class belonged those cases in which there had been a reapplication of a second portion of the nose, the phalanges of the fingers, etc., yet anaplasty from remote parts had not, as he believed, secured the confidence of surgeons in general. However, he was glad to see the subject survived, although he could understand that, ordinarily, the operation would prove a failure.

Dr. Hamilton asked if it was well settled that the thinness of the flap was essential to success, for he would have supposed different. It seemed to him that in the brief epitome Dr. Noyes had given of the cases in which the operation had been performed, he had not satisfactorily demonstrated that point.

DR. KNAPP remarked, with reference to Dr. Hamilton's statement, that he saw two cases of rhinoplasty in Leipsic, and there was also blepharoplasty of the lower eyelid, the absent part being supplied with tissue from the cheek, and the flap sloughed from one end to the other. The operator (Prof. Thiersch) thought the reason why sloughing occurred was because suppuration occurred beneath and lifted the flap, so in the next operation he punched holes in the flap to allow pus to escape, but no better result was obtained. The professor stated to Dr. Knapp that there was only one authentic case upon record of successful rhinoplasty without pedicle.

DR. HAMILTON referred to two cases under his own observation in which a portion of the end of a finger was completely separated and replaced, and union occurred; but in both instances the severed portion dwindled excessively, and was almost completely destitute of sensibility—in short, it was no gain to the patient. They were small portions of the extremities of fingers, not including bone.

DR. A. C. POST remarked that there was an essential difference between cases in which a portion of the body had been severed and then reapplied to the part from which it had been removed, where the tissues readily entered into each other, where severed blood-vessels were brought into contact, and where the circulation could be restored through the same channels, and those to which special reference had been made. The cases were not very rare in which parts of the body had been removed and in that manner caused to again firmly unite. He had studied carefully the operations by Tagliacozzi, and he did not think that he had made the transplantation of integument from distant parts without the attachment of the pedicle. Only tissue had been taken from the arm, the hand, the face, or the head, and numerous operations of that kind had been performed with more or less success.

With regard to the transplantation of flaps of integument from distant parts without the attachment

by pedicle, the question had been asked whether it was necessary that they should be thin, or whether considerable portions of cellular tissue and adipose would interfere with the success of the operation. We had something analogous in operation known as budding plants, trees, and shrubs. It was customary in treating plants by that method to use a very thin portion of bark, for it was well known that if much of the subjacent cortical tissue was left attached to the bark, it interfered with the success of the grafting.

Dr. Noyes remarked, with regard to the practical point whether the flap should be thin or should include some portion of the subcutaneous fat or connective tissue, that our only evidence was what had been obtained from the experience of Mr. Wolfe himself. In one of his operations, in place of taking a single piece of skin, he took three pieces. Of these, two were dissected thin, in the manner described, and the third, which was placed in the middle, was taken with more or less of subcutaneous tissue, and the third piece of skin underwent suppuration, while the others survived. Acting upon that hint, he had taken pains to reduce the skin to the greatest thinness possible, leaving the subcutaneous tissue entirely untouched.

Dr. C. E. Billington read a paper on the

DIAGNOSIS AND TREATMENT OF DIPHTHERIA (vid. p. 331).

Dr. A. Jacobi. Mr. President: There is a great deal to say upon the subject of diphtheria, but very little that is new. Thus, I also doubt my ability to bring much that is new this evening. Dr. Billington has reached the same conclusions he laid before us a few years ago, and they are exactly the conclusions which I had published some time previous to his reading his paper before the Academy on the occasion referred to. My first paper was written in 1860, and was the first upon the subject published in this present epidemic, which has lasted twenty-two years (*Amer. Med. Times*, Aug., 1860). I again had occasion to read a paper upon the same subject in 1868, at which time I read before the Medical Society of this county (*Jour. Obstetr.*, May, 1868). Finally, I read and published the article Dr Billington has done me the kindness to allude to in his paper this evening. It was printed in the February number of the *Journal of Obstetrics*, in 1875. He says he has to repeat the conclusions to which he arrived at the time he read his previous paper, especially with reference to treatment and its results, on which we so happily agree in every particular. He will remember that my conclusions were exactly the same that I reached from what I had seen, namely, that in a large majority of fatal cases of diphtheria death occurs because of mismanagement. That is true, particularly true of the worst cases. I believe, when we collect statistics, we should speak of severe cases only. I have in former times alluded to the fact that a well-known Paris author declared, as late as ten years ago, that every case of nasal diphtheria would prove fatal. The truth is, that, if a case of nasal diphtheria dies, it is usually the result of inefficient treatment or mismanagement. I must, however, at once admit that occasional cases of diphtheria prove fatal, no matter what you do; but those cases are so rare that I have in my own practice not seen one for a long time, and I have occasion to see a respectable number of cases of diphtheria every year.

I do not believe I have the right to discuss the subject of diphtheria at this time, and will therefore only allude to a few points suggested while listening to the reading of the paper. They are, perhaps, trifles, but, as the doctor has proved that so-called trifles are of the utmost importance, are all and everything in the way of treatment of diphtheria, I will consider myself excused for mentioning them. He is so correct in that statement that I will refer to only a few cases, in which I know that, from the time that decent cleansing and disinfectant treatment began the patients commenced to get well. You will notice, every one has noticed, that not much diphtheritic membrane may be seen in the throat, yet all at once immense cervical glandular enlargement will take place, particularly about the angles of the lower jaw. When that is seen, no matter whether any membrane is seen or not, you may be sure there is nasal diphtheria. It is not necessary to see the membrane; but, if you wait one or two days, you will have opportunity to see plenty of it. Whenever there is immense swelling below and behind the angles of the lower jaw, there is nasal diphtheria. It is a natural sequence to the fact that these glands are in anatomical connection with the numerous lymphatic ducts of the nasal mucous membrane, and their swelling shows that there is a direct poisoning from that locality. Now, when you commence nasal injections every half hour or every hour, not infrequently within twelve hours the glandular swellings will be reduced one-half, thus proving that not only poisoning takes place rapidly, but also elimination of the poison and recovery. I have seen that in many instances, and so, evidently, has Dr. Billington.

There is one point upon which I have insisted whenever I saw such a case in consultation, and that is this: the cases are left alone, frequently, at dangerous periods, and it is always urged by the parents, and also by the nurses, and frequently by the doctors, that the child must be allowed time to sleep. Now, those cases which get well under efficient treatment only, will sleep the sleep of death if they are allowed to sleep undisturbed. If allowed to sleep, they will die. The septic poisoning causes a tendency to constant sleep, do with them what you please. You may disturb them in any way, and they will remonstrate; but as soon as you cease they are off in a sleep again. To allow such patients to sleep is to allow them to die. Therefore, when there is such a dangerous case with septic symptoms, it is necessary to cure it within thirty six or forty-eight hours, or the patient is gone. Such cases must not be allowed to sleep through the day or night longer than the intervals between the times of using the injections or medicines as you have prescribed. It may be necessary to inject the nose every half-hour at the beginning, and continue to do that for twenty-four hours, when, perhaps, it may be required no oftener than once an hour. If such management is neglected, the case is lost; if adopted, the case will probably be saved. Now, I say this, not because it is anything new; Dr. Billington has said it, others have said it; but perhaps no one so urgently as he or I; but when practitioners will follow that treatment, there will always be statistical evidence in favor of cure.

These cases are dangerous for another reason. These children do not cry much; they are quiet patients; they do not give much trouble; but they will die, and therefore it is necessary to know them at once. When there is sepsis there may not be much fever. Such cases may run their entire course without a rise in temperature to more than 101 or 102 F. In the worst cases the pulse may be no higher than 70, 80, or 90, and the child is, apparently, not so very sick, is quiet, etc.; they are the worst cases, and

must be attended to in the manner mentioned, without delay.

A word with reference to the use of stimulants. Dr. Billington says that many cases require them, and many do not; but he has not told us which cases do, and which do not require their use. I should say that it is just these cases last alluded to which need stimulants—those which give any evidence of septic poisoning. A tablespoonful or two, in twenty-four hours, or two to three, looks like something for a child; but it is, in fact, but very little. An ounce or two may be given in twenty-four hours; even three, four, six, eight, ten ounces of brandy may be administered daily, and will do a great deal. But, in connection with this statement, I will simply refer you to what all have seen in bad cases of typhoid fever and other infectious diseases, and what passes as the popular opinion on the result of alcoholic treatment in severe cases of blood-poisoning.

I will refer to a case seen in consultation with Dr. Kinnicutt, and, if the doctor is present, he perhaps will give the details of the treatment. The patient was a little girl three years old, suffering from scarlet fever and diphtheria. Despite local and general treatment, she went down, down, her pulse became very rapid and small, and the septic symptoms in general increased. We almost despaired of saving the child's life. The alcoholic treatment was then begun in earnest, and she took from eight to ten ounces of brandy every day, and from the moment the alcohol was increased she began to improve and made a rapid recovery. These are the cases in which alcohol must not be omitted.

There is another point, and that is the reliance which Dr. Billington places upon lime-water. I know it is an old remedy. It is recommended for inhalations in laryngeal diphtheria (membranous croup), etc. Now, there is about one grain of lime in two ounces of lime-water, and in the quantity sprayed into the throat there is scarcely a trace. It is true that when diphtheritic membrane is put into lime-water, after six, eight, or twelve hours it begins to slowly disintegrate, and at the end of one or two days it will even be macerated. But the dose of lime introduced into the pharynx is very small, and when it does go there, it no longer is lime-water, but becomes carbonate of lime, and I fully believe it is inert, and might as well be replaced by something else.

So far as Virchow's definition of diphtheria is concerned, Dr. Billington will remember that Virchow does not exclude from the diphtheritic process the superficial cases, and that he classifies those in which the exudation is found upon the mucous membrane and those in which it is found in the mucous membrane as anatomically identical. He classifies both of them clinically as diphtheria, simply regarding them as different shades of the same disease. To this I have also directed attention, and have shown (*Obstetric Journal*, Feb., 1875), that the appearance differs as to whether the epithelial covering belongs to the cylindrical or to the pavement variety, and also as to whether the subjacent mucous membrane contains a large number of muciparous follicles, etc. Dr. Billington regards diphtheria as a local disease when in the beginning. For the last twenty years I have been in favor of assuming that at first it is a local affection, and that it became general from that locality. But I also said at that time, and say now, that there are cases in which the local manifestation of the disease does not exist. As, for instance, in typhoid fever, we have no single individual source of infection; there are at least two. The poison can enter the system through either the alimentary canal or the respiratory tract. Thus it is with diphtheria. It will be a local disease in the throat or nares from the beginning in most cases, but there are cases, undoubtedly, in which the general do precede the local symptoms, or are seen at the same time. I am positive I have seen cases in which the general have preceded the local symptoms, and as long ago as 1860 I called them cases of diphtheritic fever, and within two or three days I was able to find diphtheritic membrane. Undoubtedly, diphtheritic poison can get into the system through the immense lake of blood in the lungs, and I have no doubt that a few cases must be explained by the poison entering the system through that channel.

There is one other point to which I will briefly refer, and that is with reference to the diagnosis of follicular tonsillitis. I have not seen a case in which I could not introduce a probe into an old fistula whenever I had to deal simply with a local disease of the excretory duct of the tonsil. In many places, in tonsils which have been the seat of suppuration a number of times, it is very easy to run a probe in to the distance of, perhaps, half an inch or even more; and these patients are very apt to show white spots on the tonsils several times through the winter, and the question of diagnosis at once arises. No matter how thick the excretion is which points to the surface, you can always run a probe through it deep into the tonsil, and I think that is the best way to make a diagnosis at once. There is one other point, and that is, the doctor believes the mucous membrane is a desirable protection to the subjacent tissue. I had rather be excused from having any protection than be subjected to that kind. We must not forget that particles are rubbed off and will infect or will be inhaled, and there can be no doubt that most of the absorption takes place from the lower surface, the part of the exudation adjacent to the mucous membrane. Now, it is a fact that the diphtheritic membrane will stick thicker to the tonsils than to any other subjacent mucous membrane, and still these cases are the least dangerous. Why is that? It is because there is but little communication between the tonsils thus coated and the neighboring lymphatics. You may have diphtheria of the tonsils for two weeks, and they may be covered with exudation, and yet you may not see a single glandular swelling in the neighborhood. But, as soon as the diphtheritic membrane spreads and touches the neighboring tissues, there will be more fever, accompanied by poisoning and irritation of the neighboring glands, and poisoning of the entire system may arise from that condition. So far as the tonsils are concerned, I should let them alone when diphtheria invaded them; but, if I found such membrane anywhere else, I should remove it if possible. But certainly no one can be more alarmed by injudicious removal than myself, and I should rather wash and syringe for a long time than make a single ineffectual attempt to remove a membrane which is not perfectly loose. I do not wish, however, to claim your attention too long. I am afraid that every new paper or discussion on this subject has to repeat much that is so well known as to be commonplace.

Dr. Wm. T. White—The cases which I saw with Dr. Billington, Mr. President, were all genuine cases of diphtheria. I have used the same treatment in several cases in private practice, and, generally, with good results. I will mention only one case, and in that there was a variation from this plan. A young

la by twenty-two years of age, was attacked by diphtheria, and she was very persevering in the use of the spray. But finally the glands of the neck became so swollen, and the disease involved to such an extent that it became difficult for her to breathe and to take any nourishment. Dr. Learning saw her in consultation, and recommended that a dose of calomel consisting of twenty-five grains be administered. It was done, and in about one hour she was quiet and sleeping, the swelling began to subside, the fever abated, and she felt decidedly better. It seemed to me that the calomel was of great service in that case. At all events, seeing its good effect in the single instance, I should not hesitate to again use it, or take it myself, if in the same condition the patient was in at that time. As already stated, I have employed Dr. Billings's plan of treatment, and it seems to me that it is as good as any other.

Dr. J. H. Douglas.—Mr. President, the remarks made by Dr. Jacobi meet, in the main, all I have to say upon this subject. There is a simple method of application which I would mention, and that is something by means of which the washing can be kept up constantly, if need be, to remove the secretion which is constantly accumulating in the nares. In young children it is especially difficult to keep the parts perfectly cleansed by the apparatus more commonly employed, and I have been in the habit of attaching to the nozzle of a hard rubber syringe, say half a foot, of small rubber tubing, which can be easily introduced into the nares, and the child can be followed about without trouble and without injury to the nasal mucous membrane, and the nares can be washed out without hinderance. By this means a constant irrigation can be kept up, if necessary, with the greatest facility. With regard to the presence of diphtheritic membrane upon the tonsils and its importance: the tonsil is included in a thick, dense membrane, which is difficult to penetrate except by a sharp-pointed instrument, showing that its direct relation with other parts of the body is not very intimate. What communication there is must be through the small vessels at the upper portion of the tonsil, where they communicate directly with the posterior nares at the exact point where this secretion accumulates and where there are abundance of absorbents. My treatment for diphtheria has been to wash out thoroughly with warm salt-water, or lime-water, this region from the very beginning of the attack. In regard to lime-water I differ from Dr. Jacobi, for I think it is an agent of great value. Clinical experience is often better than theory. I use it not only for washing, but apply it to the tonsils and throat by means of cotton. But the membrane upon the tonsil is of the least trouble. The nasal discharge can be easily removed by the little arrangement I have mentioned, and in that manner I have been able to treat most of these cases successfully.

Dr. R. Taussy remarked that Virchow had shown microscopically that diphtheria of the throat was always, in every instance, a primary local affection, and he regarded that fact as one of high importance as bearing upon treatment. There must be a focus of entrance for the poison, and if that theory was correct, the most effective treatment would be by the local use of disinfectants. The main point was to disinfect, and so prevent septicemia.

He suggested that, by using the laryngoscope, membrane might be found, or gangrenous sore throat, in cases in which it could not be seen by ordinary inspection. The employment of antiseptics, it had been well shown, was most appropriate, and the only means of saving the life of such patients as manifested symptoms of septicemia. He did not believe that the membranes in diphtheria and croup were identical. Albuminuria was not necessarily present in all cases of diphtheria, as, for instance, diphtheria of the hand or arm, etc., but with diphtheria of the pharynx and larynx and the lymphatics in the neighborhood involved, it would be present. Dr. Lusky continued his remarks to considerable length, after which the Academy adjourned.

THE NEW YORK THERAPEUTICAL SOCIETY.

Stated Meeting, Feb. 13, 1880.

Dr. A. Jacobi, President, in the Chair.

HYOSCYAMUS AS A HYPNOTIC AND AN ANTISPASMODIC.

Dr. E. C. Seguin made a report which was divided into four parts: 1. A brief sketch of the history of our knowledge of the drug, and a summary of the conclusions and the views of physicians who have used it; 2. A relation of his own experience in testing the value of the drug as a hypnotic; 3. The relation of cases showing the power of hyoscyamia as an antispasmodic; and 4. Provisional conclusions respecting its utility and the best modes of administration.

The following were among the more important points noted in the first division of the report: The reliable preparations were made by E. Merck, of Darmstadt, and were two: 1. A colored resinous extractive, 87 a drachm, and 1 a white crystallized substance, 75c. a grain. The physiological effect of hyoscyamia was very like alcohol intoxication. It was a sedative to the heart, and was useful in convulsive affections. It was excreted through the urine. Reference was made to various writings upon the action of the drug, notably those of Lawson, of the West Riding Hospital, in the 6th vol. of reports, 1876. In the second division, clinical experience was given in the use of the drug as a hypnotic. It had been found most beneficial in acute and subacute mania. There was a singular unanimity of opinion with regard to the uselessness of the drug in melancholia. Dr. J. C. Shaw had favored him with the report of cases, and concluded by saying that he regarded it as a most valuable medicine, and certain in its action in acute mania, outside and inside of the asylum. He had used it in doses of one-fourth to one-half a grain of Merck's crystallized alkaloid. Cases illustrating its favorable effect were contributed by Dr. A. B. Ball, who obtained prompt results by the use of Keith's preparation; by Dr. F. P. Kinnicutt, who administered doses of $\frac{1}{4}$ of a grain of Merck's crystallized alkaloid twice a day in a case of delirium tremens; Dr. Andrew H. Smith gave $\frac{1}{4}$ of a grain of the crystallized alkaloid to a patient suffering from restless delirium and about to be removed to an asylum; by Dr. E. C. Seguin, who used hypodermically from $\frac{1}{20}$ to $\frac{1}{4}$ of a grain of the crystallized substance in a case of morbid dreams, with very satisfactory results. In the third division, hyoscyamia as an antispasmodic or paralyzing agent was considered, and the conclusion reached that it was a powerful though temporary antispasmodic. Dr. Seguin had used it in one case of paralysis agitans, and it was the only remedy which he knew had the power to do good in that affection. He also reported a case of rhythmical hysterical spasmodic hammering, prolonged for two

months, the patient sometimes striking 100 blows with the hand to the minute, which was subdued by doses of $\frac{1}{100}$ of a grain of the crystallized substance. A case of chronic chorea was contributed by Dr. R. W. Amidon, in which he used $\frac{1}{16}$ of a grain of the crystallized substance hypodermically, with good effect, giving the patient quiet, which he had not had for eight years.

Provisional conclusions.—1. It acted upon the pupil as a mydriatic.

2. It reduced the pulse gradually and increased arterial tension.

3. It checked body heat.

4. It produced hallucinations and delirium.

5. Its use was occasionally attended by a rash.

6. In large doses it produced sleep, and something like paralysis or paresis, and might induce retention and dysuria.

7. Theoretically, it was indicated in mania attended by restlessness, delusions, and suspicions, and in insomnia and convulsive affections.

8. It had been of special service in acute or subacute mania, insomnia, and those cases characterized by mischievous delirium.

9. It induced sleep more certainly than chloral, and without being followed by bad effects.

10. In paralysis agitans it could do what no other remedy could do.

11. It was a diuretic of no mean power.

12. The curative power did not seem to be great.

In acute chorea its use may play an important part.

Mode of administration and doses of.—It could be given in small doses with ease hypodermically. The doses were from $\frac{1}{30}$ to 1 grain of the amorphous, and from $\frac{1}{100}$ to $\frac{1}{25}$ of a grain for hypodermic use. Distinct effects might be obtained from $\frac{1}{100}$ of a grain. The following formula was given for hypodermic use:

℞. Hyoscyamia (Merck's crystallized)....gr. i.
Glycerine,
Water.....āā ℥ 100.
Pure carbolic acid.....gtt. i.

Each minim contains $\frac{1}{200}$ of a grain. Tablets containing $\frac{1}{50}$ of a grain were convenient for use by the mouth.

The report being before the Society—

Dr. E. R. Squibb remarked that, although not in the way of acquiring experience in the clinical use of the drug, he felt that he could support all that Dr. Seguin had stated. It had been used in several insane asylums, though generally not as a curative agent, but as a chemical restraint. He had only one suggestion to make in addition, and that was with regard to the same effects produced by different sized doses. He had some testimony that the amorphous substance was about as good as the crystallized alkaloid of Merck. In speculating upon what might be the cause of the difference in size of doses that had been found efficacious, he had been led to think that the difference in result had been produced by the difference in the *alkalinity* of the secretions with which the drug came in contact. It was easily split up by alkalies, so loosely was it crystallized, and therefore rendered inert in a great measure by their action. It was possible, as a matter of speculation, that that was one of the causes why different doses were required to produce a desired result. It was one of the most unreliable of drugs when put into the stomach, and he had been led to believe that that fact was due to two causes: 1. Because of the difference in the alkalinity of the secretions found in the stomach; and 2. The influence exerted by the digestive processes of the stomach. It was well known that many of the alkaloids were loose in their molecules, and hyoscyamia the most so of all, and therefore the experimentations of the committee in the way of hypodermic injection of the drug were most important. The drug, when put into the stomach, must, he believed, be very unreliable, because of the nature of the secretions with which it came in contact. Dr. Squibb thought that Merck's preparation was a chloride. Both the crystallized and the amorphous form were SALTS of hyoscyamia and not alkaloids. So far as he knew, Dr. Kempster, of Oshkosh, Wis., never administered the salt by the mouth; and Dr. Gray, of Utica, also stated that when the system did not respond to it when it was put into the stomach effects had readily been produced when it was used hypodermically.

Dr. Seguin remarked that his preference was for the hypodermic method.

Dr. Squibb further remarked that Dr. Kempster believed that hyoscyamia did not produce sleep by a narcotic action, but by abstracting the condition which prevented sleep. It frequently produced quietness without producing sleep, and when sleep followed it was because bad dreams and delusions, etc., were removed, and thus the patient allowed to go to sleep.

Dr. Andrew H. Smith remarked that he had taken $\frac{1}{30}$ of a grain for the purpose of studying the effect of the drug. Taken upon an empty stomach on going to bed, it produced great drowsiness, dryness of the throat, sleep was not continuous, and on the following morning he had some nausea, disinclination to eat, and a general feeling as if a dose of morphine had been taken. There was also some difficulty in the power of accommodation.

Correspondence.

CURING CATARACTS BY ELECTRICITY.

To the Editor of The Medical Record.

Sir:—I have noticed in your journal two paragraphs containing something like a sneer at me for having published in *The Churchman* accounts of remarkable cures of cataract by means of electricity. I have also been notified by a committee of the medical fraternity of this city that they wish me not to publish accounts of such cures in the future. This message was sent to me through Dr. Neftel, who performed the cures I refer to.

My answer to the medical committee is that I shall continue to publish the astounding cures which Dr. Neftel is accomplishing every week. I am publishing *The Churchman* in the interests of its readers; and the gratitude of those who, having acted on the notices I have already published, have received their sight again, is a sufficient justification for me. I only wish that I could find lightning strong enough to remove the scientific (or unscientific) cataracts from the eyes of the eminent physicians and oculists who have thus attempted to dictate to me what I shall publish. But the blindness of those who *will not* see is both more obstinate and more hopeless than that of those who cannot see.

I am sure, however, that I may say to you, and through your columns to your thousands of readers,

that score by last announcement Dr Noftel has performed several cures more wonderful even than the first. A distinguished lady of this city, now eighty years of age, has within three weeks been cured of a cataract so that she can now thread a needle with ease. A gentleman from Baltimore, who some years ago had one eye removed because of glaucoma, had become hopelessly blind in the other eye with the same disease. No "oculist" would operate upon it, for there was no chance of success, and the unfortunate man could only anticipate a life of blindness and almost intolerable pain. The notice in *The Churchman* induced him to put himself under Dr. Noftel's care about a month ago. He is now returned to Baltimore with his sight *perfectly* restored, so that he sees the minute-hand of his watch, the texture of his clothing, etc. Of course, he is entirely free from pain, and, moreover, while he had been unable to sit up on account of debility, he has walked day after day from Forty-eighth Street to Broome Street.

Do you not think such things as these require that we editors hasten to publish them to the world?

Very truly yours,

EDITOR OF THE CHURCHMAN.

[We sympathize with our esteemed correspondent in his difficulties. It seems to be a matter of conscience with him that he should publish the remarkable cures to which he refers. No one must deny him his right to do so. It was certainly very improper for a medical committee, or for any number of ophthalmologists, to dictate to him the course he should pursue. Their want of respect for his opinion on the treatment of cataract was unworthy the liberal profession of medicine. The men who, according to our esteemed correspondent, will not see, are evidently the oculists, who must long ago have fallen into the traditional ditch as unworthy leaders of the blind. Far from blaming the editor of the *Churchman* for the course he has pursued, the profession at large should feel under the greatest obligations to him and to Dr. Noftel for calling public and professional attention to this important subject. As reports of future cures are promised, it is to be presumed that they will be furnished from a properly authenticated source. In the mean time we ask the profession to suspend judgment against the oculists, and diligently read *The Churchman*.—ED.]

DISPENSING WITH DRUG STORES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Some physicians are already, in a quiet way, helping to settle the "physician and druggist" question. They are doing this by purchasing large amounts of the preparations made by wholesale and manufacturing druggists. Many of these firms now have lists of carefully prepared prescriptions, which cover a very extensive range. With a supply of these, the physician can become, to some extent, his own druggist. This may appear to be rather beneath the professional dignity, nevertheless its practical workings are satisfactory, and may benefit both physician and patient. It is in reality only a kind of reversion to an ancient custom; yet, there is a great deal of difference between the old fashion, when the doctor weighed, and measured, and mixed his own prescriptions, and that of simply handing the patient a bottle of artistically prepared pills or an enticing elixir. And there is no reason why he should not give the preparation at once, if he has it, instead of sending his patient to a druggist, where there will be fifty per cent. more to pay.

Another plan that has been strongly recommended is that of co-operative dispensaries. Here several physicians unite, buy a supply of drugs, and hire a druggist to put up their prescriptions at cost. It is doubtful if such a plan could be made extensively successful, but it has been proved practicable in some places.

We do not wish to express any unreasonable prejudice against druggists, in referring to the above measures. Many of them, no doubt, act as fairly as possible in their relations to the doctor and his patient. Their expenses are often large, and the great competition divides up their trade to an injurious extent. But counter prescribing and exorbitant charging prevail much more than they ought to do, and any measures that will legitimately lessen these evils should be encouraged.

Very truly yours,

PRACTITIONER.

ABUSE OF MEDICAL CHARITIES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—The rural practitioner knows something of the abuse of medical charity in New York City. Not long since a fashionably dressed lady called at my office for treatment for a complaint which she said she had received advice and medicine for at the Northwestern Dispensary for the last four years, free of charge. I was greatly astonished at this, and asked her to explain how she got it. "Why, I went there, and they asked what ailed me, and treated me—that's all." Now, this lady owns real estate and also personal property here to the amount of at least three thousand dollars, and, moreover, she had just paid seven hundred dollars cash for a business for her son. I have reason to know that the above are *facts*, and yet this lady for four years has been the recipient of medical charity at the Northwestern Dispensary.

Respectfully yours,

REGULAR.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—The two communications of Dr S. Seabury Jones and of Dr. Alfred L. Carroll (issues of February 14th and March 6th) are of especial importance to the medical profession as showing how much of the mischief resulting from the so-called medical charity is due to those of our own household. It is much to be deplored that both gentlemen have hitherto refrained from making these grievances, detailed in the MEDICAL RECORD, public property, inasmuch as such abuses as are described concern not only these gentlemen individually, but the entire medical profession, and it is equally to be deplored that the names of the physicians and of the hospitals should be withheld, from a foolish desire to "avoid hurting any one's feelings."

The statements alleged in these two letters are presumably correct, and, if so, the physicians guilty of such misconduct should be exposed as unworthy of professional recognition and unqualified to practice medicine, and the hospital or college which employs them should be proved undeserving of support either from the laity or from the profession. Give us, then, the names. Statements like the ones contained

in the letters should not be suffered to pass unchallenged, because it affects the good name of the entire profession to have any one of its members under charges of such atrocious misconduct without a chance of punishing the guilty ones.

One point in Dr. Carroll's letter I trust I shall be excused for commenting upon. He complains "that 'out departments' and clinics are made to conduce to the pecuniary profit of some of the officiating staff, where inquiry has shown that the patient is not in destitute circumstances, but has not been pushed to the inquisitorial extent of ascertaining whether the case were under treatment or not."

Let me ask what good reason is there why the attending physician at an out department or clinic should not profit pecuniarily by those cases which can pay him a fee? The object of the physician in seeking a position in hospital, dispensary, or any similar institution is twofold: first, as regards opportunity for studying cases; second, as regards his personal advancement through his connection with the institution. Moreover, he does not propose to give his time or services *gratis* to such as can pay him a fee, though he is willing to do so for those who cannot, upon condition that they shall give their *quid pro quo* in some other way. He is, I believe, entitled to get a fee, if he can, out of those who can pay, if such people come to his clinic to consult him.

I know that in the miserable system which passes current among us as medical charity, nearly, if not quite all of the charity (?) is done by the doctor; but then, as he seems to like that sort of thing, I suppose no one ought to complain for him. Surely, however, if he is willing to give his time and knowledge to the service of the charitable institutions which is willing to employ him for nothing, *so far as they are concerned*, it is scarcely fair to upbraid him for demanding a solid return for his services from those who can pay him for them.

I am, dear sir, very truly yours,

F. R. Sturgis.

16 West Thirty-second Street,
New York, March 16, 1880.

AFFECTIONS OF THE EYE FOLLOWING USE OF CHLORAL.

To the Editor of The Medical Record.

Sir:—In response to a question by your correspondent, Dr. G. H. Fellows, Haverhill, Mass., as to whether or not chloral has ever been known to produce any trouble with the eyes, I have to state that last year there came under my care a naval officer in the later stage of consumption, who, from excessive coughing, was unable to sleep at night. I found that opiates produced in his case great irritability of the stomach. On one occasion I gave him, on his retiring to bed, ten grains of chloral to be once repeated during the night. The effect was magical. The cough was relieved greatly, and patient slept very well. Of course, I pursued the treatment. On the second morning patient complained that the chloral was affecting his eyes, which, he said, was always the case when he took it. There was some injection of the conjunctiva and a little swelling of the eyelids. I repeated the medicine again that night; but next morning the engorgement of the conjunctiva was so great that I discontinued it. The trouble with the eyes immediately passed away.

On several subsequent occasions I was obliged to repeat the remedy, and always with a similar effect. There was never any sign of impairment of vision.

Respectfully,

L. Austine Brown, M.D., U.S.N.

U. S. F. S. Pensacola, Panama, U. S. C.,
March 2, 1880.

[This communication comes rather late for the discussion, but due allowance is made for the distant residence of our correspondent.—Ed.]

POSTURE IN THE TREATMENT OF INTESTINAL COLIC AND ILEUS.

To the Editor of The Medical Record.

Sir:—In Dr. F. H. Hamilton's recent paper on "Posture in the Treatment of Intestinal Colic and Ileus, with a Consideration of the Pathology of Spasmodic Colic," he writes: "In its application to spasmodic colic both the method and the explanation are believed to be new. My attention has been called to the fact that some one has written very recently on the value of posture in the treatment of colic; but I have not seen the paper, nor do I know the name of the author, nor am I informed that the paper was published before the publication of my paper on hernia, in which the views now expressed were foreshadowed. Of course, this is a matter of no consequence to me or to the world, but I did not wish to be suspected of appropriating the suggestions of others and of offering them as original with me."

It was unnecessary for the accomplished author to pen the last paragraph which I have quoted, since "the rich man does not need to borrow;" but his paper will doubtless have the effect of calling the attention of the profession to the great use of posture in the treatment of disease. We are accustomed to think of a sick man as on his back or side in bed, almost a fixture, whereas his relief may depend in no small degree upon the prone, perpendicular, or inverted position. In a case of strangulated hernia which I asked Dr. Hamilton to see several years ago, his suggestion of inverting the patient while under ether was followed by reduction.

There is in the *American Journal of Medical Sciences* for January, 1874, a paper which I wrote "On the Uses of the *Knees and Elbows Position*," including the "all fours" and "*a la reche*" posture, in which elevation of the pelvis is recommended as follows:

"For the replacement of hemorrhoids and rectal prolapsus, the advantages of this position are at once apparent, and since the warm air of the intestine tends toward the anus when the patient is on knees and elbows with elevated pelvis, this posture suggests itself as useful in cases of *colic connected with excess of intestinal gas*." I have used this method with apparent benefit both in colic and constipation, and, in the paper referred to, related a case of rectal stricture which occurred in my practice in 1867, in which the same method was of service. "For the purpose of diminishing the purulent discharge, I concluded to wash out the intestine with a solution of carbolic acid. In using a long elastic tube I found it difficult to introduce it satisfactorily, but placing the patient on his elbows and knees, the tube was passed far up the bowel and the solution poured into it from a small pitcher."

One word with regard to the genu-pectoral, or knee-

breast position, which we have referred to in the journals. This position is a *necessity*, and if any one doubts my assertion let him kneel upon the floor and endeavor to touch the same surface with his breast at the same time. The accomplishment of this may be termed a *feat*, since only few can perform it, for the head cannot, as a rule, be sufficiently extended to permit the breast to touch the floor. With regard to the atmospheric pressure which is said to dilate the vagina when a woman is placed in the so-called genu pectoral position, and which idea of atmospheric pressure is, I think, unscientific and erroneous, how is it that the air rushes *out* of the rectum, if it rushes into the vagina when the hips are elevated? As we were taught in our philosophies, we must, I think, still believe that the pressure within and without the body are equalized, else would the abdominal wall collapse against the spinal column, or burst outward anteriorly. The apparent atmospheric pressure is, it seems to me, caused by the rushing of the air into the space produced by the falling forward of the viscera in consequence of gravity.

I may diverge one step further in conclusion. Allied to the effort to be secured from posture, is the mechanical aid which may be derived in introducing the cylindrical speculum, in some cases where the vaginal walls do not easily yield, by causing the patient to exhale forcibly. This removes the downward pressure of the intestines and facilitates the introduction of the instrument. Respectfully,

F. A. BURRALL, M.D.

48 WEST SEVENTEENTH STREET, N. Y.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from March 14 to March 20, 1880.

FINLEY, J. A., Capt. and Asst. Surgeon. Having reported in person at these headquarters, assigned to duty at Fort Adams, R. I. S. O. 41, Dept. of the East, March 15, 1880.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending March 20, 1880.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
March 13, 1880.	0	4	43	2	121	32	0	0
March 20, 1880.	0	5	28	6	93	38	0	0

SIR THOMAS WATSON ON THE NATURE OF COW-POX. —Sir Thomas Watson has for some time been an advocate of the theory that cow-pox is not small-pox inoculated in the cow and there modified in its course, but that it is a separate disease generated, perhaps, by the inoculation of grease from horses. In a recent letter to the *British Medical Journal* he acknowledges his error on this point. It may be presumed, therefore, that he adopts now the more prevalent view that cow-pox is the same disease as small-pox.

ANOMALOUS CASE OF NEPHROTOMY. — At Guy's Hospital Mr. Clement Lucas recently removed a suppurating kidney from a man aged thirty-six. The Bigelow method was adopted and antiseptic precautions were employed. At last accounts the patient was considered almost free from danger. The man had had a purulent discharge through the loin for six years.

THE PREVENTABLE DEATHS IN AMERICA are estimated to be over 100,000 annually. The preventable cases of sickness are about 150,000.

TRICHINA IN SWINE. — In Prussia, in the year 1878, there were 2,524,105 pigs examined for trichinæ. About one in every 2,000 was found to contain the parasite. Of American hams 865 were found infected, but all the trichinæ were dead. Fifteen outbreaks of trichinosis came under the notice of the police in Berlin.

SICK-ROOM COOKERY. — One of the teachers in the Edinburgh School of Cookery has been giving some practical demonstrations of sick-room cookery before the Edinburgh medical students. The preparation of beef-tea, arrowroot, bread-crumb pudding, gruel, custard and other articles of diet was shown. Much interest was manifested by the students.

HEALTH OF NASSAU. — The report that there is or has been yellow fever at Nassau is officially contradicted by Dr. Frederick Duncombe, Chairman of the Board of Health.

EXPERIMENTS WITH DISINFECTANTS. — Dr. George M. Sternberg states, as the result of certain recent experiments with vaccine lymph, that exposure for six hours or more to an atmosphere of sulphurous acid gas, chlorine, or nitrous acid gas is a reliable method of disinfection.

MEASLES is spreading throughout the Southern States; the mortality from scarlet fever is growing less in the same regions.

In England during the past six months the mortality from measles has been unprecedented. In the last quarter of 1879 there were 3,607 deaths from the disease, being an increase of 2,118 upon the corresponding period in 1878.

MINISTERS MAKING DOCTORS—WHY TWO METHODIST CLERGYMEN WERE PUNISHED BY THEIR CONFERENCE. — The New York *Times* of March 20th, says: "Annually there are turned out from the University of Pennsylvania and the Jefferson College (representing the old school of practice), and the Hahnemann, (the new school) about 500 doctors. Some bogus medical colleges, with high-sounding titles, have sprung up here in consequence of the high standing of the regular colleges. One of these has been discovered in the Philadelphia University of Medicine and Surgery, where diplomas could be had upon the payment of a small amount of money, and the applicant given the right to begin the practice of medicine at once. This institution was managed until a few years back by Dr. William Payne, who figured extensively in the George O. Evans case. He closed the place out to a party of Methodist ministers, who preached on Sundays, and ran the college during the week. The Rev. T. B. Miller was Dean, the Rev. William Major, Secretary, and the Rev. W. V. P. Ingraham, President. These men were all well known in the Philadelphia Conference, and their

standing in the Church served their purposes well in leading many persons to become students at their college. Two weeks ago, John Norris, of the *Record*, of Philadelphia, called at the college, and paid Dean Miller $25, in return for which he received a certificate entitling him to begin the practice of medicine immediately.

"Then the exposure began, and has been carried on since with unremitting energy. It was developed that the charter under which the institution operated was repealed by the Legislature in 1872, but this has not deterred the Faculty from issuing diplomas. Men who had attended at this place only four months had been given diplomas. Among these was Frank Gratton, who will be remembered as a witness in the Latroumeille murder trial at Albany, in June, 1879. He had a diploma from this college, but was only here a short time. While all these flagrant violations of the law have been shown, and the evidence has been at hand, the District Attorney of the county has seen fit to allow this institution to continue its operations. The Methodist Church, however, took up the fight against its ministers, and the Annual Conference, which adjourned last night, appointed a court to try the Dean and Secretary of the bogus college. Both men were tried, and the result was that Dean Miller was expelled from the Church and the Conference, and the Rev. Mr. Major was suspended for one year."

The Contagious Diseases Acts in England.—A select committee of the House of Commons has been lately appointed to continue the inquiry into the workings of the contagious diseases acts. The committee consists of nearly the same members as those of last year. The investigations, as far as they went last year, were, on the whole, favorable to the working of the acts.

Professor S. D. Gross has just been elected President of the Board of Trustees of the Pennsylvania Dental College.

Doctors in Parliament.—According to the correspondent of the *Louisville Medical News*, there are nine medical men who are candidates for election or re-election to Parliament. Dr. Andrew Clark, Dr. Lyon Playfair, Dr. Farquharson, and Dr. Cameron are among the most prominent. Mr. Ernest Hart has been invited to stand for a large metropolitan borough, but has refused.

Dr. James G. Hyndman, one of the editors of the *Cincinnati Lancet and Clinic*, has been elected to the position of Professor of Medical Chemistry and Physics in the Medical College of Ohio. Dr. Frederic Kebler has been appointed Lecturer on Pathology in the same institution.

The Union Medical College is the name of a new institution which is to be organized in Chicago. It is to include on its Faculty representatives of all the schools and pathies.

The Bogus Medical Colleges of Philadelphia have lately had a stirring up at the hands of the local press. Reporters interviewed the Dean of one of the colleges, assuming to be anxious to purchase diplomas. They were offered one for $100, and as the Dean had three charters the applicants were allowed their choice. They were also furnished with a set of lecture-course tickets, and were instructed how to write a prescription. They left, telling the Dean that he would hear from them again in the morning, and so he did, as a full description of the performance was published in the next day's *Public Record*. A number of attempts have been made to abolish these bogus colleges, but without success.

Inhalations of Lime-vapor in Diphtheritic Croup.—In an interesting letter from Dr. J. M. Cummins, of Larned, Kansas, on the treatment of diphtheria and diphtheritic croup, he states that he has had very uniform success with the lime-vapor bath. The method which he follows is original with him, although it is a well-known one with others. He puts a piece of unslaked lime into boiling water and conducts the vapor so that the patient not only inhales but is enveloped in it. This method of obtaining the lime-vapor is the only practical one, unless atomizers are used, since slacked lime itself when put in boiling water is not carried over in the steam at all.

Dr. Cummins's experience leads him to believe that diphtheria is a disease which has a local origin in the throat. He has found that early local treatment with, preferably, liquor ferri persulph. will sometimes cut short the disease by preventing constitutional infection. After an application of the liq. fer. persulph. the membrane, "like the cow the old Deacon kicked, curls itself right up." Dr. C. employs the usual constitutional remedies of iron and chlorate of potash.

Sloan, Wm. J., Colonel and Surgeon, U. S. Army, Medical Director Dept. of Dakota. Died at St. Paul, Minn., March 17, 1880.

The Lying-in Hospital at Vienna.—This enormous institution is a department of the general hospital of the city, and is in three divisions. The first, under Professor Carl Braun, is frequented by physicians who go to Vienna to study; the second, under Professor Spaeth, is attended by university students; the third is entirely devoted to the instruction of midwives. More than 10,000 women are delivered in the course of the year.

Twelfth Annual Report of the New York Orthopædic Dispensary.—The total number of cases treated in the nine months ending October 1, 1879, was 1,031. Of these 248 were cases of Pott's disease, and 274 of hip-joint disease. Knee-joint diseases, infantile paralysis, lateral curvature, and club-foot, make up a large proportion of the remaining diseases. The expenses of the dispensary and hospital were $7,086,75.

The American Drug Trade.—There was in 1879 an increase of 2¼ per cent. in the amount of druggists' goods entered for consumption—an increase proportionately greater than that of 1878.

A number of drugs which used to be imported are now being produced in this country to a sufficient extent to supply the demand. Among these are mercury, borax, bicarbonate of soda, citric acid, carbolic acid, and the ammonia salts. The amount of opium imported in 1879 was 278,554 pounds, which is 70,000 pounds more than in 1878.

The importation of quinine was 228,348 ounces, against 17,549 ounces in 1878. After the passage of the act repealing the duty on quinine 110,000 ounces were imported, so that the repeal did not affect the importation for that year.—*Druggist*.

Annual Report of the New Jersey State Lunatic Asylum, at Trenton, 1879.—This asylum treated during the past year 655 patients, and, at its close, had 506 under its care. The per cent. of cures was 27, the death-rate was 7 per cent. The superintendent urges the necessity of provision for the early treatment of the insane.

Fourth Annual Report of the State Asylum for the Insane, Morristown, N. J., 1879.—There were 480 patients in the asylum at the close of the year. During the year 104 were admitted, 34 discharged cured, and 30 improved. This gives a little over twenty per cent of cures. The asylum will accommodate 500 patients, and is one of the few that are not overcrowded. The medical staff consists of a medical superintendent and two assistants. The superintendent recommends the study of physiology as an aid to mental therapeutics.

The Pellagra in Italy is devastating the population to a most alarming extent, nearly 100,000 being affected by it. It prevails throughout almost one-half the provinces, and is causing a mortality of over 7 per 1,000 of the total population. It is more destructive than the cholera epidemic that ravaged France in 1884-5.

The Oxytocic Properties of Viscum Album.—Dr. W. P. Manning, of Shepherdstown, W. Va., writes: "Sir: In your issue of March 6th, I notice an article by Dr. C. L. M., of South Carolina, in which mistletoe had been used for the purpose of abortion with the desired effect.

"I am not surprised at this communication, for that viscum album, as a fluid extract, has decided and superior oxytocic properties I am convinced from frequent and repeated trials; having used it in post-partum hemorrhage with the most pronounced and gratifying results. Menorrhagia and Metrorrhagia, not dependent upon organic disease, are—as far as my experience goes—better controlled by this remedy, than by any other. In emmasio mesnum it exerts surprising effects, having established the flow after thirty days' treatment in two cases, which had resisted the usual methods, in one a year, and the other a still longer period. My usual plan is to give in menorrhagia and metrorrhagia teaspoonful doses three times daily, in emmasio mesnum 30 drops 3 t. d., but post-partum hemorrhage requires more energetic measures—teaspoonful doses every twenty to thirty minutes till the bleeding stops.

"I hope others may give the remedy an honest trial in order that its actual value may be ascertained, for I feel that we have in viscum album a remedy powerful for good."

The Medical School of the University of Maryland intends to make a number of changes in its curriculum so as to furnish a more thorough course and a higher standard of graduation. It will abolish its present beneficiary system and confer beneficiary scholarship upon such young men as have distinguished themselves in a study or laboratory work. Laboratories are to be constructed, and a number of special courses will be given. This change we are informed by the *Maryland Medical Journal* is much needed.

The Prize Essay of the Baltimore Academy of Medicine has been adjudged to Dr. W. T. Councilman, of Baltimore. The subject of the essay was: "A Contribution to the Study of Inflammation, as Illustrated by Keratitis."

A Bone Setter from Abroad.—For many years a peasant-woman in one of the smaller towns of Italy has practised the art of "bone-setting." She has claimed to have the usual natural skill of this class of persons, but her success has been much greater than is ordinarily the case. The fame of her cures gradually extended throughout the country and even attracted foreigners to her "clinics." She was once brought up before the Court by a neighboring Faculty, and charged with practising surgery without knowing the name of a single bone. The authorities could not let to neglect her, however. In course of time a number of Americans received her care and became deeply enthusiastic over her successes. An article describing her and her ways appeared in a number of *The Century* in 1872.

About a year ago, a wealthy American family brought the bone-setter over to this country with the philanthropic desire of giving relief to the crippled limbs of their fellow-countrymen.

Of the many marvellous tales about her, one, not so marvellous we know to be authentic. A lady, living in Albany, received a fall by which her shoulder was, according to the surgeons who examined it, either dislocated or partially dislocated. The lady, being of a nervous temperament, absolutely refused either to take ether or to suffer the pain that the manipulation to replace the arm would cause. After waiting five months, therefore, she finally heard of the Italian bone-setter, and came on to Brooklyn to receive treatment at that specialist's hands. She was told that the arm could be replaced without difficulty and without pain. She was ordered to poultice the whole shoulder three times a day with a mixture of bran and marsh mallow. At the end of three days the bone-setter performed her manipulation and returned the arm (if it was out) to its proper place, causing no pain by the operation.

It is her usual practice to have poultices of the kind mentioned applied before returning dislocations. The plan is of course a good one. It is known that most of the so-called bone-setters perform their marvellous cures, as a rule, upon joints not dislocated, but which have become rigid from disuse or from some inflammatory adhesions, which injuries have brought about. The manipulation breaks up the adhesions and the patient is soon able to walk or use the extremity. This fact, the application of poultices and a really delicate handling, will explain all that our Italian visitor does.

Answers to Correspondents.

Professional Competition.—A correspondent asks:—Is a physician entitled to receive the courtesy of the code who will ride several miles to visit a patient and make three such calls for a dollar, when patient has abundant means to pay more, and the resident physician charges one dollar a call, and the society to which both belong has a fee bill which provides for no call less than a dollar and mileage; and what is the best course for a regular physician to adopt toward the above-mentioned "cheap John," when he tells people freely that he will ride several miles and render his services in all cases at the same or less rate than the resident physician, and consults with irregulars whenever it so suits his convenience?

[The better way is to have as little as possible to do with such a professional brother. Probably his time and services are not worth more than he charges for them, and he has a right to keep his conscience clear. In any event most of his time is spent on the road, and consequently he can visit but few patients. If he consults with irregulars he is a fit subject for discipline in his county society.—Ed.]

THE BROMIDE OF ETHYL AS AN ANÆSTHETIC.

By J. MARION SIMS, M.D., LL.D.,
NEW YORK.

(Read before the New York Academy of Medicine, March 18, 1880.)

THE bromide of ethyl is now making considerable reputation as an anæsthetic. It was discovered by Serullas in 1827, but attracted no special attention till Dr. Thomas Nunnelly, of Leeds, made some experiments with it on animals in 1849. Dr. Nunnelly brought the subject again before the profession by a paper read at the British Medical Association in 1865, in which he says he had employed it as an anæsthetic "in all the principal operations at the Leeds General Eye and Ear Infirmary." This was at the time when chloroform held such complete sway in England that no importance was attached to Nunnelly's experience, and he had no followers.

In 1876 some experiments were made with it in France by Rabuteau on the lower animals, but without a knowledge of the fact that this had been done previously in England by Nunnelly.

To Dr. Laurence Turnbull and Dr. R. J. Levis, of Philadelphia, we are indebted for what we know of the anæsthetic properties of the bromide of ethyl.

Dr. Turnbull began to experiment with it in September, 1877, using it first on himself, and then on his patients. After satisfying himself as to its efficiency and safety as an anæsthetic, he laid the subject before the Pennsylvania State Medical Society in 1878. In August, 1879, he brought it before the British Medical Association at Cork, and in September of the same year before the International Medical Congress at Amsterdam. In April, 1879, Dr. Turnbull had the good fortune to interest Dr. Levis in the subject. Dr. Turnbull's operations under the ethyl were mostly in ophthalmic and aural surgery, and were generally of short duration. But Dr. Levis being surgeon to two large general hospitals (the Pennsylvania and the Jefferson Medical College Hospital), had ample opportunities of testing its qualities and proving its excellence as an anæsthetic in general surgery and in prolonged operations; and through his influence and teachings at these hospitals it seems to be coming rapidly into common use.

The bromide of ethyl has been pronounced by Maisch and Stillé, and by Dr. Greene, of Philadelphia, to be hydrobromic ether.

There are two or three processes for making the hydrobromic ether. Our friend Dr. Squibb will explain them to you. The most economical is the phosphorus, alcohol and bromine one. The disagreeable odor belonging to the hydrobromic ether made by this process is supposed to be due to the phosphorus. Another process is by distilling absolute alcohol with about three times its weight of bromine. Another process consists in the combination of potash and bromine. Its formula is:

C_2H_5Br; boiling-point, 105° F.; density, 1,419 at 59° F.

Dr. Turnbull defines hydrobromic ether to be "a pure, colorless, very volatile liquid which evaporates with great rapidity on bibulous paper, leaving no residue, and having a strong ethereal odor which remains upon the patient's breath long after its use. It has a sweetish and hot taste. Its boiling-point is intermediate between that of chloroform and ordinary ether. It is sparingly soluble in water, but mixes with it, and in all proportions with alcohol and ether."

I here show you samples of it made by four different manufacturers in Philadelphia. That marked No. 1 was made by Wyeth & Bro., and is mostly used by the surgeons in Philadelphia. You see how readily its vapor extinguishes a flame. No. 2 contains ether, and ignites. These two have a peculiar but not disagreeable odor. Nos. 3 and 4 have a very strong, unpleasant odor, which is repulsive. This is the kind that was used by Turnbull and Levis before Wyeth made a better article.

It is claimed for hydrobromic ether that it produces anæsthesia more rapidly than chloroform, and is eliminated from the system more rapidly by the lungs and kidneys than any other anæsthetic, and that it is less apt to produce vomiting than ether or chloroform.

It usually produces anæsthesia in two or three minutes—sometimes four; and consciousness returns in two or three minutes after its administration ceases. It is given (according to Turnbull and Levis) "on a handkerchief or small napkin folded up to a space of about four inches square, and then laid on a larger napkin folded so as to be large enough to cover the entire face of the patient."

About two drachms are poured on the napkin to begin with, and a drachm is added afterwards at intervals as required.

Hydrobromic ether has been administered in Philadelphia as an anæsthetic about two hundred times, and it is greatly lauded by all who have used it. Of course, this is a small experience upon which to base its absolute safety. Chloroform was administered to thousands of cases before we heard of a death from its use, and now we know that it has slain its hundreds.

Bichloride of methylene has been given by Spencer Wells most extensively, perhaps a thousand times without an accident, and yet a voice comes up from the profession saying that it is quite as dangerous as chloroform; and outside of the personal influence of Spencer Wells it is rarely used in England, and has not been generally adopted elsewhere.

The profession have been for a long time in search of a new anæsthetic. We have been waiting for one as pleasant to take as chloroform and as safe as ether. When we are convinced that we have one answering this description, it will be heartily welcomed by the profession all over the world. Does the Turnbull-Levis anæsthetic come up to our expectations? Time alone will show. It is the duty of every man who has had any experience with it to lay it before his brethren. With this obligation pressing heavily upon me, I came here to-night to lay my contribution on this important subject before you.

For my knowledge of the use of hydrobromic ether I am indebted to Dr. Levis. I made him a visit on the 28th of January last, when he told me of his experience, gave me his paper on the subject, and gave me a bottle of the ether for experiment. I came home saturated with Dr. Levis's views. From his experience I felt quite convinced that we had at last found the long looked-for anæsthetic.

Three days after my visit to Dr. Levis I gave the hydrobromic ether to a young lady at St. Elizabeth's Hospital; but, not understanding the proper method of administering it, I failed utterly to produce its anæsthetic effect. In eight minutes we had wasted

eight drachms of hydrobromic ether, and it produced only a stage of excitement in which the patient was wholly uncontrollable. I then laid it aside and resorted to ether. On the next day I gave it to a young lady, twenty years old, who was completely anæmic from uterorrhagia which had continued many months. She was so exhausted from loss of blood that she occasionally had syncope, even in the recumbent posture. By the inhalation of two drachms of the hydrobromic ether given by Dr. White she was completely anæsthetized in two minutes. The operation was performed in about five minutes, and she was placed in bed and recovered consciousness in two or three minutes more. I was so well pleased with the anæsthetic in this instance that I felt encouraged to give it further trial. The effect produced in this case differed widely from that in the first, and depended entirely upon the different methods of administration in the two cases. In the first, the bromide of ethyl was poured on a folded handkerchief, and held close to the mouth and nostrils, but not in absolute contact with them. In the second case, it was poured on a folded handkerchief and laid in contact with the mouth and nose, and held firmly there by a towel folded into a square of eight or ten inches. By this method no air could be breathed that was not loaded with the ethylic vapor. With this experience as a guide I determined to administer it in a case of Battey's operation.

Miss B——, of Tallahassee, Florida, twenty-five years old, in perfectly good health, had been subject to epileptic attacks for the last five years. They came regularly on the fourth or fifth day after the cessation of the menses. Menstruation was scanty, lasting but two days. She had retroversion, and the right ovary was enlarged and painful on pressure.

Bromides had been largely used without any permanent improvement. The uterus had been replaced, but with no improvement; afterwards the cervical canal was enlarged by incision; then menstruation became normal in quantity and painless, and yet the post-menstrual epileptic seizures were not modified in the least. Her physicians, Dr. Betton and Dr. Bond, had advised Battey's operation, and from my failure to give her any relief by the tentative efforts just alluded to, I did not hesitate to advise her to submit to Battey's operation, and it was performed on Monday, February 9, 1880.

Everything being ready, a drachm of bromide of ethyl was poured on a folded napkin and held closely over the mouth and nose. In a minute more another drachm was poured on the napkin, and at the end of two minutes she became insensible and relaxed; but the conjunctiva was sensitive to touch, and her eyes rolled about, and her breathing was very rapid. At the end of five minutes (the hydrobromic ether added as required) she was perfectly insensible and breathing sixty times a minute. This very rapid breathing would moderate whenever the ether-napkin was removed so as to allow the admission of pure air, and would always increase by pouring fresh ether on the napkin. At the end of ten minutes she could be kept quiet, breathing softly and regularly, but always above the normal standard. The pulse was now 86, full and strong. During the first twenty minutes we had used about two ounces of the hydrobromic ether. At that time she vomited freely the contents of the stomach. At the end of forty minutes she vomited again, with severe straining.

On three occasions during the operation there was considerable opisthotonos, with twitching and rigidity of the muscles of the extremities, and constant rolling of the eyes in every direction.

Dr. Nash thought these were similar to her epileptic attacks, in one of which he had seen her.

The operation lasted an hour and a half. Her condition was good during the whole time, and her pulse was strong and full. The rapid, short breathing was a peculiar feature; the sensitiveness of the conjunctiva existed from the beginning to the end of the operation, and her eyeballs were in almost constant motion. There was no unusual dilatation of the pupils. In all, about four and a half or five ounces of the ethyl were used.

She recovered quickly from the anæsthetic after being put to bed, but she had the most distressing retching and vomiting imaginable. The straining was so violent that Dr. Nash more than once placed his hands over the abdomen to prevent the wound from bursting asunder. From the moment of returning consciousness she complained of violent pain in the head, and to relieve this pain she got a fourth of a gram of morphine hypodermically. In an hour this was repeated. Two hours after the operation (6.30) the pulse was 60, full and strong.

6.45.—Distressing retching and vomiting continued almost uninterruptedly ever since the operation was finished. Headache very severe. Quarter-gram of morphine hypodermically for pain in head. One ounce of urine drawn by catheter.

7.30.—Nausea and retching, but no vomiting; still has severe pain in the head. Thin, yellowish brown movement from the bowels, watery, but a few ounces, odor very offensive, having the smell of bromide of ethyl.

8 P.M. Another movement from the bowels, the same character as the first.

9 P.M. Another movement of the same brownish water; each attended with some tenesmus.

9.30 P.M.—Milk and brandy, to be repeated at intervals.

10.15 P.M.—Two ounces of urine drawn; bowels moved twice in the last hour. This makes five movements of bowels in three hours. The odor of the bromide of ethyl in the passages was so strong that it attracted the notice of the inmates of the house.

11 P.M. Pulse, 117; temperature axilla, 99.4; respiration, 25. Still complains of pain in the head; small, brownish, watery discharge from the bowels, attended with tenesmus and mucus.

12.35 A.M., Tuesday, Feb. 10th.—Very restless; complains of pain and desire to go to stool. Gave one-fifth grain of morphine hypodermically. Hiccough occasionally since 10 P.M.

3.15 A.M.—Has slept since the administration of the morphine 2 h. 40 m.). Drew off two ounces of urine. Hiccough occasionally since 10 o'clock. Tenesmus and effort at movement of the bowels. Pulse, 125; temperature, 101°. Sleeping.

5 A.M.—Pulse very feeble. Stimulants.

5.30 A.M. Pulse scarcely perceptible.

6 A.M. Small, brownish, watery movement from the bowels, with tenesmus.

6.40 A.M. Recurrence of hiccough; quietly sleeping; perfectly conscious when spoken to.

7 A.M.—I saw the patient and made the following note: pulse imperceptible; no pain except in head; somewhat restless. I fear internal hemorrhage, because the diarrhœa does not seem to have been sufficient to prostrate her to this extent. Her breath is highly charged with the ethyl odor. The movements from the bowels are brownish dirty water, with some tenesmus and mucus. Passed a catheter into the

sigmoid flexure and injected thirty grains of tannin and twenty drops of laudanum, which passed off immediately.

7.45 A.M.—Very restless; wishes to sit up; growing weaker; mind wandering.

8.40 A.M.—Catheter introduced, no urine in the bladder; pulse imperceptible. Respiration, 36; temperature, 102⅕°.

10.30 A.M.—Catheter introduced, teaspoonful of high-colored urine drawn.

11 A.M.—Severe convulsion, with frantic ravings. Convulsions ceased at 11.40 A.M., with heart-rending screams, and she died at 12.15 P.M., about twenty-one hours after operation.

Wednesday, Feb. 11, 1880, 8.45 A.M.—Post-mortem made (twenty hours after death) by Dr. S. Waterman, Dr. Waterman, Jr., and Dr. Nash. External wound three inches and a half long. Sutures (8) removed; edges of wound adherent throughout. Abdomen laid open by free incisions, longitudinal and transverse. Two and a half ounces of bloody serum in the peritoneal cavity, three drachms of it being in the Douglas pouch below the retroverted uterus. There was no exudation of lymph, and no signs of peritonitis.

The left broad ligament united to sigmoid flexure by old and strong adhesions were broken up, and then the uterus and broad ligaments were removed, together with utero-sacral ligaments, a portion of bladder, and the upper part of vagina. The lower part of the ileum for about eighteen inches looked dark and congested, and about twelve inches of it were removed, severing it at the caput coli. The colon was also of the same dark brown color, and five or six inches of the descending colon were removed, and also both kidneys. The kidneys seemed to be healthy.

Now, the question arises: What was the cause of death in this case? Before the post-mortem was made I supposed that the uncontrollable straining efforts to vomit had resulted in displacing some of the pedicle ligatures, and that my patient had died of slow internal hemorrhage. But the post-mortem proved otherwise.

In a letter received from Dr. Levis (Feb. 19th) he says:

"It seems to me that the only unpleasant symptoms which could possibly be referred to the anæsthetic were those of the head, and it is evident that the death of the patient is not to be attributed to cerebral causes. As to the diarrhœa or cholerine, which, probably with shock, seemed to cause death, that could not be attributed to the anæsthetic. Ethyl has been used in this city about two hundred times, uniformly with the most happy results. In my experience there has been no headache or other evidence of cerebral disturbance following the administration. No bowel affections have been observed, and none would be thought of. Do not be too hasty in the association of the anæsthetic with the cause of death. Many thousands of patients have died within twenty-two hours after the administration of ether and chloroform."

Some persons think that death was produced by chlorine. Let us sum up the evidence bearing on this point.

The patient took three drachms and fourteen grains of Rochelle salts at 8.30 A.M. It operated freely twice before 11 o'clock, and no more till 7 o'clock, about two hours after the operation. She then had six thin, brownish, watery discharges from the bowels between 7 and 11 o'clock P.M.—not large, but attended with tenesmus, and the last with a little mucus. At 12.15, 2.40, and at 6 and 7 next morning, there were other thin, watery, brown discharges, with tenesmus and a little mucus, and the patient wanted the bed pan under the pelvis constantly.

Thus, we see that, between 7 P.M. and 7 the next morning, there were not less than ten watery, not profuse, but exhausting evacuations, over which opiates and astringents did not exercise the least influence. Dr. Nash says: "A few hours before death there were several (two or three) large involuntary movements from the bowels, such as she had previously had—dirty, thin water, with the disagreeable ethyl odor." The lower portion of the ileum and the colon were black and congested, and altogether presented an appearance far from a normal, healthy one.

This is a strong array of facts to sustain the theory of death by cholerine; and in all probability this cholerine had an important bearing on the termination of the case. But from my standpoint of view this was only secondary. Was death, then, caused by the anæsthetic?

Let us here sum up the evidence bearing on this point.

The patient was under the influence of the anæsthetic for an hour and a half. Its effects were different on her from what has been observed by Dr. Levis and others in Philadelphia. She breathed often sixty times a minute. She had opisthotonic convulsions three times during its administration. When she recovered from its effects she complained all the time of severe pain in the head. She had a congested state of the eyes and eyelids; and she had convulsions before death; and the discharges from the bowels smelt so much of the ethyl that the inmates all over the house noticed and complained of its peculiar, disagreeable odor. The woman who washed and dressed the body after death says that the odor of ethyl from the lungs, when she would roll the body over, was as strong as when it was being administered. When we came to make the post-mortem we found the ethyl odor pervading the intestinal canal and other organs of the body. At 8.45 A.M. the post-mortem was made, and I wrapped up the portions of intestine removed, the uterus and its appendages, and the kidneys, in a sheet of newspaper, and took them home, and placed them (as I was hurried) on a table in the distal end of my consulting-room, where they lay till 9 P.M.—about eleven hours. During the afternoon and evening the ethyl odor emanating from these pathological specimens was particularly noticeable in the part of the room in which they were laid.

At 9 P.M. they were unrolled in the presence of Dr. Nash and Dr. Gilliam, to be placed in spirits for preservation. When the specimens were examined separately we found the intestine, which had been split open, smelling strongly, not of fæces, nor of dead animal matter, but of the anæsthetic; and when the kidneys, which had been laid open, were brought near the nose, it was almost like smelling ethyl from an open bottle. From this it would seem that every fibre, every tissue of the body, in its minutest parts, was saturated with the ethyl.

We know that anæsthetics, whether ether or chloroform, must be eliminated from the body, and that the lungs and the kidneys are the usual emunctories selected by nature for this purpose. But in this case the kidneys were locked up as it were, and hence the bowels were called on to aid the lungs in

getting rid of the poison. It is altogether probable that the cholerine was due wholly to the action of the ethyl, and not to the salts, which, as is usual with such a dose, exhausted itself by 11 o'clock in the morning, four and a half hours before the anæsthetic was given, and eight hours before the thin, brownish, watery discharges began. It is hardly probable—I should say possible—for three drachms of Rochelle salts to produce such a condition of the mucous membrane of the ileum and colon as we found here.

I sent the pathological specimens to the histologist for examination on the 12th February, and I received a verbal report a fortnight afterward saying that the kidneys were healthy. But a few days ago I received the following:

"The kidneys to the naked eye looked normal. Under the microscope there was a slight increase of the interstitial connective tissue. Many of the convoluted tubules showed swollen and coarsely granular epithelia, and considerable narrowed central calibre, a characteristic feature of acute catarrhal nephritis.

"Slight cirrhosis of the kidney, with acute catarrhal nephritis, often exists without marked clinical phenomena, and may be overlooked by the physician."

Now, if this account of the kidneys (which I do not understand) amounts to anything, let us look at the case from this point of view.

Dr. Nash, in his report to me, says:

"From the time she was laid in bed she was excessively nauseated, and had great restlessness and intense straining efforts to vomit; her eyes were red, both conjunctivæ and lids, and when asked what pained her, replied, 'Oh! my head! my head!' When spoken to she would answer intelligently, but at no time addressed any question or conversation to any one.

"After answering questions she would relapse into a state of restlessness and groaning, often throwing her hands up to her head. In order to quiet her, sulph. morph. was given hypodermically, which never completely controlled her. It was difficult for two nurses to keep her covered, on account of constant motion of arms and legs, and rapid turning from side to side for two hours after operation. I frequently asked her if she had pain at the seat of operation, and she invariably replied, 'No, my head!' The expression of face was never natural after operation; jaws much sunken, and eyes often rolled upward. The discharges from the bowels were saturated with the odor of the ethyl, and the lady of the house and others told me that the medicine we gave to put her to sleep had gone through her bowels, as they smelt it when the bed-pan was emptied into the closet. Not until about ten hours after the operation did she acknowledge having pain in the abdomen, and that was merely the tenesmus attending the cholerine evacuations.

"I never considered her as having entirely recovered from the effects of the anæsthetic. The convulsions consisted in frantic ravings, with agonizing screams; eyes wide open, glaring, and intensely red. Then followed a few minutes of quiet, and then death.

"A few hours before death there were several (two or three) large involuntary movements from the bowels, such as she had previously had—dirty brown, thin water, with the disagreeable ethyl odor."

In reading Dr. Nash's report carefully, we are led to ask: "Was this a case of uræmic death?" We know very well that ether, as an anæsthetic, often proves fatal where there is organic disease of the kidneys. Dr. Lente was, I believe, the first to impress this on the medical mind.

I have seen two deaths from etherization in women over fifty years of age, where no disease of the kidneys was suspected till fatal coma was produced by the ether. In these cases the secretion of urine was almost instantly arrested, and the little found in the bladder was loaded with albumen. One of these was a patient of Dr. James R. Wood's; the other, a lady from Brooklyn.

In cases of organic kidney disease, the hydrobromic ether may be just as dangerous as ordinary ether.

In the case under consideration, between the time of operation and death, twenty-one hours after, there were drawn off but five ounces and one drachm of urine, viz.

One ounce at 6.15 P.M., and two ounces at 10.15 P.M. on the 9th; two ounces at 2.40 A.M. on the 10th, bladder empty at 8.40 A.M.; one drachm at 10.30 A.M., death at 12.15 P.M.

Of course the purity of the article is essential to its successful action, just as the purity of chloroform and ether is essential to theirs. Was the ethyl given to my patient pure or impure? You will perceive what a difference there is in odor between the two. The Wyeth sample is not unpleasant to the smell; the other is execrable. It is very important to determine this point before we condemn this new anæsthetic. It has many qualities to recommend it: it is easy to administer; the patient goes quickly under its influence, and recovers rapidly from its effects. But, if it is dangerous, all these qualities pass for naught. Would it be asking too much of the Academy to order an analysis of these two specimens of the hydrobromic ether to be made for the benefit of the profession at large? If the two are identical in their chemical characters, then I should not advise the use of hydrobromic ether as an anæsthetic. But if it be proven that one specimen contains noxious properties not in the other, then I would advise further experiments with the pure article.

We know that ether is safe in long operations, and that chloroform may be unsafe in short ones. It may be possible that hydrobromic ether will prove safe in short operations, and unsafe in long ones.

In some of Dr. Laurence Turnbull's cases it produced very distressing effects, which, if prolonged, might have ended, as my case did, fatally.

Dr. Turnbull gave the hydrobromic ether to a nervous, hysterical woman, aged twenty-five (Case 8), for the purpose of replacing a retroverted uterus and adjusting a pessary to hold it in position (Case 8,* . . . . "With a little less than one ounce of hydrobromic ether there was produced complete anæsthesia in four minutes, long enough for placing of a pessary to relieve the above symptoms. During the administration the pulse was but slightly accelerated; return of consciousness was accompanied by excessive gagging and vomiting of large quantities of mucus, great burning in stomach and throat, severe headache, cold perspiration, weak and rapid pulse, all of which continued for twenty-four hours, with more or less severity. Both sulphuric ether and chloroform had previously, on several occasions, produced similar symptoms, but not so severely."

Any agent which in four minutes' time could produce "excessive vomiting, burning in stomach and throat, severe headache, cold perspiration, and a weak and rapid pulse" which continued for twenty-

* Artificial Anæsthesia, etc., 2d edition, p. 74.

four hours, would, if the anæsthetic had been continued (as in my case) long enough for the whole mass of blood to become poisoned and for every tissue in the body to become saturated with it—would, I say, certainly have ended in the death of the patient.

Dr. Levis has had a larger experience with this anæsthetic than any other surgeon, but his longest operation was but forty minutes, whereas my unfortunate case lasted an hour and a half. It may be that we did not administer the ethyl as skilfully as it should have been done. But I do not think we could have given less and maintained the anæsthesia sufficient for its purpose.

If the operation had been comparatively short—if it had lasted only twenty or thirty minutes—if it had terminated before my patient's system, solids as well as fluids, became thoroughly saturated with it, she would in all probability have recovered; but, as it was, it seemed to kill by supersaturation which could not be eliminated, even with the aid of the whole mucous tract of the alimentary canal to aid the lungs. If mine had been a short operation, I might to-day have been lauding the new anæsthetic as a veritable boon to surgery. But, as it was otherwise, I must raise a warning voice, especially in prolonged operations.

It would be an interesting scientific inquiry to determine if ethyl-poisoning by inhalation produced cholerine with adeeply congested condition of the mucous membrane of the lower portion of the alimentary canal, and also to determine what other pathological changes it might induce.

This could easily be done by experiment on the lower animals, and it is to be hoped that some of our physiological *savans* will soon tell us by such experiments what we have to hope and fear from the long continuance of the bromide of ethyl as an anæsthetic.

The inference that I draw from the facts in the history of this case is that the anæsthetic was the cause of death, while the manner of death may have been by uræmic poisoning. The lesson from this is, never to give bromide of ethyl in prolonged operations, and never to give it where there is organic disease of the kidneys. What, then, shall we give?

CASE OF

COMPLETE OBSTRUCTION OF THE BOWELS,

OF THREE WEEKS' DURATION, RELIEVED BY LUMBAR COLOTOMY—DEATH FROM EXHAUSTION AFTER AN INTERVAL OF FORTY-FOUR DAYS.

REPORTED BY ALFRED C. POST, M.D., LL.D.

(Read before the New York Academy of Medicine, March 18, 1880.)

On the 27th Dec., 1879, I was called to see Mr. A. B ——, a gentleman, 52 years of age, who had enjoyed good health until the previous June, when he had an attack of acute dysentery, by which he was confined to the house for two weeks. Since that time his bowels were never free from irritation. On the 4th November he was out of the house for the last time. For two weeks he lay upon a lounge, and after that time was confined to his bed. His evacuations at first were liquid, of a dark brown color and of an offensive odor, mixed with blood and mucus, and occurred as often as once in two hours. On the 5th December he had a sudden gush of pus tinged with blood, amounting to half a pint, and attended with a chill. Soon after that he ceased to have any fæcal evacuations, but had very frequent discharges of bloody, purulent matter, with much tenesmus.

On the 26th December, after a digital examination of his rectum, he had another chill, followed by a discharge of clots of blood. He had been treated all along by homœopathic physicians, who had finally informed him that he had cancer of the colon, that nothing could be done for his relief, and that death within a few days was inevitable.

When the patient was transferred to my charge on the 27th December, he had been three weeks without a fæcal evacuation. I found the intestines distended with gas, and every part of the abdomen yielding a tympanitic resonance on percussion. I examined carefully along the whole course of the colon, and could not find any point where there was dulness on percussion. The patient was then placed on his left side, and I introduced my right index finger into the rectum, and I could feel at the point of my finger, along the anterior wall of the rectum, beyond the prostate, an obstruction caused by a hard swelling with irregular outlines, which I could not very accurately define on account of its distance from the anus. I did not form a decided opinion as to the benign or malignant character of the morbid growth. On the following day, Dr. H. B. Sands met me in consultation, and after a digital examination, the patient being in a supine position, he expressed the opinion that there was a cancerous deposit in the anterior wall of the rectum. He agreed with the opinion which I had previously expressed, that colotomy held out the only prospect of relief. The patient was very much emaciated, his muscular system was much debilitated, and he had a rapid and feeble pulse. He had been troubled with nausea and anorexia for some time before I was called to see him, and had only been able to take liquid nourishment, and in very small quantities.

On the 28th December he began to have stercoraceous vomiting, which was repeated on the 29th.

On Monday, December 29th, with the assistance of Drs. Sands and Briddon, and of Dr. William A. Fanning, who administered the anæsthetic, I performed lumbar colotomy on the left side, making the incision midway between the twelfth rib and the os ilii, the middle of the incision being half an inch behind the middle of the crest of the ilium. After dividing the oblique and transverse abdominal muscles I came down to the external margin of the quadratus lumborum, and to the layer of fat which covers the descending colon. On dividing the fat, the colon, distended with gas, presented itself at the wound, and I was able to recognize one of its longitudinal bands. Two ligatures, about an inch apart, were passed through the lips of the cutaneous wound and through the colon, and the two ends of each ligature were separately tied so as to form two loops, and then a vertical incision, an inch long, was made in the colon between the two ligatures, giving issue to fetid gas and a small quantity of liquid fæces. The mucous membrane of the intestine was then attached by sutures to the lips of the cutaneous wound, and a drainage-tube was passed between the gut and the deeper part of the wound, projecting three inches beyond each extremity. The cutaneous wound on each side of the artificial anus was then closed with sutures. During the operation, sponges wet with carbolic acid, 1 to 20, were freely employed. After the wound was dressed, a carbolic lotion, 1 to 40, was injected through the drainage-tube. The surface of the wound was covered with lint moistened with the

same lotion; over this was laid a thick compress of oakum, kept in place by a flannel bandage.

Dec. 30th.—Patient is more comfortable than before the operation. There has been no tenesmus, and no discharge of blood or pus through the rectum. There was a discharge of liquid fæces through the artificial anus about seven o'clock last evening, and another about ten this morning. There has been no vomiting since the operation. The tympanitic distention of the abdomen has subsided. The patient has been able to take milk pretty freely; he does not desire to take other food.

Dec. 31st.—There have been five small discharges of liquid fæces through the artificial anus since my visit yesterday. The patient complains of soreness in the wound, but there is no appearance of inflammation. I removed the drainage-tube. There is an offensive, purulent discharge from the rectum, but without tenesmus.

Jan. 1, 1880.—Since the last report there have been two fæcal discharges of more consistence through the artificial anus. The patient takes milk and cream quite freely.

Jan. 5th.—The patient does not seem to gain strength. Pulse about 100, feeble and irregular; temperature about 101°. His bladder is irritable, and there is an almost constant dribbling of urine. This morning I introduced a catheter, and drew off a pint and a half of high-colored urine.

Jan. 6th.—This evening, about 10.30 P.M., there was a flow of blood from the wound, which soaked through the bandages. I was summoned to see him, and arrived a little before midnight. I had the bandage removed, and found that the bleeding had ceased. I estimated the whole quantity of blood lost at about three ounces. I suppose that the hæmorrhage may have been excited by the distention of the wound with fæcal matter. I directed the tight bandage around the abdomen to be discontinued, and a loose bandage to be pinned around the body.

Jan. 7th.—There has been no return of the bleeding. To-day I removed most of the sutures. There has scarcely been any primary union. The dribbling of urine continues, but the patient absolutely refuses to have the bladder emptied with a catheter.

Jan. 8th.—The wound being much distended with solid fæcal matter, I removed the remaining sutures, and squeezed out the mass of excrements, leaving a deep cavity containing some fæces at the bottom. The edges of the wound receded throughout their whole extent. The lower lip of the wound remained at its proper level, being supported by the crest of the ilium; the upper lip fell backward and upward into the cavity. I introduced picked lint, moistened with carbolic oil, so as to support the upper lip of the wound at its proper level, and directed the nurse to repeat the application as often as it became displaced by the passage of fæces.

Jan. 10th.—For several hours the patient had been unable to pass urine. I introduced a catheter and drew off four or five ounces of a dark color.

Jan. 11th.—On visiting the patient to-day, I found that he had passed urine frequently in small quantities. He had also had several passages of thin, semi-liquid fæces through the rectum. The fæces passed through the artificial anus continued to be solid, but somewhat less in quantity. I introduced my finger into the rectum, and it appeared to me that the swelling and induration were somewhat less than before the colotomy. At the highest point which I could reach with my fingers I found a perforating ulcer in the anterior wall of the rectum, three quarters of an inch in diameter. It was so high up that I could not explore the cavity into which it opened. My finger was thoroughly smeared with semi-liquid fæcal matter.

Jan. 14th.—Since the last report the discharge of semi-liquid fæcal matter through the rectum has been frequent and very considerable in quantity, amounting to not less than two or three quarts. There has been no change in the character of the discharge through the artificial anus. Mist. creta with tinct. opii camphorat. has been ordered to diminish the frequency of the discharges. Patient continues to take milk and cream freely. He has been averse to the use of stimulants, but I have persuaded him to take a teaspoonful of brandy hourly, as his pulse is feeble, frequent, about 130, and his tongue is dry. The edges of the wound in the colon, constituting the artificial anus, have receded to the distance of half an inch from the skin, and the process of granulation is very tardy. The semi-liquid fæcal discharges through the rectum continue quite free. I removed to-day, with the handle of a spoon, a considerable quantity of solid fæcal matter through the artificial anus. I then injected through the same channel two or three pints of warm water into the colon, and it brought away an additional quantity of lumpy fæces, exposing to view the interior of the colon to the depth of about three inches. The mucous membrane, thus exposed, appeared somewhat reddened, but otherwise normal.

Jan. 19th.—The semi-liquid fæcal discharges through the rectum continued until the evening of the 17th, when they were replaced by watery evacuations, and towards morning by a pretty copious discharge of pus. Yesterday morning the discharges per anum again became fæcal, and have continued so to the present time. The discharges through the artificial anus continue solid, but less copious than they were, and of a much lighter color. The patient continues feeble; his tongue, which was quite dry, has become moist at the edges. He continues to take milk and cream freely; he has also taken brandy, as at the last report. I directed the dose to be increased to two teaspoonfuls every hour.

Jan. 21st.—He has watery evacuations through the rectum about once in two hours, without any appearance of fæcal matter.

Jan. 22d.—The nurse directed my attention to an inflammatory swelling, about the size of a black walnut, on the right side of the anus. There was tenderness on pressure, and an obscure feeling of fluctuation. I directed hot yeast poultices to be applied, and to be renewed once in two hours.

Jan. 23d.—Dr. H. B. Sands saw the patient with me. The swelling by the side of the anus has increased in size, and the fluctuation is quite distinct. I etherized the patient, and made a free incision, evacuating an ounce or more of thick, tenacious pus. On introducing a finger through the anus, the swelling in front of the rectum, which seemed to be the cause of the obstruction, could be felt as a moderately hard, rounded mass. While the finger was in the rectum there was an escape of a dirty fluid, like dish-water, having a somewhat offensive odor. About two hours after my morning visit the patient had a chill, which lasted nearly an hour. About the same time there was a pretty copious discharge of pus, as if a new abscess had broken into the rectum. I saw the patient about an hour after the chill had subsided, and found him in as good a condition as before its occurrence.

Jan. 27th.—The abscess beside the anus is granu-

lating, and presents a healthy condition. There is a small bed-sore over the sacrum, about an inch in length and half an inch in breadth. I directed a perforated cushion to relieve pressure. Since the last report the evacuations through the artificial anus have diminished in quantity, but their quality remains the same. There have been frequent semi-liquid fæcal evacuations through the rectum, having nearly the same color as the more consistent evacuations through the artificial anus.

Jan. 29th.—Since yesterday fæcal evacuations through the rectum have ceased, and there have been frequent passages of thick mucus, slightly tinged with blood. I ordered an enema of tinct. opii ℥ ss., with infus. sem. lini ℥ ss., to be occasionally repeated, if necessary, but not at intervals less than two hours.

Jan. 30th.—Two anodyne enemata were given. The slimy passages have ceased, and fæcal evacuations in small quantity have taken their place. The bed-sore has improved since the perforated cushion has been used.

Feb. 9th.—No remarkable change has taken place since the last report until to-day. This morning he vomited a dark-colored liquid, and since that time he has not been able to retain his milk and cream. He appears much more prostrated. His pulse at the wrist is almost imperceptible. I ordered the milk to be temporarily discontinued, and a wineglassful of wine-whey to be given once in two hours.

Feb. 10th.—He has retained the wine-whey, but he appears to be growing more feeble. I injected three or four ounces of milk punch into the colon through the artificial anus. I directed milk and cream to be given again by the mouth, and repeated if retained. I also directed a tablespoonful of milk punch to be poured into the artificial anus once in two hours. I saw the patient again in the evening, and learned that soon after my previous visit the principal part of the milk which I had thrown into the colon had been discharged through the rectum. The patient had retained the milk and cream which he had taken into his stomach, and did not appear quite as much prostrated as in the morning.

Feb. 11th.—Death took place at 4 A.M. A post-mortem examination was requested, but was not allowed.

In reviewing this case it appears to me that there are several points which are worthy of special attention.

In the first place, there is good reason to believe that if the operation of colotomy had been performed at a much earlier period, before the strength of the patient had been so greatly reduced, he would have rallied more perfectly, and perhaps might have been restored to health.

Second. Even at the late period at which the operation was performed, when the vital powers were greatly prostrated, his life was prolonged a number of weeks, and his condition was very much more comfortable than it was before the operation.

Third.—Although the opportunity was not afforded to demonstrate the exact pathological condition by a post-mortem examination, yet the history of the case seems to me to indicate that the obstruction of the bowel was not the result of cancerous deposit, but rather of inflammatory hyperplasia, resulting from perforating ulcer of the rectum, consequent on dysentery. The fact that, on several occasions, there was a sudden and copious escape of pus, seems to favor this view of the case. There is reason to believe that serious obstructions of the bowels, undermining the health and jeopardling the lives of patients, often occur as the secondary consequences of severe attacks of dysentery. A memorable instance of this kind was the case of Richard Clark, which I presented to the academy on the 20th of November, 1879, exhibiting the successful result of lumbar colotomy performed on the 27th of March of the same year.

Another instance of very formidable obstruction of the rectum, in which very incomplete relief was afforded by the use of bougies, occurred in the person of an army surgeon in the war of the rebellion, who had suffered severely from camp dysentery, and who consulted me about his case several years after the commencement of the obstruction. If I had then been as familiar with the operation of colotomy as I am at the present time, I should have had no hesitation in recommending it.

An interesting case of obstruction of the bowels, occasioned by pelvic cellulitis, was published by Dr. Homans, of Boston, in the *Boston Medical and Surgical Journal* for October, 1878. The patient was a woman, thirty-two years of age, who had numerous chills after parturition, followed by fever and pain in the lower part of the abdomen, and, at a later period, by constipation, relieved at first by cathartic pills, but gradually increasing, and ending in complete obstruction. She was examined on the 20th of March, 1878, about two months after her confinement, and her uterus found to be fixed, the pelvic cellular tissue being distended and pressing upon the rectum. Left lumbar colotomy was performed on the 22d of March, and free evacuations took place through the artificial anus. About the 1st of June she began to pass fæces through the rectum, and on the 14th of July, when she left the hospital, nearly all her evacuations were through the natural channel. When she was last heard from, the artificial anus was reduced to a narrow fistula.

In the MEDICAL RECORD of January 10, 1880, is a notice of a case communicated to Dr. L. A. Sayre, in which obstruction of the bowels existed for more than two weeks, and was relieved by an incision into the colon in the right lumbar region, through which there was a copious discharge of liquid fæces with blood and pus. The cause of obstruction in this case was intussusception. About two weeks after the operation a portion of intestine eight inches in length was discharged through the rectum. The natural course of the fæces was gradually restored, the artificial anus was entirely closed, and the patient was restored to full health.

The dangerous character of obstruction of the bowels from various causes has long been familiar to the medical profession. But it appears to me that there has been too great a disposition to rely on the use of internal remedies, to the exclusion of surgical operations, in the treatment of these formidable maladies. In cases of intestinal obstruction which do not yield to internal remedies after a fair trial, I believe that true conservatism consists in the early performance of laparotomy or colotomy, the choice between these operations being determined by the nature and seat of the obstruction, as far as these conditions can be ascertained; and in cases of extreme danger, even when there is great obscurity as to the nature and seat of the obstruction, an effort should be made to effect relief by an operation, according to the old adage, "anceps remedium potiusquam nullum."

THE TREATMENT OF EMPYEMA BY VALVULAR DRAINAGE.

A PAPER READ BEFORE THE STATE MEDICAL SOCIETY AT ALBANY, FEB. 4, 1880.

BY A. M. PHELPS, M.D.,

CHATTANOOGA, S. T.

As we examine the authors, and read the different plans of treatment recommended in empyema—varying from the simple puncture with the trocar and canula to the radical operation of the Germans—one is as much amused as when gazing upon the body of the beautiful and changeable chameleon. Like the chameleon it seems to assume the color of the soil upon which it derives its nourishment. The Germans recommend one plan of treatment, the French and English another, and the Americans still another; but all seem to agree upon one point; and that is, that thorough drainage and ablution are the first principles, the "*sine qua non*" of all treatment.

I believe these are but *auxiliaries* in treatment.

But lying away down underneath all this, is a *first principle*—the corner-stone upon which all prognosis and treatment should be based. I allude to the *speedy obliteration of the pleural cavity by the greatest possible expansion of the lung.* This principle, and this alone, should be the one upon which all operative interference should be based.

The cure of an empyema is not effected by washing or evacuating the pus *per se*, but by the expansion of the lung and falling in of the chest-wall—one or both. The pleura adhering together brings about the object at which we aimed—viz., the obliteration of the pus-secreting cavity.

This process can never take place if pus is allowed to accumulate or decompose in the pleural cavity, and only very imperfectly *if air is permitted to freely pass in and out the drainage-tube during the act of respiration.* When the lung ceases to expand sufficiently to perfectly fill the pleural cavity, adhesions form between the pleural surfaces. What is the result of this? A large pus-secreting cavity; and unless kind nature bends in the chest-wall to obliterate this cavity that should have been filled by the lung, we find our patients dying from exhaustion, or going through life with a thoracic fistula. The lung, in this collapsed condition, is very prone to caseous pneumonia, and a large per cent. of cases die from this secondary malady, even after the empyema is entirely cured.

The question that should arise in every case of empyema is not, How shall I evacuate and wash this pleural cavity? but, How can I speedily obliterate it? The principles of treatment involved in the above are—

1st. Evacuation of the pleural cavity as speedily and judiciously as possible, thus preventing the permanent collapse of the lung.

2d. Thorough ablution and disinfection.

3d. Strapping the chest with strips of adhesive plaster over the affected side, following the direction of the intercostal muscles, thus keeping the chest quiet and allowing the pleural surfaces to unite.

4th. The introduction of a valved drainage-tube.

This keeps up pneumatic pressure upon the lung, by preventing air from entering the pleural cavity, and acting as a brace underneath the collapsed lung.

A large per cent. of these cavities are obliterated, and the patient cured by repeated aspiration in cases where it is admissible. It should be performed often enough to allow the pleural surfaces to come in contact and not be disturbed by pressure. If the pus is fetid, warm carbolized water, 1 part to 80, should be injected, and in quantities not so large as to make pressure sufficient to tear up adhesion, and all to be aspirated before the needle is withdrawn.

The aspirator and needle, which is my modification of Potain's, will be found to be the most convenient form of aspirator for washing and evacuating these abscesses, and for general use. It has a third tube with which to empty and fill the receiver, thus avoiding the necessity of removing the screw-cap; also the fluid tube extends to the bottom of the receiver. By this we can inject a cavity without inverting the receiver.

The needle has a movable point with a screw packing, which prevents air from entering the cavity, and also an obturator to dislodge any obstruction during aspiration. This instrument and the valve drainage-tube were made for me by J. Reynders & Co., New York, to whom I have presented the models.

A very valuable and interesting history of aspiration can be found in Gouley's able work upon Diseases of the Urinary Organs.

In cases not cured by repeated aspirations, the "radical operation" of the Germans, or free incision into the pleural cavity between the fifth and sixth rib in the axillary line, has become a favorite one with many of our most eminent surgeons.

While this operation possesses the merit of thoroughly evacuating and cleansing the pleural cavity, it accomplishes nothing toward the obliteration of the cavity by the expansion of the lung. Pneumatic pressure is taken off the lung by the air entering the pleural cavity. Plugging the drainage-tubes does not help matters, and it certainly prevents perfect drainage.

Then the operation punishes the patient more than is necessary to accomplish the end desired, and he almost always recovers with more or less deformity, owing to the non-expansion of the lung.

Fraentzell reports five recoveries in eleven cases. Moutard Martin reports five recoveries, seven deaths, and five fistulas in seventeen cases (Ziemssen).

Caseous pneumonia was found in a majority of the cases upon post-mortem. This was probably due to the collapsed condition of the lung. If valvular drainage had been instituted, pneumatic pressure kept up, and the lung capable of expansion, the per cent. of deaths might possibly have been diminished.

Chassaignac devised an operation which consisted in making two openings into the chest-wall, one in the sixth intercostal space, the other in the fourth interspace, two or three inches anterior to the first, and two ribs above. A perforated rubber drainage-tube was passed through the pleural cavity between the two, and tied together upon the outside of the chest. This is a favorite method with some of the English surgeons, and is highly recommended by Dr. Hingston, of Montreal, P. Q. He furnishes better statistics from it than the Germans from the "radical operation." This operation makes no application of the first principle, and owing to the fact that a large per cent. of cases are discharged with thoracic fistulas, owing often to the accumulation of pus in the posterior cul-de-sac below the drainage-tube, it seems as if some more perfect means should be devised. For his labors in operating and furnishing to the world statistics of operations which have been verified and proven true by operators in almost every country on the face of the earth, and which has almost completely revolutionized the treatment of purulent effusions, the profession owes its deepest debt of gratitude, not to Germany, France, or England, but

to the United States, in the person of Dr. Henry I. Bowditch, of Boston, Mass. He was the man who first introduced into practice capillary trocars attached to an exhaust syringe, and taught and proved that better results could be obtained in empyema from a simple puncture with a trocar and canula, and a soft rubber drainage-tube in the ninth interspace in the back, than from any other operation up to 1878.

The operation that appears to evacuate and cleanse the cavity most perfectly with the least punishment to the patient, was first performed by Drs. Baker and Southy, in Guy's Hospital, England, and reported in the January number of the London *Lancet* for 1878. They made two openings into the pleural cavity: one low down upon the diaphragm in front; the other between the ninth and tenth ribs in the back, as recommended by Bowditch. Rubber tubes were inserted into each opening, and the cavity thoroughly washed out by means of a rubber tube and funnel, the current of water passing from the front to the back opening. The patients recovered with but little deformity of the chest. This procedure drains and washes the pleural cavity thoroughly with as little inconvenience to the patient as possible, but the value of pneumatic pressure is completely lost sight of.

In the method which I propose, the greatest possible advantage is taken of this pneumatic pressure, by allowing no air whatever to enter from the outside during the whole time of treatment.

To accomplish this, I introduce into the posterior opening a tube which I made for the purpose, and

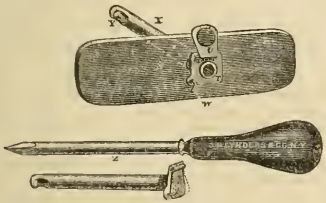

FIG. 1.—Drainage-tube, trocar, and rubber plate: S, rubber plate perforated by drainage-trocar, T; U, valve open; W, hook for valve; X, trocar; Y, opening in same. Below tube is shown with valve closed.

which is supplied by a valve opening outward. This tube is made of silver, of two sizes, according to the age of the patient, is fenestrated at its extremity, and is introduced by means of a trocar. Before penetrating the chest-wall the trocar is made to pass through a rubber plate (Fig. 2, D) which is applied to the outside of the chest, prevents air from entering around the tube, and, being held in place by adhesive straps (Fig. 2, G), keeps the tube in position. The valve is prevented from opening too far by a hook at the extremity of the tube (Fig. 1, W). A small india-rubber bag envelops the extremity of the tube and serves as a receptacle for the pus. This bag is easily cleansed by means of a stop-cock, M, in its lower extremity. If the discharge is very profuse, the pus may be drained through the rubber sac into a bottle carried in the inside lining of the vest. This tube should be introduced last and as pus escapes the same quantity of water should enter through the exterior tube. By this procedure the cavity will be more thoroughly washed, and no air will enter it. The point should be the ninth interspace in the back.

The anterior tube is introduced low enough to rest upon the diaphragm, and thus avoid the pressure upon it by the expanding lung. To do this, the pleural cavity should be explored with a hypodermic needle, to ascertain the attachment of the diaphragm to the chest-wall. The point selected should be upon a line drawn downward about one and a half inches external to the nipple upon the right side, in the sixth interspace if possible, taking care not to wound the liver and diaphragm, and two inches external to the nipple in the sixth interspace upon the left side, taking care not to wound the pericardium or diaphragm.

If, upon hypodermic exploration, pus is drawn off at the points designated, a large trocar and canula should be plunged into the pleural cavity in front, and while the pus is escaping a soft rubber tube (B), six inches in length, is passed through the canula, penetrating the pleural cavity one inch, when the canula is removed. The rubber tube should now be plugged, to arrest the further escape of pus. With a needle pass a thread through the rubber tube close to the chest-wall and make it fast to the chest by means of adhesive straps (C). This will prevent the tube from slipping in or out.

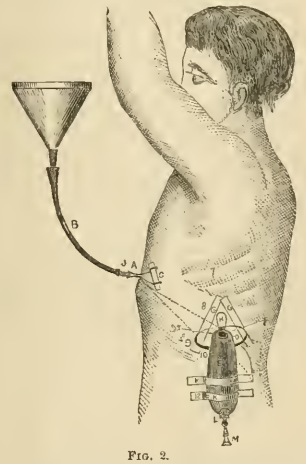

FIG. 2.

When both tubes are introduced, carbolized water may be introduced through the anterior one by means of a funnel, and the cavity can be thoroughly washed without the danger of any air entering, and with the advantage of draining from the lowermost parts of the suppurating sac.

This process should be kept up till the cavity is thoroughly cleansed, indicated by the water escaping unchanged. After the cavity is perfectly cleansed, the long rubber tube and funnel is removed, and the anterior tube A is plugged with a piece of wood. The valve H, of the drainage-tube, is now dropped to its place and made fast by the hook (See W, Fig. 1), and the rubber bag E (a rubber condom with a puckering string of rubber will answer the purpose) is placed over the end of the drainage-tube F, and the lower end made fast to the chest by strips of adhesive plaster, laid on as indicated in the cut.

This rubber bag can be removed, cleansed, and disinfected as often as the occasion may require. If the lung is incapable of rapid expansion, before dropping the valve H to its place and attaching the

rubber bag allow all the fluid to escape from the pleural cavity and air to enter it, as it will not give the patient so much distress as the weight of the fluid upon the diaphragm; then lay the patient in a position so that the drainage-tube will be at the highest point to facilitate the air rising to it, drop the valve H to its place, and direct the patient to make a few forced expiratory efforts, when the excess of air will rush out of the cavity, and the valve preventing its entrance upon inspiration, pneumatic pressure is increased by the calibre of the pleural cavity being diminished, and the lung, if it is capable of expansion, will do so rapidly. The rubber bag should now be attached as described above. The patient should lie upon his back during the washing. The adhesive straps K should be so adjusted as to prevent all pulling upon the drainage-tube. The washing should be repeated as often as the temperature rises from the accumulation of pus. The valve and tube and rubber plate should be kept carefully cleaned as often as it becomes unclean, and the valve kept in a good working condition. If the tube should be too long it can be removed, and with an ordinary file and pair of shears cut to the desired length. It should lie tight against the rubber plate to prevent articles of clothing from coming in contact with it, and penetrate the pleural cavity about half an inch, thus avoiding the irritating effect of a long drainage-tube, which is unnecessary. The piece cut from the tube should be put upon the trocar; this will keep the point of the trocar at its proper place, otherwise it would be too long for the tube. Flakes of fibrin obstructing the drainage-tube at any time should be moved aside with a stylet or a perforated catheter. If the anterior tube becomes obstructed by the lung expanding down upon it, a small catheter can be passed through the valved drainage-tube to the anterior chest-wall and the rubber tube and funnel attached to it. By this means a current of water is conducted to the front, and the cavity is perfectly cleansed by allowing it to escape through the valved drainage-tube. Baker and Southy recommended carbolized water: temp. 100°, 1 part to 80; also Condy's fluid, and—

℞.	Acid. salicylic	ʒ i.
	Alcohol	℥ iv.
	Aqua	℥ xxviii.
M.		

I used each of these, and have no preference. They each act by disinfecting or preventing fermentation. Strong injections should be condemned.

The cure is effected by the pleura coming in contact and uniting, this obliterating the pus-secreting cavity. Washing should be suspended when the discharge ceases to be fetid, and the pus healthy. When the lung is incapable of expansion—ceases to expand, or has fully expanded—the whole side of the chest should be surrounded with strips of adhesive plaster laid on in the direction of the intercostal muscles, crossing each other, and several layers in thickness. This will keep the side at rest, and favor union of the pleural surfaces.

Deformity of the thorax will depend upon the expansibility of the lung. If it is incapable of expansion, a large cavity which should be filled by lung will have to be obliterated by the falling in of the chest-wall. To facilitate this process portions of rib should be resected, when the health of the patient will admit of it; but if the lung is capable of perfect expansion, and the cavity is kept free from pus and disinfected, and the valved drainage-tube kept in good working order, patients ought to and will recover with no deformity, and I am almost inclined to believe that a large per cent of cases which have hitherto resulted in permanent thoracic fistulas will be discharged perfectly cured.

The following case illustrates this method of treatment:

Patrick H——, farmer, Irish by birth, aged 20 years; was first seen by me March 25, 1878. He had been suffering from pleuritis for ten days. On physical examination I found a large pleural effusion in the left pleural cavity. He had been unable to be down for the previous week. He complained of intense pain in the side, was somewhat delirious, tongue dry and furred, temperature 104°, respiration 30, pulse 130. There was considerable œdema of the left side, and also of the lower extremities. By the introduction of a hypodermic needle between the fifth and sixth rib in front, a small quantity of serum mingled with slightly fetid pus was evacuated. Prescribed diuretics, tonics, and blister. The twelfth day, or the third day of my attendance, I explored the effusion again lower down in the lateral region, and withdrew thickish, fetid pus. I think if I had made my first puncture at this point, I would have found pus, as it had evidently gravitated to this locality, and the serous portions floated upon it. There had been no remission of the symptoms. Temperature 104°, pulse 135, respiration 28 per minute. With the assistance of Dr. Mott, of our village, I introduced a trocar in the tenth interspace in the back, and three and a half quarts of thick, decomposed, fetid pus was discharged. The patient felt relieved, but owing to his feeble condition the operation was deferred until the next day, when I found the effusion was as large as the day before. I introduced a rubber tube for washing purposes in the sixth interspace in front, and reopened the posterior opening. There was a discharge of three quarts more of thick, fetid pus, making in all, at both operations, thirteen pounds, or six and a half quarts. I then introduced into the posterior opening a No. 12 catheter, for want of a better tube, three inches long, the inner end just penetrating the pleural cavity; then, by means of a rubber tube and funnel, I passed through the chest one gallon of warm carbolated water—temperature 100°, 1 part of acid to 80. The mass of decomposing fibrin was, of course, washed perfectly and disinfected. After the washing the temperature fell to 100°, but, as pus accumulated, the temperature would rise to 103° or 104°, when, after thorough washing, it would again fall to 100°. The washing was repeated from one to four times during the day and night; from one quart to one and a half gallons of water was used each time as the temperature was high or low, and pus profuse or scanty. On the fourth day after the operation, I removed the patient on a bed to our village, where I could oversee the management of him. The abscess was discharging about one pint a day at this time. The lung had partially expanded, and pressed upon the anterior tube the tenth day, so that I was obliged to remove it, as it did not rest on the diaphragm. This proved to be a serious embarrassment, as by simply injecting into the posterior tube I could not reduce the temperature after washing, and the pus became more fetid. As the condition of the patient at this point was very low and critical, I did not dare risk an operation to introduce the anterior tube again, but at each washing a No. 5 catheter was passed through the posterior tube forward to the front of the chest, and a current of water conducted through it to the

anterior cul-de-sac. This answered the same purpose as the anterior tube, and by this means the cavity was thoroughly washed from one to four times a day for five weeks. The cavity at this time only discharged about two ounces a day, but during the whole time before it discharged from two to eight ounces.

The patient now seemed to be improving, and washing was only repeated once a day for a few weeks, when it was stopped entirely. One serious difficulty in injecting through the posterior tube without having any escape from the cavity, was the tearing up of new adhesion between the pleural surfaces, thus exciting inflammation. This accident did not occur after injecting through the inner tube or small catheter was commenced, as the fluid was permitted to freely pass out through the drainage-tube, and no pressure was made within the cavity. I noticed that, at the beginning of the second week from the time of operating, the lung stopped expanding, and the pleural cavity would be filled with air, do the best I could to prevent it. Now, the cavity had to be filled either with pus, water, or air, and the air did not seem to distress the patient so much as the pus or fluid, where it was retained by plugging the drainage-tube; but it prevented the expansion of the lung. This led me to have made the valved tube which I introduced the second week after the operation. Through this the pus and fluids could drain, and, on expiration, air rushed out of the cavity and was prevented from entering on inspiration. The lung and chest-walls being thus pulled upon from pneumatic pressure, the lung began rapidly to expand, and at the end of four months perfectly filled the cavity with scarcely no perceptible deformities of the chest, and, October 1st, six months after operating, I removed the drainage-tube and discharged the patient perfectly cured. I think the tube might have been removed at the end of the third month. He is now at work in the silver mines of Colorado and is perfectly rugged. Dr. Wilber, of Constable, Dr. Wentworth, of Malone, and Dr. Chisholm, of Chateaugay, saw the patient with me, and examined him when he was under treatment. By actual measurement, the amount of water passed through the chest during three months was sixty-four gallons.

The patient was kept upon animal broth, milk, etc. Cod-liver oil, iron, wine, and quinine were given freely. This was, I think, a case of pleuritis acutissima of the Germans.

I am very sure, as the record of temperature will show, that unless thorough ablution had been performed, and the pleural cavity speedily obliterated by the lung expansion, the patient must have died of acute ichorization of the pleural sac.

I used a great amount of ablution because the patient could stand it, but I would not recommend this as a routine for all cases. But if the discharge is fœtid, I would use as much ablution and disinfecting as my patient could endure, remembering that it is the last straw that may break the camel's back.

New York Diet Kitchen Association.—The seventh annual report of this institution shows that it is doing an extensive and useful work. Its object is to supply food to the sick poor, doing for them in this regard what dispensaries do in the way of medicine. It thus forms a very important adjunct to the latter institutions, as testimonials from their medical officers show. The Association has three branches, and during the past year has supplied food to over 3,000 patients.

HIGH TEMPERATURE IN PUERPERAL FEVER.

By W. R. UPHAM, M.D.,

YONKERS, N. Y.

Case I.—In the latter part of last December I attended a young woman, aged 22, in her first confinement. She had always enjoyed good health, and had been remarkably free from any bad symptoms during the period previous to her delivery. The labor was rather tedious and painful, but she was safely delivered of a large-sized female child. She did well until the third day following her confinement, when, in the evening of that day, she experienced a severe chill, followed by a high fever, the thermometer, one hour after the chill, showing a rise of 105½°. This was entirely unexpected, as every precaution had been used, the patient having been kept very quiet; her diet had been simple and light, and nothing had occurred to excite or disconcert her. The next day I was informed by the nurse that the lochia, which had been quite free up to this time, was very scanty, and the odor offensive. The abdomen was moderately tympanitic, quite painful to the touch, particularly in the inguinal regions, and the passage of urine was attended with much pain and difficulty. During the following six days the patient's symptoms were of such a character as to give rise to great anxiety. She laid most of the time upon her back, with the knees flexed upon the abdomen, the straightening of the limbs being attended with much pain. The lochia became entirely arrested, the abdomen greatly distended and very tympanitic, obstinate constipation at first, but followed, in about forty-eight hours, by a slight diarrhœa; great difficulty in passing water, and the flow of milk was arrested. She also suffered most of the time with a severe pain in the frontal region, and the countenance assumed an anxious expression and became of a dusky hue. There was much loud delirium, especially when the fever was the highest. The temperature, taken in the axilla, would range from 101° to 103° in the morning, and from 104° to 106¾° in the evening, the thermometer registering the latter figures on the seventh day after confinement. Patient experienced a chill of greater or lesser intensity nearly every day, and these were invariably followed by a high fever. The pulse was most of the time weak and rapid, reaching 150 beats at the time of the highest temperature. On the tenth day the temperature fell considerably, the discharge from the uterus became more abundant, the tympanites somewhat subsided, the pain was not nearly so severe, and the patient soon made a rapid recovery.

The treatment employed was as follows: Poultices and turpentine stupes over entire abdomen; from twenty to twenty-five grains of the sulphate of quinine in the twenty-four hours; sulphate of morphia in ¼ to ½ grain doses, administered at sufficient intervals to keep the respirations at about ten per minute. Sponge-baths and uterine douches, to be repeated at intervals of three hours during the day and every four hours during the night. The baths and douches had unquestionably a marked influence upon the temperature, the latter always falling from one to three degrees after their use, and the patient invariably feeling more comfortable and easy, often asking if they could not be given more frequently.

Case II.—On the 16th of last month was sent for, late in the evening, to see a young woman, who had been delivered of a child the week previous. On

seeing the woman, I was informed that the lochia had been scanty from the very first, that she had had more or less fever most of the time, it being greater in the afternoon, and diminishing toward morning, was at times quite delirious, and again would be in a semi comatose state. The patient, I was told, had always enjoyed the best of health up to the time of confinement, she had had rather a tedious labor, and was partially under the influence of chloroform during the last three hours of the same.

On examination, I found the abdomen soft, no tenderness except over fundus of uterus, temperature, 101½°, pulse, 120. Mildly delirious and complaining of great pain in the head. Lochia very scanty and offensive, and great difficulty in passing the water. Had slept but very little for the past three days and nights. Ordered at once a foot bath of hot water and mustard, hot poultices to be applied to abdomen. Quinine, in five grain doses, to be repeated every four hours. I washed the uterus out thoroughly with a solution of carbolized water, of the strength of one to fifty, and gave her a wet pack. Ordered the intra-uterine injections to be repeated every two hours. In one hour after the intra-uterine injection had been given, the temperature had fallen to 102°.

17th.—Morning temperature, 103°; pulse, 124. Evening temperature, 105½°; pulse 136. Pain over fundus of uterus more severe; the poultices over bladder have relieved patient, and she passes her water without difficulty. Much more rational; takes her nourishment well, which is administered in moderate quantities and at frequent intervals.

18th.—Morning temperature, 102°; pulse, 110. Evening temperature, 103½°; pulse, 116. Has been comparatively comfortable most of the day. Pain in the head greatly relieved. Urinates freely and without pain; tenderness over uterus somewhat less; washings from womb tinged with blood and some clots, and shreds of membrane came away with each injection.

19th.—Morning temperature, 101½°; pulse, 104. 2 P.M., temperature, 107½°; pulse, 154. 6 P.M., temperature, 104½°; pulse, 130. 8 P.M., temperature, 105½°; pulse, 138. 10 P.M., 104½°; pulse, 134. Midnight, temperature, 104°; pulse 130. The temperature of 107½° was preceded by a chilly feeling, which lasted for three quarters of an hour. Wet packs were given every hour, and the intra-uterine injections at the same intervals. In the evening, being very restless and unable to sleep, one-sixth of a grain of morphine and ten grains of chloral hydrate were administered with good effect.

20th.—Morning temperature, 102°; pulse, 100. Evening temperature, 100½°; pulse, 90. Passed a very comfortable night, and feels greatly refreshed this morning. Pain much less over womb. Gave the intra-uterine injections at intervals of four hours only.

21st.—Morning temperature, 100½°; pulse, 92. Evening temperature, 98½°; pulse, 76. The bad symptoms have nearly entirely disappeared; the head is clear, and the appetite returning. From this time on the patient did remarkably well, regaining her strength rapidly, and making a most satisfactory convalescence.

The two cases are interesting in connection with the high temperatures, 106½° in the former, and 107½° in the latter, and the decided influence that the intra-uterine injections in conjunction with the wet packs, had in subduing the fever. In every instance, where the temperature was excessive, did the injections cause a marked diminution in the fever, generally within the hour—and the ease and comfort afforded the patients by their use is not to be estimated.

Progress of Medical Science.

HUMANIZED LYMPH VERSUS ANIMAL VACCINE.—A letter from Dr. Cameron, M.P., that appeared in the *Times* newspaper, urging the introduction of heifer vaccination into the system of public vaccination of England, has called forth a reply from Dr. Edward Ballard, of the Medical Department in the Local Government Board. In this reply two points are made, and statistics adduced to support them; the first is that the protection afforded by vaccination with humanized lymph is *not* failing, the second is that inoculations with humanized lymph present a smaller percentage of failures than is found where animal vaccine is used. The first vaccination act was passed in 1840, and vaccination was made compulsory in 1853. Examining the mortality statistics of England and Wales from 1838 to 1878, and averaging the small pox mortality for periods of five years, there is found a steady decrease from 571 deaths to every 1,000,000 of inhabitants during the first five years, to 97 per 1,000,000 during the last four years. During the period of five years ending 1874, the rate jumped to 445, but this was due to the very severe epidemic of 1871–72, which spread from the French army over all Europe. These figures, Dr. Ballard thinks, effectually disprove the assertion that the protection afforded by vaccination is weakened by prolonged cultivation of the cow-pox in the human system. Comparing the results of vaccination in Amsterdam, the Hague, Rotterdam, and Berlin, where animal vaccine is used, with those obtained by Dr. Cory, the chief vaccinator at the national vaccine establishment, vaccinating with humanized lymph at Surrey Chapel, he found: (*a*) complete success of all insertions in children vaccinated: at Amsterdam and the Hague, 34 per cent.; at Rotterdam, 54; and at Berlin, 21. (*b*) Complete failure of all insertions in children vaccinated: at Amsterdam and the Hague, 2.2 per cent.; at Rotterdam, not stated; at Berlin, 7.1. (*c*) Insertion success (calculated), that is to say, the number of vesicles produced per 1,000 insertions: at Amsterdam and the Hague, 700, or less; at Rotterdam, not stated; at Berlin, 678. The results obtained at Surrey Chapel in the vaccination of the last thousand children vaccinated with fresh lymph from the arm and leg, five scarifications, were as follows: (*a*) Complete success of all insertions, 97.8 per cent. of all the children vaccinated. (*b*) Complete failure of all insertions, 0.0. Insertion success, *i. e.*, number of vesicles produced per thousand insertions, 978. As the gentlemen were in each instance among the best and most experienced operators, in the one case with animal, and in the other case with humanized lymph, it is to be supposed that the results were the best producible in each instance. Dr. Ballard regards the danger of imparting syphilis in arm-to-arm vaccination as infinitesimal, since during his experience of several years as an inspector of public vaccination, he has never seen or heard of such a case; the only occurrence of the kind of which he has any knowledge being the case brought to the knowledge of the profession several years ago by Mr. Hutchinson.—*The Practitioner*, February, 1880.

A SUDDEN OUTBREAK OF SCARLATINA SUPPOSED TO BE CAUSED BY INFECTED MILK.—An epidemic of scarlet fever occurred last August in Fallowfield, a village three miles from Manchester, the origin of which was investigated by Dr. Hubert Airy, a medical in-

spector of the Local Government Board. The only common tie between the affected families was their milk supply, and, owing to the frequent vomiting, and the severe and continued diarrhœa present in most of the cases, the opinion prevailed among the medical men in attendance that in all probability the poison entered the system through the alimentary canal. On investigation it was found that one of the milkers lodged at a house in which his little grandchild was lying sick in the desquamative stage of scarlet fever. Keeping these conclusions regarding milk as much as possible in the background, inquiries were at first directed to other possible modes of fever dissemination, but no other thing was found that would explain the circumstances of the case. The produce of each cow was poured into the gathering-can, and from it, when full, into one of two delivery-cans; the first half of the milking being thus placed in one delivery-can, and the second half into the other. There was no order observed in milking, each milker going from one cow to the next, so that it was impossible to trace the probable destination of the milk handled by any one milker, which, if discovered, might explain the fact that the epidemic was confined to a limited number of the families supplied from this dairy. The supposition is that the old man's hands became contaminated from touching the child, or some article of clothing worn by the child on one or more mornings before leaving home, and that the milk handled by him was unequally distributed to the two delivery-cans. One case reported by Dr. Thorburn, of Manchester, points pretty clearly to the dairy as the infecting focus. On August 4th, a child, E. B., residing more than two miles from Fallowfield, was attacked with the scarlatinal rash and fever. There were smart premonitory symptoms on the evening of the 3d. She had returned with the rest of the family from an out-of-the-way country residence where scarlatina was untraceable, on August 1st. On the 2d, she, with four others of the children, was sent to the dairy, whence the family intended to get their regular supply, and while there, drank some milk. Being more fond of milk than the others, she probably had the largest quantity. This history, Dr. Thorburn remarks, taken in connection with the Fallowfield outbreak, "seems to establish an almost certainty that the child was infected by one drink of milk, that her brothers and sisters, who tasted more sparingly at the time, were unaffected, though one of them was very feverish for a few hours, and that the period of incubation can have been little over thirty-six hours."—*The Practitioner*, February, 1880.

On the Employment of Iron and Oxygen in Anæmia and Chlorosis.—Professors Hayem and Regnauld, who have been studying the mechanism of the action of iron preparations, were led, by the failure of iron to improve the appetite in many cases of anæmia and chlorosis, to try inhalations of oxygen as a substitute for it. Under their use they found that the appetite increased, that the digestion improved, and that the quantity of nourishment taken daily was augmented three or four fold. In spite, however, of the improved color and increased weight of the patients, the red blood-corpuscles remained unchanged, and the improvement was only temporary, the patients again returning to their previous condition as soon as the inhalations were discontinued. When, however, the inhalations were combined with the internal administration of iron, the general improvement was attended by a rapid change in the red blood-corpuscles, which soon became normal both in quantity and quality. It results from these experiments, that: 1st, the active preparations of iron have the property of making blood, of furnishing to the red blood-corpuscles in particular, a specially serviceable nutritive element; and, 2d, that the iron preparations alone may fail, especially in dyspeptics, and that it may be necessary to supplement them with inhalations of oxygen in order to cure the chlorosis and anæmia completely.—*Allg. Med. Cent. Zeit.*, No. 98, 1879.

On the Treatment of Phthisis with Inhalations of Benzoate of Sodium.—In September of last year, Dr. Kroczak reported fifteen cases of phthisis that were treated with inhalations of benzoate of soda in the Innsbruck hospital, with the most astonishing success. Three of the patients had been admitted to the hospital in a, so to speak, moribund condition, but they were discharged cured after only a few weeks' treatment. Such wonderful success naturally led to repeated trials of the remedy in other places, and the *Berliner klin. Wochen.*, for Dec. 8, 1879, contains papers giving the results of two observers. Dr. Guttmann, of Berlin, has employed the inhalations in thirty-one cases of phthisis, most of them far advanced and with large cavities. He has used a five per cent. solution, and made the patients inhale from 5 to 50 grammes of the salt daily, or from 100 to 1,000 grammes of the solution. The trials were continued from one to three weeks. The conclusion deduced from these cases was that the benzoate of soda has absolutely no curative and even no beneficial action on phthisis. The fever was not reduced, nor was it even influenced in its variations by the treatment. The emaciation and the night-sweats, when present, were likewise not benefited in the least. During the inhalations the patients coughed and expectorated freely, and were correspondingly relieved for a short time afterward, but in no case were the cough and expectoration permanently relieved. On the other hand, the inhalations frequently caused nausea and vomiting, and in one case, at the autopsy, a general, recent capillary hyperæmia of the gastric mucous membrane was found. In two cases the inhalations were followed by hæmoptysis. Nine of the thirty-one patients died, and at the autopsies nothing was found to indicate that a process of resolution had begun in any of the affected portions of the lungs.

Dr. Wenzel, of Berlin, gave the inhalations of benzoate of soda a thorough trial in ten cases of phthisis, five of which were in an advanced and five in an early stage of the disease. The results, like those of Dr. Guttmann, were entirely negative. The phthisical process was not influenced in the least by the treatment, either in the mild or the severe cases, and it could not even be said that the symptoms were temporarily relieved by it. Four of the five bad cases died while still under treatment, and the remaining patient was rapidly sinking. In one of the mild cases the lung began to break down and a cavity formed during the treatment. The benzoate of soda exerted no influence at all on the fever in any of the cases.

The Annual Report of the Eastern Dispensary for 1879 shows that 22,538 persons were treated in the past year, this being a slight decrease over that of the year before. For the past nineteen months the dispensary has adopted the system of charging a small fee for medicines. Only 1¼ per cent. of the applicants have refused to pay this fee, and the success of the measure seems to be assured.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, April 3, 1880.

THE HEALTH OFFICER OF THE PORT OF NEW YORK.

In a recent number of the RECORD we made a quotation from a venerable professor in a medical college in this city, who is in the habit of telling his students to shun political life. Indeed, we know that this same professor once severely rebuked a young medical man who went to his office to obtain his signature to a petition on a matter affecting the general health of the State. His remonstrance was very emphatic, and he warned the young practitioner that whatever else he might do, he had better keep out of politics.

Despite this advice, our opinion is that if the medical profession of this State continues to keep out of politics, as its representative men now do, politics will work sad havoc in the hygienic and sanitary affairs of the commonwealth. If they never meddle with politics, politics will certainly meddle with them. The recent nomination for health officer of this port suggests this line of remark. It was promptly confirmed. The only remonstrance, as far as we have been able to learn from the daily press, was that from a veteran member of the Senate, who doubted whether a man who lived so far from salt water should be made health officer of the port of New York. We respectfully ask where were the representatives from New York City when that vote was taken? Especially do we inquire where was the gentleman who represents the culture and wealth of this city, that he did not rise and make one inquiry about this important appointment? He is certainly well acquainted with representative men in our profession in New York, and he might well have inquired as to the professional career of Dr. Smith, the gentleman who has been placed in this position by the Governor and the Senate. The new Health Officer is a very respectable man, however, and a member in good standing of the regular profession; he has served his country as a member of Assembly from Allegheny County for two terms, and he is also an active member of the State Committee of one of the great political parties. But, after the most careful examination—an examination made the more difficult on account of our inability to get facts other than political in the history of this gentleman, we fail to find that he has ever rendered any considerable medical service to the profession or the State, except such as may have been given in private practice in his own county and a service more or less lengthy as a surgeon of volunteers during the rebellion.

The port of New York is the most important one in the country. Its quarantine arrangements involve the health of the whole union. The officer who superintends these arrangements, who directs the carrying out of the details of their management, should be the best man, trained by years of experience and study in the special department of sanitary science, that can be found in the State. The interests involved are vast. They affect the health of the whole community. Yet in the face of these facts, which are indisputable, and in face of the fact that we have been undoubtedly preserved from epidemics by the wise supervision of one of the most distinguished of our medical men whose term as health officer has just expired, the Governor of the Empire State has had the temerity to fill his place by an appointment which has surprised the entire medical profession. This action can but be regarded in a single aspect—namely, that it is an appointment solely for political purposes. One of our former governors once informed a prominent medical man of this city that he had a list from which to nominate a health officer for this port, containing a large number of names recommended by the medical profession. He avowed his intention, with the aid of that eminent medical adviser, to reduce the list to two who should be the best representatives of their class, and from those two he proposed to select the one who had the most political influence. Certainly, there could be no fault found with such discrimination. There is no valid objection to the appointment of a man who has political power, if besides that he has the complete confidence and respect of the medical profession because of his professional ability.

Another governor also informed one of the editorial staff of this journal, that, when he named a man for the position of health officer, he proposed to nominate one who had won a high place in medicine, and while the gentleman whom he did nominate was a personal political adherent, no criticism could be made against his professional fitness for the office.

We feel sure that Governor Cornell has not followed this example of either the one or the other of his predecessors. The facts are all against him. A medical practitioner has been appointed who is unknown to his brethren at large in this city and

throughout the State, but who has the credit among politicians of having done a great deal of hard work in county and State committees for the party to which he belongs.

We sincerely trust that he will now spend all his best energies in the work so ably inaugurated and carried out by Dr. Vanderpoel. We hope that he will gather about him, as assistants, men who are well versed in all the laws of epidemics, the construction of hospitals, the fumigation of vessels, the periods of quarantine, and other subjects which are of much more importance to national health than the management of a political convention. What we have said should in no way be considered as expressive of hostility to the gentleman named by the Governor, for we feel none. We regret very much that the executive head of this great State has seen fit to make an appointment which does not have as its chief merit the fact that the appointee has distinguished himself in his own profession. Dr. Smith now has a position where a large and exact knowledge of sanitary affairs will not only be useful, but absolutely indispensable. Without it, however much executive ability he may have acquired in the political world, he will be an inefficient and dangerous health officer.

The Governor has sinned against light in this step. His acquaintance among the profession of this city is large. We happen to know that he has had ample opportunities to learn their views concerning the necessary qualifications for a health officer. He had sufficient knowledge to have chosen one of the very best of our representatives, and, at the same time, to have selected a disciple of his own political faith; or, if embarrassed by the richness of choice, he might have allowed the recent incumbent, who is said to be identified with the dominant political party, to remain in office. But he has chosen to disregard the opinion of the profession, and to use his high office as if it were his personal property, and as if his appointments were to be such as would carry out his political and personal wishes. The Czar of Russia could not have been more autocratic.

If the medical profession continues to submit to this kind of encroachment upon its vested rights as the sanitary advisers of the commonwealth, then they had much better settle down to being humble prescribers for the accidents and ailments of the families which they attend, and never again lift their voices to direct the sanitary affairs of the State. An executive, however chosen, is the executive of the whole State and its interests must be paramount in the consideration of any appointment. Even our friends of the daily press are almost unanimous in the assertion that this responsible medical position has been given on a political consideration.

From one other medical appointment which has been made by our Governor we ought, perhaps, to be thankful that we have in this position a member of the regular profession, and that is all the occasion for congratulation or thankfulness that we have as yet been able to get from his present action.

We now return to the point where we began. If the American medical profession does not see to it that there are representative physicians in its legislative councils, where so many matters pertaining to the sanitary affairs of the State are constantly being brought up, these important affairs will soon be in the hands of mere politicians. Meddling with the details of politics certainly can never be safely indulged in by a man engaged in active professional work; but on the large questions, however political they may be, we should have such representatives as Andrew Clark, Lyon Playfair, Dominick Corrigan, James Paget, have been, or will be, in the English House of Commons. The great city of New York at this moment should be represented by a physician who, when a medical nomination is made "by and with the advice and consent of the senate," would state with authority whether that nomination will subserve the best interests of the State. No severer blow can be struck at the aspirations in our State for the hygienic advancement of the people, than the appointment to the most responsible sanitary position, perhaps, in the country, of a gentleman who lacks many of the qualifications necessary to the proper discharge of the duties of this exalted position. In behalf of the profession which we represent; in behalf of the public, of whose health that profession are the guardians; in behalf of the gigantic interests of the great commerce of this city,—we ask our governor if he can conscientiously say that he has considered the proper requirements in the appointment which he has just made?

THE USE OF THE BROMIDE OF ETHYL.

The paper on the use of bromide of ethyl, by Dr. Levis, in our previous issue, and the communication by Dr. Sims on the same subject, in this number, present different sides of a question of great importance to the profession. It seems almost a pity that after so much of good was said for this anæsthetic by a gentleman of such experience and discrimination as Dr. Levis, that so soon afterward Dr. Sims should be ready with the report of a case of death following its use. Still, such an account comes in good time, and the profession will feel under obligation for the promptness with which it is made public.

The remarkable and somewhat extensive experience of Dr. Levis seemed to prove that in bromide of ethyl we had an agent which could take the place between chloroform and ether, and combine the benefits of the two without incurring danger to the

patient. The facts as related by Dr. Levis were strikingly in favor of such a belief, and every surgeon who read his article must have felt a willing need to give the drug a trial. The rapidity of its action, the small quantity used, the readiness with which the patient recovered from its effects, the comparative freedom from vomiting, and the non-inflammable character of its vapor were points which were calculated to impress every man with the practical value of the anæsthetic. But, above all, it was considered safe. That there should be a reasonable presumption to the contrary of such opinion there can be no doubt, after a careful study of the case in the present Record. With many the proof as to the cause of death being the anæsthetic will be absolute, while, with the great majority of surgeons, there will be enough of doubt as to its safety to deter them from using it at least in protracted operations. It does not appear that the particular manner of administering the ethyl in Dr. Sims's case had anything to do with the result. On the contrary, every precaution against accident seems to have been taken. The best proof of this is that the patient did not suffer from any of the symptoms which could be referred to carelessness on the part of the administrator. The really urgent symptoms occurred after the period when any accident could have been expected from such a cause. Concerning the purity of the article, there could hardly be a question. It was precisely the same manufacture of ethyl which had been used in Philadelphia by Dr. Levis with the best of effects. But here we come to a point where the parallelism of the unfortunate case with the two hundred successful ones in Philadelphia ceases. In none of Levis's cases did the period of ethylization exceed forty minutes. In Sims's case the period was prolonged for a full hour and a half. In the absence of equally marked differences, it would seem that the element of time consumed in the administration and the consequent increased quantity used have a very important bearing in summing up the result. What might be innocuous when used for forty minutes, might be fatal when that period of time was extended to an hour and a half.

Before undertaking to analyze the symptoms in the given case before us, we may be permitted to assume that to the bromide of ethyl was at least indirectly due the cause of death. That is to say, it is easy to believe that the patient would not have died at that particular time, and in that particular manner, if the anæsthetic had not been used. When we attempt to make out any direct relations between supposed causes and effects, we are engaged in an entirely new study, and are compelled to start *de novo*. It is true the same result might have obtained if ether had been administered to the same patient.

If the only symptoms from which the patient suffered were those of uræmic poisoning, such a possibility of fatal result might be entertained. It is well known that etherization invites fatal coma in cases of Bright's kidney. Dr. Sims refers to two such in his paper. Although there were undoubtedly symptoms of uræmia present, they were by no means so prominent as those which referred to another kind of poisoning. And here by a method of exclusion, we get down to the symptoms in this case which are peculiar, and to the indications which they furnish, which, to say the least, are instructive and significant. Aside from all other symptoms, we notice those of an active irritant poison. The phenomena which were presented were quite distinctive, and in the absence of any proof to the contrary, would appear to belong to the continued action of the particular anæsthetic employed. At least, the symptoms were not only those of an irritant poison, but pointed directly toward those of bromism proper. There was the persistent suffusion of the eyes, the strange restlessness of the patient, and the vomiting—but, above all, the obstinate cholerine. The odor of the hydrobromic ether in the discharges and in the breath of the patient, its permeation into the texture of the internal organs, and its persistence so long after the anæsthesia, are facts which should have their due weight in evidence of direct poisoning. Uræmia may have had considerable to do with the death of the patient; but with such a condition of kidney, independent of the ethylization, it is difficult to explain all the symptoms. It is quite possible that the two conditions may have combined in producing the unfortunate result; that ethylization, by introducing an extra poison in the circulation, may have turned the balance against the patient. Even in such an event it is impossible to escape the conviction that ethyl was an active and determining factor in the result, and that, all things being considered, it is by no means an absolutely safe remedy. It has proved useful in short operations, and may, with certain precautions, continue to be so employed, but we cannot believe that any surgeon, in the light of the evidence furnished by Dr. Sims's case, will take the responsibility of using this ether for prolonged periods. The whole question is now so entirely *sub judice* that it would appear to be wiser to attempt to answer it by further experiments upon the lower animals, rather than upon man.

REFORM IN MEDICAL CHARITIES AT PHILADELPHIA.

THE Committee appointed by the Philadelphia County Medical Society to examine the subject of the abuse of medical charities made its report on the 10th ult. The document represents an investigation covering two years, and contains a good deal that is of value in the way of statistics and suggestions for reform.

The Committee began its work by ascertaining whether the general impressions and beliefs as to

the abuses of medical charities were really well founded. Investigation showed that they were. Thus it appeared that in 1877 one hundred and twenty thousand persons had been prescribed for at the different dispensaries, and a very great number of instances were discovered of persons with abundant means who availed themselves of free dispensaries. Fifty-nine cases of this kind are reported specifically, and in the list we notice many persons owning property assessed at $5,000 or $8,000.

The Committee, having satisfied themselves that the evils were present and flagrant, then addressed inquiries to the various dispensary and hospital officers. It was desired to learn the views of these persons upon the matters in question, and to obtain from them such suggestions as might help in securing a better state of affairs. The universal opinion given in answer to the inquiries was that there were great abuses, and that there was great need of careful investigation into the position of applicants for medical relief. At the same time, it did not seem practicable for the medical charities to undertake these investigations. This was found to be the universal feeling, and is quite a matter of course. Medical men have not time to bestow charity and investigate the case also. And institutions for medical relief have not money enough to support a corps of officers for such investigations.

When arrived at this stage of the matter, the committee received an offer of help from the Society for Organizing Charity. It was suggested that a plan of coöperation between the Ward Associations of this society and the various dispensaries might be devised. A plan for such coöperation was drawn up, and was subsequently approved by the Philadelphia County Medical Society. It recommends the assignment of a certain territorial district to each general dispensary, so that overlapping may be prevented and all parts of the city may be supplied with opportunities for medical relief. It also recommends the small-fee system, and would oblige all who cannot pay this fee to get a certificate from the Society for Organizing Charity before medical relief be given. Another recommendation is that applicants with families in receipt of nine dollars a week or more, unmarried persons receiving six dollars or more, and persons living out at service, shall be refused treatment, as being able to pay a physician.

It appears from a review of the committee's report that although the abuses of medical charity are not so great proportionately in Philadelphia as in New York, yet the system of medical relief there is not so well organized as it is with us. Some reform has been greatly needed, therefore, and the present Committee has done much to set it on foot. They emphasize the fact that investigation of the condition of those applying for medical relief is of the first importance. The correctness of this position will be admitted, and the fact that there is a society which is willing to undertake this work of investigation will make the correction of the present evils much easier.

MEDICAL SECRET SOCIETIES.

We have already referred to the very extraordinary action of the Philadelphia County Medical Society in forbidding all reports of its proceedings to be published first-hand in any but its chosen organ. *The Clinical News* has also complained of this resolution of the society, and it has printed two letters from one of the members, in reply to the strictures that have been made. The only defence which can be made appears to be that the proceedings of the society, as reported in journals heretofore, have been garbled and incomplete. In self-defence, therefore, the society was obliged to have the proceedings printed under its own supervision. This is all very well so far as it goes; but it forbids all reports except the supervised one, and it has chosen for its medium of publication a bi-weekly journal of comparatively small circulation. Other journals are kindly allowed to copy from this; but this is a slight concession, as it is not the practice of the better class of journals to publish society proceedings second-hand. It seems to prefer no circulation at all, therefore, to the possibility of an incomplete report. Furthermore, while the issuing an authorized report of proceedings is a sufficiently proper measure, it is not wise to forbid other medical journals from obtaining first-hand reports at the same time if they chose. By the course which the society has adopted it practically locks up its proceedings, narrows its influence to the smallest possible medical circle, and stultifies its members in the estimation of the profession at large.

RIOTOUS MEDICAL STUDENTS.

It has been customary at the medical commencements of the University of Pennsylvania for the academical students to fill the upper galleries and sing "Saw my leg off" during the progress of the exercises. The rendition of this surgical melody, accompanied with the rhythmical fall of the boot-heel, though a venerable custom, has never been officially recognized as a part of the regular programme, and has, indeed, at times been strongly protested against.

At the last annual commencement the chorus was so loud and the boot-heels were so demonstrative that the medical students could stand it no longer. They threw off their caps and gowns and rushed upstairs, intending to expel their disturbers. At this point the police came in and took a large number of both parties in custody. In subsequent reports in the daily papers the medical students (of course) got all the blame, and a New York daily gravely deplored

the bad manners of the prospective members of the noblest of professions. From the facts that have been given, however, it looks as though the medical students had no other course to pursue. They could not sit still and submit to a continual insult.

The medical student gets enough blame at all times, and has, indeed, a character very much worse than he deserves. We have about fifteen hundred of them in this city during half the year, all, of course, young men, and with the usual exuberance of spirits; yet for a number of years there have been but three cases of arrest here among them, and these cases were promptly discharged the next morning with a rebuke to the policeman for his action in the matter. This speaks very well for the character of our students, and is certainly more than can be said of those of London and Paris. Most medical students who go through a full course in city colleges have possibly a bibulous stage; but, as a rule, they have not time for much dissipation. They find that they have to work hard in order to cover the ground before them and get through the examinations. Consequently, sobriety is the rule, and the career of the American medical student is, on the whole, a steady and creditable one. He should have his due for this.

Reports of Societies.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 18, 1880.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

THE Academy was called to order at 8.15 P.M. The minutes of the last stated meeting were read by the Secretary, DR. EDWIN F. WARD.

The Statistical Secretary, DR. F. V. WHITE, announced the death of Dr. Benjamin I. Raphael.

DR. LAURENCE JOHNSON, Librarian, then read a

MEMOIR OF EDWIN R. PURPLE,

late Assistant Librarian, in which was paid a fitting tribute to one who generously donated both time and money in the upbuilding of the Academy's library.

The President introduced to the Academy, and invited to take seats upon the platform, Drs. Levis and Roberts, of Philadelphia, and Dr. Nichols, Superintendent of the Bloomingdale Insane Asylum.

The second paper for the evening was by Dr. A. C. POST, which appears in this number of the RECORD (See p. 365).

A CASE OF ENTIRE OBSTRUCTION OF THE BOWELS FOR THREE WEEKS—TEMPORARY RELIEF AFFORDED BY COLOTOMY.

The paper read by Dr. A. C. Post on the above subject being before the Academy for discussion,

DR. JAS. L. LITTLE referred to a case as follows: About four years ago he saw a patient in Vermont who had had complete intestinal obstruction for about sixty days. The patient had had difficulty in having passages from the bowels for some eight or ten years previously, and finally complete obstruction occurred. For two weeks the patient had vomited more or less, had hiccup, the abdominal walls were distended, and the only relief which Dr. Little could suggest was in the operation of colotomy. No definite cause for the obstruction could be found by digital examination. He had a great variety of internal treatment, but entirely without benefit. Colotomy was performed, and an enormous quantity of fæcal matter, at least three quarts of semi-solid clay-colored material, came through the wound during the first twenty-four hours after the operation. The patient recovered, was still living, and yet had the artificial anus. One peculiarity of the case was the difficulty in keeping the wound open. About two months after the operation the parts were united completely, and Dr. Porter, the attending physician, was obliged to make an incision, empty the colon, and afterward to maintain the tegumentary opening by means of tents. The opening, however, closed the second time, and the patient went without any discharge of fæces for six weeks. The knife was again used, but the wound again closed entirely; and that was repeated in all four times, when it remained open permanently. No fæces had passed through the rectum. Before the operation a flexible tube could be easily pushed up into the bowel for the distance of two and a half feet, and through it injections were given, but without avail, although occasionally, when the tube was withdrawn, its extremity was smeared with fæcal matter. The only point at which there was anything that felt like a tumor was just within reach of the finger. The only diagnosis made was probable stricture high up in the colon.

DR. GARRIGUES referred to a case of intestinal obstruction occurring in a nun *æt.* 20 years. No passage from the bowels occurred between August 4th and August 18th. She had vomited everything that had been put into the stomach, but no fæcal matter. A variety of remedies were used without benefit. A tube was introduced as high as the junction of the descending with the transverse portion of the colon, and injections given several times. The last one given contained a teaspoonful of green soap, and all at once the patient felt as though something had given way, and was at once relieved. Two days afterward a large pultaceous evacuation from the bowels occurred. He had at one time contemplated laparotomy for the relief of volvulus, and the sudden getting well suggested that it may have existed. He asked whether any of the members had used quicksilver in cases of intestinal obstruction—a remedy which at one time was recommended and used in doses of a pound or two.

DR. POST remarked that he had a brother who had a scirrhus contraction of the rectum, and in his case quicksilver was used, and it passed through, but brought nothing with it. He lived twenty-nine days without a fæcal evacuation. At that time the present modes of relief were not usually practised, and he was allowed to die with complete obstruction of the bowels.

THE PRESIDENT alluded to cases of lead colic, in which quicksilver had been used in half-pound doses. In one case the quicksilver passed through without the passage of any fæcal matter, was collected by the patient, placed in a bottle, and carried about as a trophy.

DR. J. MARION SIMS then read a paper on

HYDROBROMIC ETHER—BROMIDE OF ETHYL—AS AN ANÆSTHETIC.

[See MEDICAL RECORD, p. 361.]

The paper being before the Academy, the discussion, on invitation by the President, was opened by DR. LEVIS, of Philadelphia, who made some general remarks which were contained in a paper upon the subject to be published in the MEDICAL RECORD. [See MEDICAL RECORD, p. 342.] The only explanation he could give with reference to the difference in results obtained by Dr. Sims and himself was, that there might be a difference in the method in which it was used. He thought that some of the errors were such as he made in his first cases in which he administered it, when he began very cautiously. He now knew that the proper method of administration was to make a rapid impression, such as was done in giving nitrous oxide gas. He had been able, nearly always, to produce complete anæsthesia, by the use of two drachms, in two or three minutes. He had produced anæsthesia in forty-five seconds; but if the patient could be made to inspire and expire freely, the average time was about three minutes. The only point in Dr. Sims's case which impressed him especially was the duration of the operation, and the large quantity of the anæsthetic used. In his own cases the operation had not lasted longer than forty minutes, and the entire quantity of the ethyl used was eleven drachms. He had not seen any after-effects whatever. As to nausea and vomiting, it perhaps was almost as likely to occur after the use of the ethyl as after the use of ether, if a considerable quantity was given. The quality of the article he regarded as very important, and he was sure that, since he had used Wyeth's preparation, there had been less tendency to nausea. With reference to the persistent odor in the breath, vomited matters, etc., he had noticed it when he had used the same preparation that Dr. Sims used.

THE PRESIDENT.—It will be noticed that the symptoms and phenomena manifested differ entirely from the symptoms and phenomena manifested after the administration of any other anæsthetic which has been used. I therefore take the privilege of calling upon Dr. Squibb, of Brooklyn, with the view of receiving an explanation of its failure to be eliminated from the system; that is, whether there are any constituents, either bad or good, in the ethyl, which of itself might destroy life.

DR. E. R. SQUIBB.—I fear, Mr. President, I have but little to add to the elucidation of this subject, and I must premise my remarks by saying that all I have to say upon the question is entirely theoretical. I confess to having had a prejudice against this agent from the earliest I knew anything of it, and it is upon theoretical principles, and upon those only, that I am capable of speaking or throwing out hints which possibly may be useful. As a chemical rule, I think that the anæsthetics which are the least dangerous are those which are the most simple, and when decomposed yield elements which, physiologically, are known to be most innocuous. If we commence with the nitrous oxide, we find that it is decomposable only into innocuous elements. If we go one step further and take the oxide of ethyl (and here I wish to protest against the bromide of ethyl being called an ethyl), it can be decomposed into comparatively innocuous elements. In the bromide of ethyl the oxygen of the ordinary ether is replaced by bromine, and the compound contains 73 per cent. of bromine, the other 27 per cent. being the ethyl. Now, when we compare the effects of all the known anæsthetics, we will find that those are more easily borne which are simplest in their nature; that is to say, the compound ethers are less safe than simple ethers, and both the compound and the simple ethers seem to be proportionately safe to the simplicity and innocuousness of the elements of which they are composed.

We all know that bromine is an irritant poison. We all know that bromide of ethyl is a loosely molecular article, is decomposed very easily, much more so than bromides of ordinary bases which act as salts and are eliminated as such. Now we will suppose that the bromide of ethyl, under certain circumstances, is decomposed, and its irritant property, the 73 per cent. of bromine, goes into the system; it is easy to understand that grave effects might be produced, and perhaps we shall be able in this way to account for the exceptional cases in which the anæsthetic has been used with unpleasant results, whereas, if it had remained as bromide of ethyl, it may not have been harmful.

Let us take an analogy found in chloroform, which contains 89 per cent. of chlorine. Chlorine is one of the organic bodies which does not possess the irritant properties that bromine does, and two atoms of chlorine are not so active in producing toxic effects as one atom of bromine found in the bromide of ethyl. The point can be illustrated still further by supposing the existence of an arsenite of ethyl, the activity of which in producing dangerous effects as compared with the bromide of ethyl would be represented by the difference between the activity of bromine and the activity of arsenic as irritant poisons. If it is admitted that such theoretical argument has any value, I think we could understand some of the dangerous effects produced when compound ethers are used as anæsthetics; and I think Richardson's observations point us toward the conclusion that compound ethers are less safe than simple ethers, and that simple ethers are less safe still than the oxides. This brings us down to the oxides and nitrogenous oxides of ethyl, which are the safest of all known anæsthetics.

There is another point; and that is, any agent that can be powerful and active for good, can be powerful and active for evil. We see that in chloroform, and we see it in the bromide of ethyl. I think we can logically argue something from the chemical composition of agents as to which will be useful to us, and especially in the application of agents which carry us so near the dividing-line between life and death.

DR. J. C. DALTON.—I should be very happy, Mr. President, to give to the Academy, in response to your invitation, any information, did I have it, with regard to this subject. But unfortunately I am worse off than Dr. Squibb, for I had never even seen any hydrobromic ether before this evening. There were some points in Dr. Sims's paper, however, which struck me forcibly, and one is the different kinds of danger which may be developed by different kinds of anæsthetics. I suppose that the profession are tolerably well convinced now that ether, when it is dangerous as an anæsthetic, is mainly so in consequence of the presence of some morbid change in some vital organ; that when the entire body is perfectly healthy, ether comes as near to being a perfectly safe anæsthetic as we can have. I do not know of any modification with regard to that statement.

In this case, reported by Dr. Sims, if the death

was due to the hydrobromic ether, it was a death which took place long after the substance was administered. It was a death apparently due to the persistent obstinate possession which the bromide of ethyl had taken of the entire system. The system could not get rid of the substance with which it was saturated, and which in some unexplained way produced those symptoms which have been so faithfully detailed. I do not wish to proffer any opinion regarding the cause of death in the case, but it seems that there was a repetition of peculiar symptoms in the midst of which the patient finally died, and that after death the entire system did retain, during a long period, the bromide of ethyl in sufficient quantity to indicate its active properties. How entirely different deaths from chloroform take place. They occur without any convulsions, without any marked symptoms, and odoriferous bodies of persons who have died under its influence have not been specially observed. I do not suppose, however, we have yet exhausted all the methods by which various anæsthetics are dangerous or may prove fatal. But the difference between the manner in which death is produced by chloroform and by ether when given to animals has, in my experience, been very striking; so much so that I long ago abandoned the habitual use of chloroform while experimenting, because it was so annoying to lose an animal just before the experiment was required and could not be postponed. Not long since, in order to avoid the disturbance produced by ether, I chloroformed a cat for the purpose of making an ophthalmoscopic examination. With all the recollection of frequent previous disappointment fresh in mind, I was extraordinarily careful in giving the anæsthetic, both with reference to quantity and time occupied in its administration and all the circumstances that could effect the result, and yet, just as I wished to use the instrument, the animal was dead. Here, however, we seem to have another mode of death, and one which, if real, is perhaps as difficult to avoid as sudden death in the use of chloroform. I am unable to see how any greater care could have been used than was exercised by Dr. Sims, although it is possible that Dr. Levis, who has a much greater experience in the use of the agent, might point out some improvement in the method adopted.

Dr. A. C. Post remarked, with reference to the prolonged action of anæsthetic agents, that he had been in the habit, for several years, in cases in which he anticipated a long operation, to use Prof. Nussbaum's method, premising the use of the anæsthetic by the hypodermic injection of seven or eight minims of Magendie's solution of morphia. He had found by so doing that the anæsthetic effect could be kept up for a long time with more quietude and less quantity of the anæsthetic than where the morphia had not been thus administered, and he was inclined to think it added to the safety of the patient as well as to the comfort of the surgeon.

Dr. Jas. L. Little referred to two cases, as follows: Case I.—Last Tuesday, having received a specimen of the bromide of ethyl from Wyeth of Philadelphia, he determined to test its anæsthetic properties, and accordingly gave it to a boy three or four years old, upon whom he proposed to perform Heaton's operation for the radical cure of hernia. The ethyl was administered in the manner proposed by Dr. Levis; probably less than *two* drachms were used, and the patient went under its influence in less than two minutes. The pupils were contracted. Within five minutes after the cloth was removed from his face the child was able to respond intelligently. There was no vomiting.

Case II.—An adult, in good general condition, had two or three drachms held close over his mouth and nose on a napkin, and at the end of three minutes no special effect had been produced by the anæsthetic except to excite powerful struggling on the part of the patient. The ethyl was applied more freely, the patient struggled very violently, the face was suffused, not however like that seen in other inhalation: the pupils dilated and contracted alternately, the eyeballs rolled about; and at the end of *eight* minutes Dr. Little became somewhat alarmed at the condition of the man and discontinued the ethyl. The patient sneezed, within three or four minutes, to come from under what influence of the anæsthetic he had received. The quantity used was *two ounces* and *two drachms* by weight, and the time occupied *eight* minutes. There was neither nausea nor vomiting. Both the pulse and the respiration became exceedingly rapid. The condition was entirely different from anything he had ever seen in connection with the inhalation of either chloroform or ether. Ether was subsequently administered, and the operation performed.

The President.—It will be noticed that Dr. Sims reported in his case that the respiration became exceedingly rapid. In the administration of this anæsthetic it seems, from what has been said, that it is necessary to produce its anæsthetic effect as rapidly as possible; that no atmospheric air is admitted, or just as little as possible. Of course, associated with this is another influence. We know that the exhalation of carbonic acid gas is limited, and, therefore, the question naturally arises: May not that fact be one which contributes to the danger, may not a part of the poisoning be due to the carbonic acid gas? I will next call upon Dr. Wylie, who has had experience with Dr. Sims in the administration of this agent.

Dr. Wylie remarked that he had nothing to add to the details of the case which Dr. Sims had reported, except that he endeavored to follow Dr. Levis's directions regarding the mode of administration, in the most exact manner. In three cases in which he had administered it he had seen the muscles in general convulsed. He was satisfied that hydrobromic ether could not be used as an anæsthetic with the same freedom as could ether. He had not had any difficulty in administering either chloroform or ether, having used both many hundreds of times, yet it was just possible that he failed to give a sufficiently large quantity of the ethyl just at the beginning. He could see no other explanation for his failures in attempting to produce safe anæsthesia with the new agent.

Dr. Sequin made special reference to two points: 1. In the many substances employed, the anæsthesia is separate from other effects produced by the agent. Therefore, it is necessary to be cautious in regarding the disappearance of the anæsthesia as the disappearance of the entire effects of the agent; that is to say, the disappearance of the anæsthesia suddenly after the administration of the agent has ceased does not indicate that the effect produced by the anæsthetic has passed away. 2. Many of the symptoms in Dr. Sims's case looked very much like those belonging to bromine poisoning. If it was a case of poisoning by bromine, that fact was to be separated from the known character of the agent as an anæsthetic. A better illustration of the effects of an irritant poison, he thought, could hardly be found, not

only upon the alimentary canal, but also upon the kidneys. The idea that the organic condition of the kidneys, discovered only by the microscope—and that after they had once been thought to have been healthy—was a condition that had anything to do with producing the death of the patient, did not look probable in view of the presence of other well-marked irritant symptoms. He would say, therefore, that he should abstract the anæsthetic element altogether from the case, and study it as a simple case of irritant poisoning. The color of the eyes, and their peculiar movements, and the intense pain in the head, together with the other symptoms, pointed directly to the irritant effect of some such agent.

Dr. Roberts, of Philadelphia, on invitation, remarked that he had administered the bromide of ethyl many times as an anæsthetic, both for Dr. Levis and in his own practice, yet he had nothing special to add to what had already been said. He had had no experience whatever in the use of chloroform, and therefore was unable to compare the bromide of ethyl with that agent. His own experience with ether had been that it was a safe anæsthetic, sometimes, however, requiring large quantities to produce the desired effect. The most troublesome symptom he had observed with ether was the expectoration of large quantities of mucus and the existence of coarse bronchial râles, due to hypersecretion into the bronchial tubes. He always felt specially disturbed with reference to the respiration of a patient inhaling ether. One of the chief benefits arising from substituting the bromide of ethyl for ether was, that the ethyl affected the respiration but little, except to a certain extent, to increase its frequency. In no case had he seen hypersecretion of mucus, such as was so annoying in etherization, when bromide of ethyl was used As a rule, the pupils had been dilated during the period of the most profound anæsthesia. It was a little difficult to judge of the pulse. The eyes were not so suffused as in etherization. As a rule, patients had come from under its influence promptly. In two cases he had observed nausea. He was not at all an advocate for the agent, but simply felt interested in assisting to place it upon record as an anæsthetic that had been used successfully. He thought it possible that in Dr. Sims's case sufficient stress had not been laid upon the operation itself as a factor in producing the death of the patient, as some deaths had followed the abdominal incision for removal of the ovaries, or Battey's operation. With reference to the tetanic convulsions, he thought they were not infrequently seen in connection with the use of ether. He also called to mind a case in which the patient had severe convulsions occurring with etherization, and it was subsequently found that the patient was an epileptic. It was possible that some such influence might have been at work in Dr. Sims's case. He thought that it might be difficult to use the ethyl in plastic operations about the face, because its effects were so evanescent.

The Academy then adjourned.

Roosevelt Hospital.—Eighth Annual Report, 1879:—The total number of cases treated in this hospital last year was 1,617. The mortality was 8¼ per cent. The number of operations was 156, of which 92 were successful and 38 attended with improvement. The operations included a lumbar colotomy, a litholapaxy, and two median lithotomies.

THE MEDICO-LEGAL SOCIETY.

Stated Meeting, March 3, 1880.

Dr. C. S. Wood, President, in the Chair.

THE PROBLEMS OF INSANITY.

Dr. George M. Beard read a paper on the above subject, in which he considered first, the causes of insanity, and of its increasing prevalence in modern times; second, difficulties in the diagnosis; third, the probabilities of cure; fourth, defects of the present system of treatment in Europe and America; and fifth, the future of insanity and influences that may check the rate of increase. The following is a brief abstract: The speaker said that it was one of the paradoxes of astronomy that the constitution of the sun was best studied when that orb was in an eclipse. It was one of the paradoxes of psychology that the mind was best studied when it was eclipsed by disease. Through insanity we learned of sanity. Pathology was the aid of psychology. Dr. Beard thought that psychology was destined to be the chief of the sciences, and that its study was greatly aided by the study of insanity. The first problem of insanity was how to define it. Insanity was a disease of the brain, in which mental co-ordination was seriously impaired. There might be disease of the brain without mental inco-ordination, but in all cases of insanity disease of the brain was implied. The word mind was used in a broad and generous sense. There was no mathematical dividing-line between sanity and insanity. Sanity shades into insanity like twilight into night, and the different forms and subdivisions shade into each other like the colors of the rainbow. There were two general divisions of insanity—intellectual and emotional. Delusions were not necessary to insanity. In very many cases there were no delusions, simply emotional disturbances. The ideas implied by the terms moral insanity and impulsive insanity were correct and sound. In some cases patients afflicted with what was called moral insanity, developed into forms of insanity in which there were delusions. Insanity with delusions and insanity without delusions ran together constantly, and were intermingled in different cases. The term moral insanity might be an unfortunate one, but the idea was scientific and demonstrable.

A second problem was, why was insanity increasing in frequency? Insanity was a barometer of modern civilization. Though existing in all recorded ages, and among all peoples, and known under various and inconsistent names and superstitions, yet it was rare and had always been rare with the savage, the barbarian, and the partly enlightened. There was no race, no climate, no institution, no environment that could make insanity common save when united with and reinforced by brain work and indoor life. Besides those general differences there were features of the modern and pre-eminently of the nineteenth century civilization that were peculiar to it—unprecedented in history—the printing press, the telegraph, steam power, the sciences and the mental activity of woman. Bringing arithmetic to aid us in our comparative estimate, it seemed quite within the facts to aver that the modern brain must carry and endure tenfold more than the ancient, and without a correlated increase of carrying and bearing force. Insanity was increasing more among the poorer than the higher classes. Civilization ground hardest on the poor, depriving them of the healthful influences of barbarism without the compensating

advantages that the higher classes enjoyed. Dr. Beard stated that he had reached that conclusion from years of study of the special subject. A number of years before, while studying the subject of stimulants and narcotics, together with the drinking customs of different nations, he had occasion to study very thoroughly the customs of different nations so far as could be obtained from accessible sources, works of travel and conversations with travellers, and, making due allowance for sources of error, there was an entire agreement with regard to the variety of allied nervous diseases among savages and barbarians. Quite recently he had studied the subject himself among thousands of negroes upon the island of Beaufort, between Savannah and Charleston. These negroes had been for years isolated, had not advanced a great deal beyond their original ancestors in Africa, and furnished an excellent opportunity for him to study the subject himself. He had investigated the psychology of these people carefully, by the aid of persons who, for years, had lived among them and employed them, and diseases such as neurasthenia, hay fever, symptoms of spinal irritation, and insomnia, to any extent were not known. They drank to excess, but there was no inebriety.

Poverty made us insane, and insanity made us poor. In England the increase of insanity among the poor during the last forty years had been 300 per cent., while the population increased in the same time only 45 per cent. But statistics relating to insanity were crammed with elements of terror.

The main defects in this present treatment of the insane in Europe and America were these: First, neglect of the early stages. The insane should be treated before they were insane. The practical problem of the future was to educate physicians in the study of insanity so that they should know premonitory symptoms and treat the patients in many instances without taking them to an asylum. The time would come when physicians would treat insanity just as much as they treated typhoid fever; would be able to diagnosticate it in the early stages; would be able to cure it; and, what was still better, would be able to prevent it by treating the conditions which lead to it. In a number of cases under his own observation he had thought of referring the patients to an asylum, but satisfactory results had been obtained by treatment at home. Each case in that respect must be judged by itself. A number of his medical friends, general practitioners, he knew were treating certain forms of insanity very successfully in that way.

The solution of that problem was already going on. Patients in the early and premonitory symptoms were constantly and successfully treated both by neurologists and general practitioners. Even those who were positively insane were treated successfully in that way at home. Second, the error was in depending on simple isolation in asylums without positive medication. The same mistake had been made in inebriate asylums, but was being corrected in them. The third evil was in the use of narcotics and sleep-forcing agents. The fourth error was the crowding together of curable and incurable cases. Three-fourths of the cases in asylums were cured in the first nine months. It was one of the facts of human progress that reforms usually came from outside of institutions that needed to be reformed. Long ago, John Bright, in the House of Commons, declared that all the reforms of English law in favor of justice and mercy had been opposed by the judges.

The diminished proportion of cures for the insane in asylums in recent years was explained partly by this, that hereditary influences were every year growing stronger. Hereditary disease of all kinds was harder to cure and more likely to relapse than any accidental or primary nervous disease. The future of insanity was a part of the future of sociology. Hundreds of millions of people were to occupy this continent, and among them were to be hundreds of thousands of lunatics. The late president of the British Psychological Association predicted that if insanity was to increase in England and Wales as it had increased during the last forty years, there would be 1,250,000 lunatics upon that island in the year 1912.

But the relative increase of insanity might probably be checked somewhat in all civilized countries. First, by inventions which diminished the fractions of modern life. Types of those inventions were the telephone, the type writer, palace cars, and elevated railways in great cities. The inventions of thirty or forty years ago, the telegraph and the like, all tended to increase the friction of life. Second, by the development of the intellect at the expense of the emotions. Insanity was caused not so much by intellectual as emotional activity. Third, improved system of education, primary and university. The whole system of mental training for the young must be and would be revolutionized. Fourth, the successful treatment of the nervous diseases and conditions that lead to insanity as nervous exhaustion, cerebral congestions, hysteria, hypochondria, and the like. In that respect great progress was being and had been made. There was also going on improvement in mental hygiene. The better classes of the American people were today growing stronger and larger, and now presented some of the best specimens of physique in the world. The criticisms on the defects of the treatment of the insane applied to all countries more or less, but England had the great advantage of supervision of all asylums, public and private, by a central authority, composed partly of physicians, partly of lawyers, and partly of business men. For forty years that commission had been in operation in England, and had given satisfaction. A bill to increase the number and enlarge the powers of the New York State Board of Charities, so that it might fulfil the duties assigned to the English Lunacy Commission was before the Legislature. It ought to be introduced not only in this State, but in other States. It would not solve all the problems of lunacy, but it would be one step in the direction of the solution of some of them. Lunacy reform would not be accomplished by leaps or jumps, but by slow increments.

During the discussion that followed the reading of the paper, there was considerable dissent expressed from some of the views contained in it, and it was voted to call a special meeting for the thorough discussion of the entire subject.

A QUERY.—Dr. J. J. Boynton, of Stowe, Vt., writes to us concerning the nitrite of amyl in chloroform narcosis, of which an account is given by Dr. John Burke in the MEDICAL RECORD of February 21st. He asks the doctor to tell us how the nitrite of amyl could restore a patient who was "apparently dead, pulse gone, heart ceased, face blanched, no breathing, mouth shut." Our correspondent does not see how any drug can have much effect after heart and lungs have stopped action.

Correspondence.

THE TREATMENT OF DIPHTHERIA.

To the Editor of The Medical Record.

Dear Sir:—On looking over the report of the discussion which followed the reading of my paper in the Academy of Medicine, and the editorial comments thereon in your issue of to-day, I find two points to which it seems necessary that I reply, if I may be kindly permitted to occupy for the purpose yet a little more of your valuable space.

The first point is the objection made by Dr. Jacobi to the use of lime-water spray, as practised and recommended by me in the treatment of diphtheria.

Dr. Jacobi's objection is, that the very small amount of lime in the lime-water spray must be changed by the action of the carbonic acid in the breath on its way to the throat, so that "when it does go there it is no longer lime-water," but carbonate of lime and consequently "inert."

As I know that Dr. Jacobi agrees with me that in combating this disease even slight aids are not to be despised, I wish to submit to him the following considerations, in the hope of obtaining from him a modification of his verdict against a therapeutical measure which, as I fully believe, has rendered me very valuable service.

There are two questions of fact raised by this objection—a chemical one and a therapeutical one. The chemical one is, does the lime under these circumstances change into the carbonate with such rapidity as Dr. Jacobi supposes? It occurred to me that the question might be answered by a very simple experiment. I was permitted by a patient who has an unusually patent and tolerant throat, to hold a bit of red litmus-paper at the end of a wire, and protected from the action of the saliva by coils of wire, well back in the pharynx—the patient being instructed to breathe naturally. I then, with the atomizer which I use in treating diphtheria, and in exactly the same manner, threw the spray of lime-water into the throat. In fifteen seconds the red litmus-paper was turned blue—this change occurring quite as rapidly and as completely as when the same experiment is performed in the outer atmosphere. In other words, it was not appreciably modified by the breath. Again, litmus-paper moistened with lime-water can be held in the breath for some minutes before its blueness is perceptibly affected by it.

This experiment seems to me to show that lime-water spray reaches the fauces and pharynx as lime-water, and does not immediately thereafter cease to be lime-water. When spray thrown into the throat by this method enters the larynx it does so by being drawn in thither by the *inspired* breath which is comparatively free from carbonic acid, and it therefore reaches the walls of the larynx as lime-water, and there continues to be lime-water for a certain length of time.

It should be remembered that my method of using this agent in ordinary cases of diphtheria is to require it to be thrown into the throat for some minutes every half-hour, and in laryngeal cases as nearly constantly as is practicable—never employing it at all except in patients who are old enough to favor its free entrance by holding the mouth widely open. Is it therefore unreasonable in me to suppose that the affected surfaces are actually bathed in lime-water for a sufficient portion of the time for some positive effect to be produced?

Now as to the therapeutical question. That any portion of the benefit which has seemed to me to attend the use of this agent has been due to its solvent or softening action upon diphtheritic membrane I am not prepared to assert, though experience such as I have previously published (see Transactions of N. Y. Academy of Medicine for 1876, pp. 309 and 310) favors such a conclusion. But there are other indisputable therapeutical properties of lime-water spray (with the addition, as I employ it, of a minute proportion of carbolic acid) which are desirable in the treatment of diphtheria. It is cooling, sedative, antiseptic, and mildly astringent. It is therefore adapted to assist in subduing inflammation, which is a most important part of the indication in the treatment of diphtheria. I have accordingly found it useful not only in this disease, but also in catarrhal pharyngitis and laryngitis, and I was glad to learn from the remarks of Dr. J. H. Douglas that his experience had been decidedly in accord with my own.

The other point to which I must refer is, that it is evident from your own comments, as well as from those of Dr. Jacobi, that my meaning was misapprehended in the remark that "such membrane is probably a desirable protection," etc. (*vide* p. 341). The misapprehension is probably the result of the conciseness which I was obliged to employ in order to bring the length of my paper within tolerable limits. By reference to the context of this remark, however, it will be seen that it refers to "deep and firmly adherent membrane." It will be seen also that I stated that the "*under* surface"—not the "superficial parts"—of the membrane is the source of septic poisoning. I thought it fair, also, to presume that in using the term "desirable protection," I would be understood as meaning not absolutely but relatively desirable, or *as an alternative*. Most *un*desirable and dangerous as this protection is then, in an absolute sense, let us consider the alternative. By the sudden removal of such membrane, a raw surface is left without epithelial or other protection, in a state of inflammation, exposed to both mechanical and chemical irritation, and, as experience has shown, particularly liable to become the site of renewed diphtheritic disease. In many instances, it becomes at once more inflamed than before, and its membranous covering is not only speedily reproduced, but extended—the "last state" of that throat being "worse than the first." I have observed such results follow the premature detachment of membrane by the coughing or retching of the patient, and, with fatal effect, its disturbance by rude manipulation, or its destruction by chemical agents. The successful treatment of diphtheria, as of other diseases, must often consist in the wisest choice of evils—the lesser one being "desirable" in comparison with a greater.

I have made this explanation merely to rescue my meaning from fatal misapprehension, as it is evident that you, Mr. Editor, and Dr. Jacobi, in common, as I believe, with most judicious practitioners at the present day, are in accord with me on the very important point of deprecating any premature or irritating interference with diphtheritic membranes; and no one, on the other hand, can in any case be more anxious than I "to get rid of them as soon as possible," consistently with safety.

Very truly yours,

C. E. Billington, M.D.

DOCTOR VERSUS DRUGGIST.

To the Editor of The Medical Record.

SIR:—Allow me to suggest a plan which will remedy the evil from which particularly the younger members of the profession suffer. I refer to counter-prescribing, high rates for prescriptions, renewing prescriptions without order from the physician, and other sins of which the great majority of druggists are guilty. Let every eight to ten physicians practising in a given area, associate, subscribe from thirty to forty dollars each, rent a small store centrally located, suitable for a laboratory, purchase a supply of drugs from the manufacturers, and engage the services of a competent chemist or prescription clerk, the whole matter to be under the supervision of a committee appointed for this purpose. All prescriptions are to be put up at this laboratory at cost, with enough margin to cover the running expenses, and a careful calculation has shown that all ordinary prescriptions for which druggists charge seventy-five cents to one dollar can readily be compounded at from fifteen to twenty-five cents. No articles for sale to be kept in the laboratory, and only the prescriptions of those who are stockholders to be put up at cost. The advantages of such a system are obvious, and could not fail to be popular. It would, above all, do away with the pernicious system of counter-prescribing which exists only by reason of the inability of many to pay both doctor and druggist, the latter generally charging more than the former. To the same reason is undoubtedly due the success of so-called homœopaths who furnish medicines gratis. I would therefore urgently recommend the adoption of the remedy proposed, which has met with the approval of all to whom it has been suggested, and will shortly be put in practical operation in several cities.

E. J. D.

PORTLAND, ME.

"ARTERIAL ANOMALIES."

To the Editor of The Medical Record.

SIR:—During the session of 1875–76 at Miami Medical College, Cincinnati, Ohio, the remarkable manner in which the brachial artery was given off in the subject I was dissecting led me to ask some of my fellow-students if they also had been treated to one of nature's freaks, when to my surprise, in some thirteen subjects examined, in five the brachial artery was unusual in its arrangement, and in one case the popliteal was abnormal.

CASE I.—*On the right side.* The brachial artery at the inferior border of the pectoralis major, divided into two branches, the *inner* branch giving off the superior profunda and anastomotica magna, and the *outer* branch the inferior profunda and musculo-cutaneous branches. The two branches reunited at the bicipital fascia and formed one distinct branch for about one and a fourth inches, and then divided into the radial and ulnar arteries. Both of these branches were of equal magnitude, and the diameter of either branch being as great as the normal brachial artery. The relations of these branches were the same as the normal brachial except that the median nerve was in relation to the *inner* branch by its outer side, and to the outer branch by its *inner* side. *On the left side*, the brachial artery was normal.

CASE II.—The radial and ulnar artery *on the right side* arose from the axillary about five-eighths of an inch external to the acromial thoracic, beneath the pectoralis minor. The ulnar artery giving off the long thoracic, subscapular, posterior circumflex, superior profunda, and anastomotica magna, and the radial artery giving off the inferior profunda and musculo-cutaneous branches these arteries did not reunite, but passed down the arm and were distributed in the forearm in the usual manner. *On the left side* the radial and ulnar arteries commenced at the lower margin of the tendon of the teres major. The superior profunda and anastomotica magna were given off from the ulnar, and the inferior profunda and musculo-cutaneous branches from the radial arteries. They did not reunite again, but were distributed in the forearm in the usual manner.

In Cases III., IV., and V. the radial and ulnar arteries were given off from the axillary at the lower margin of the teres major *on both sides*, and passed down as two distinct arteries, not reuniting; but in the arm the superior profunda and anastomotica magna were given off from the ulnar artery, and the inferior profunda and musculo-cutaneous arteries from the radial artery in the forearm; the radial and ulnar were normal.

CASE VI. The popliteal artery divided *on the right side* into three branches—the posterior tibial, anterior tibial, and peroneal arteries. *On the left side*, the popliteal artery also divided into three branches—anterior, posterior tibial, and peroneal arteries.

It will be observed that in Case II. the radial and ulnar arteries arose from the axillary artery on the right side, most unusually high, there being scarcely any axillary artery on that side. In Cases III., IV., V., and VI. the anomaly was symmetrical on both sides.

Cases I. and II. are especially of rare occurrence, and I thought it might be of some interest to note them.

M. H. DEAN, M.D.

WAMPUM, PA., March 10, 1880.

THE TREATMENT OF FRACTURE OF THE PATELLA BY THE WIRE SUTURE.

To the Editor of The Medical Record.

DEAR SIR:—In the number of your journal for March 6, 1880, page 274, under the heading "Treatment of Transverse Fracture of the Patella with the Wire Suture," appears: "Dr. J. E. Van der Meulin, of the University of Utrecht, reports to the *Lancet* the first case of transverse fracture of the patella ever treated with the wire suture. It was one that came under his care July, 1878." Now it has been my impression, received from good authority, that this same operation was done successfully many years ago by Dr. George McClellan, in Philadelphia, and I published an account of it in a paper contributed to the May (1876) number of the *New York Medical Journal*, "On the Wire Ligature in the Treatment of Ununited Fractures, and in Resection of Bones for Deformity." On page 463 is: "As to the kind of wire to be used, surgeons differ. Some use silver or silver-plated copper, but I have a preference for iron wire, imbibed perhaps from the teachings of the late Prof. Joseph N. McDowell, of the Missouri Medical College. I first heard him mention it in connection with fractures of the patella, in a lecture to his class during the 1866–67 session. He spoke about thus: 'Gentlemen: Between twenty-five and thirty years ago, while passing along the streets of Philadelphia, the late Dr. George McClellan, an illustrious surgeon

of that city, called me to his buggy and requested me to accompany him, to assist in an experiment he said he was going to perform upon a fractured patella. When we arrived at the bedside of his patient, he cut down upon the fracture with a longitudinal incision, and bored holes slantingly from about half an inch in each fragment from the edge of the fracture to the centre of the fractured surfaces, and passed through these holes a soft-iron wire, and tied the fragments nicely in apposition. Dr. McClellan's experiment was a success. The patient got well with the only bony union I believe I ever saw of a fractured patella. Dr. McClellan used the best metallic substance for a ligature that, in my opinion, has yet been found. But, gentlemen, my advice to you is, don't try the same experiment.'"

I have noticed this operation credited to Mr. Lister and other European surgeons by various home journals, among them the *Medical News and Library*, to the editor of which I wrote concerning it; but he did not see fit to give the credit at home where it belongs.

Very truly yours

WILLIAM A. BYRD.

407 JERSEY STREET, QUINCY, ILL.

THE ABUSE OF MEDICAL CHARITIES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—The letter of Dr. F. R. Sturgis, in your issue of March 27th, seems to demand an explanation on my part.

As regards my tardiness in publishing the cases referred to in my previous communication, I long ago learned the inutility of individual efforts to reform abuses which are tolerated by general apathy; and that such apathy exists throughout the medical profession is too evident to require argument. I have seldom, if ever, met with a brother practitioner who did not know of instances of interference as glaring as those which I described, occurring either to his own detriment or to that of his friends; but, as a rule, the private sense of grievance appears to be overmastered by a traditional reverence for the distinguished consultants whose quasi public position raises them above the code of ethics which is designed to keep the rank and file of the profession in order. The private practitioner is expected—and properly so—to be cautious in the case of a new applicant for advice, lest he entertain unaware the patient of another physician; is a similar precaution always exercised—even outside of hospital or college clinic—by all consulting surgeons and specialists? or are professional felonies sometimes compounded with "no questions asked"? Let me not be misunderstood as generalizing in such a query. Many whom I am proud to rank among my friends merit their eminence not less by their scrupulous sense of honor than by their professional attainments; to intimate that there are exceptions, is only to admit that in all pursuits there are men who will make base use of their opportunities for self-aggrandizement.

Touching the publication of names and places, it is to be observed that the cases to which I adverted were seen by me in consultation, and that, even were I inclined to assume the championship of other people's quarrels, I had no right to publish personal details without the consent of the persons who were directly aggrieved. Moreover, as the worst features of the matter rest upon the statements of the patients, it would be manifestly unjust to make specific charges in print without full investigation and verification of the evidence. The abstract existence of such abuses is fit subject for public discussion; but I think that individual examples would be better dealt with by our corporate medical societies, which are the proper tribunals to weigh the testimony and apportion the blame.

Finally, in answer to Dr. Sturgis's comment upon a paragraph in my former communication, whilst I fully agree with him as to the right—nay, the duty—of the hospital or clinic physician to refuse "to give his time or services *gratis* to such as can pay him a fee," he seems to have overlooked the pivotal clause of my criticism—viz., the "ascertaining whether the case were already under treatment or not." This being considered, I am sure that Dr. Sturgis will concur with me in maintaining that if a patient be already under the care of a private practitioner, neither officiating professor nor any member of a clinical staff should divert such patient's fees from his regular medical attendant; in other words, that the same courtesy should rule in "out department" and clinic which is supposed to obtain in ordinary professional intercourse.

I am, sir, faithfully yours,

ALFRED L. CARROLL.

NEW BRIGHTON, March 28, 1880.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from March 21 to March 27, 1880.

PERIN, G., Lieut.-Colonel and Surgeon. Upon being relieved by Surgeon Magruder, to report in person to Comdg.-General, Dept. of Dakota, for duty as Medical Director of that Dept. S. O. 63, A. G. O., March 22, 1880.

MAGRUDER, D. L., Major and Surgeon. Relieved from duty in St. Louis, Mo., and to report in person to Comdg.-General, Dept. of the Missouri, for duty as Medical Director of that Dept., relieving Surgeon Glover Perin. S. O. 63. C. S., A. G. O.

BYRNE, C. C., Major and Surgeon. In addition to his duties as Post Surgeon, Fort Snelling, Minn., to take charge, temporarily, of the Medical Director's office at these Headquarters. S. O. 30, Dept. of Dakota, March 20, 1880.

GIRARD, J. B., Capt. and Asst.-Surgeon, Fort Davis, Texas. Granted leave of absence for twenty-five days, with permission to go beyond the limits of the Dept. S. O. 55, Dept. of Texas, March 16, 1880.

MCCREERY, GEO., 1st Lieut. and Asst.-Surgeon (recently appointed), now at Fort Columbus, N. Y. H. To report in person to Comdg. Officer, Dept. of Arizona, for assignment to duty. S. O. 63, C. S., A. G. O.

SCHUÉ, E. D., 1st Lieut. and Asst.-Surgeon (recently appointed), now at David's Isld., N. Y. H. To report in person to Comdg. Officer, Dept. of Arizona, for assignment to duty. S. O. 63, C. S., A. G. O.

NEWTON, R. C., 1st Lieut. and Asst.-Surgeon (recently appointed), now at Fort Stanton, N. Mex. To report by letter to Comdg.-General Dept. of the Missouri for assignment to duty. S. O. 63, C. S., A. G. O.

COCHRAN, J. J., 1st Lieut. and Asst.-Surgeon (recently appointed), now at Ft. Wingate, N. Mex. To report by letter to Comdg.-General, Dept. of the Missouri, for assignment to duty. S. O. 63, C. S., A. G. O.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending March 27, 1880.

Week Ending	Typhus Fever	Typhoid Fever	Scarlet Fever	Cerebro-Spinal Meningitis	Measles	Diphtheria	Small-pox	Yellow Fever
March 20, 1880	0	5	28	6	93	38	0	0
March, 27 1880	0	11	48	6	70	45	0	0

HEALTH OFFICER FOR THE PORT OF NEW YORK.—Dr. William M. Smith, of Angelica, Allegany County, has been nominated and confirmed as Health Officer of the Port of New York, in place of Dr. S. Oakley Vanderpoel. Dr. Smith is a member of the Allegany County Medical Society, has represented his county in the Assembly twice, and was a surgeon of volunteers during the war.

NEW YORK DISPENSARY.—The name of the newly appointed House-Physician of the New York Dispensary is Dr. W. A. Valentine, instead of Dr. W. E. Valentine, as previously stated.

THE COLUMBIA VETERINARY COLLEGE.—The Commencement exercises of this college were held in Chickering Hall on the 26th of March, when the degree of Doctor of Veterinary Science was conferred upon seven members of the Senior Class, and certificates were granted to eight members of the Junior Class. The degrees were conferred by Dr. Alexander Hadden, President of the Board of Trustees. The following prizes were awarded, on behalf of the Faculty, by Prof. Thomas H. Hawkins: The gold medal for the best general examination, to John Lindsay, of Long Island; the silver medal for general excellence in the junior examination, to M. L. Frey, of New York; the anatomical prize to N. F. Thompson, of New York; the Hadden prize for the best general showing, to J. A. McLaughlin, of New York; the medical jurisprudence prize to John Lindsay; the prize for the best report of operations in the college, to N. F. Thompson, who also delivered the valedictory. Addresses were delivered by Fordyce Barker, M.D., LL.D., and Hon. George B. Loring, of Massachusetts. The stage was tastefully decorated with flowers. The music was under the leadership of L. N. Soltan.

INFLUENCE OF PILOCARPINE ON BALDNESS.—The following occurs in the *Moniteur Scientifique* for February, 1880.—"Dr. G. Schmitz has twice noticed the reproduction of hair on the head of bald patients, whom he had treated with hypodermic injections of pilocarpine for eye diseases (*Berl. klin. Wochensch.*). On an old man, aged sixty, who had been operated on for double cataract, he made three injections in the space of fourteen days; the membrane over the pupil disappeared, as he had expected, but at the same time the head of this man, who was completely bald, became covered with a thick down, and afterward his hair grew and became thicker, so that at the end of four months there was no trace of baldness left, and the patient became the possessor of an abundant crop of hair partly white and partly black. In the case of another patient, thirty-four years old, suffering from detachment of the retina, the top of the head was entirely without hair on a surface as large as a playing card. In this case also two injections of the same kind not only in curing the eye disease, but also in the reproduction of hair.

MEDICAL STUDENTS IN BERLIN.—At the University of Berlin, 475 students of medicine attended this year's winter course of lectures and clinics.

DUTY ON QUININE.—Mr. Kelley, Representative from Pennsylvania, introduced a bill, March 22d, to impose a duty of 10 per cent. on quinine.

NIGHT MEDICAL SERVICE IN CITIES.—Dr. Henri Sachtel has recently been in Philadelphia and has explained his plan for a night medical service to the Philadelphia County Medical Society. A committee of nine, with Dr. Benjamin Lee as chairman, was appointed to consider the subject.

COLLEGE OF PHYSICIANS AND SURGEONS.—Dr. Geo. H. Fox has been appointed lecturer on diseases of the skin, vice Prof. W. H. Draper, resigned.

ILLINOIS STATE MEDICAL SOCIETY.—The next annual meeting of this society will be held at Bellville, Tuesday, May 18, 1880.

THE COMMON-LAW RIGHTS OF AUTHORS AND LECTURERS.—A suit is now pending in the New York Supreme Court which, in view of a recent decision, is of considerable interest to lecturers either in the class-room or on the public stage. Drs. Darling and Ranney, who are both anatomical lecturers in the University Medical College, have written a book called "Essentials of Anatomy." By the usual publishing contract they conveyed to Messrs. G. P. Putnam's Sons the exclusive right to publish this book. Dr. Leo T. Meyer undertook to publish a book containing substantially the same matter, which matter he claims to have obtained from Dr. Darling's lectures while Meyer was a student under him. A preliminary injunction against the publication of Meyer's book was granted by Mr. Justice Lawrence. A motion has just been argued to make this injunction permanent, and Mr. Justice Donohue has denied this motion upon two grounds: First, because it appears by Dr. Darling's own affidavit that he had given Dr. Meyer permission to print some portions of his lectures before he made the publishing contract with Messrs. G. P. Putnam's Sons; second, because Dr. Darling's lectures became public property by his delivery of them in his class-room, and that, therefore, any one was at liberty to publish them. This proposition of law, if not entirely new, is of a nature to interest if not to alarm instructors and lecturers, not to say dramatic authors. An appeal has been taken by the plaintiffs, Messrs. G. P. Putnam's Sons, from this order, with the belief that the papers do not sustain the proposition of fact on which this decision is based, and that the General Term will not sustain the proposition of law on which it is also based. Messrs. Alexander & Green, and William C. Gulliver appear for plaintiffs, and Messrs. Curtis and Neville for the defendant, Meyer. Dr. Darling conducts his own case.

NORTHERN DISPENSARY—EIGHTEENTH ANNUAL REPORT, 1879.—The total number of patients treated during the past year is 24,239, being an increase of 907 on the previous year. Of these, 11,445 paid ten cents for their tickets, thus turning $1,144.50 into

the treasury. The annual expenses of the dispensary are about $4,500, and its financial condition is at present very satisfactory.

Medical Examiners.—A bill has been favorably reported to the State Senate creating the office of medical examiner.

New York Charitable Institutions.—On March 26th, Mr. Grosse introduced a bill into the State Assembly providing that after July 11, 1880, no charitable institution in New York shall receive from any fund, or moneys raised by direct taxation, a greater sum than $1.50 per week for each of its inmates for whom it is now by law entitled to receive money.

Abolition of Private Lunatic Asylums.—There has been for some time in England a cry for the abolition of private lunatic asylums. Dr. Bucknill has been one of the leaders in the movement, and he asserts that their superintendents are, as a rule, medically incompetent and only anxious to make money. Their venality also renders them liable to receive and retain persons not really insane, and abuses of this kind have been pointed out.

These charges have been denied by the supporters of the private asylums, and it may be gathered from the controversy that the truth lies half-way between the combatants. A bill has been introduced into Parliament which puts these asylums under local civil jurisdiction. But the bill is unsatisfactory, and will probably not be passed.

A Fund for the Discoverer of Anæsthesia.—The Hon. Alex. H. Stephens is said, by the editor of the *Virginia Medical Monthly*, to have prepared a bill asking an appropriation by Congress for the discoverer of anæsthesia. Three years ago Dr. J. Marion Sims proposed that the medical profession unite in asking Congress to appropriate $100,000 as an "anæsthesia fund," to be distributed equally among the families of Long, Wells, Morton, and Jackson. We presume that the bill referred to is the practical outcome of that suggestion.

Dr. Frank West has been elected resident physician to the Maryland University Hospital.—*Maryland Med. Jour.*

Medical Registration in Iowa.—A bill has been introduced into the Iowa Legislature by Dr. Von Lackum, Physio-Medicalist. It provides that an incorporated society of each medical school shall have power to appoint its own Board of Examiners and issue licenses. These licenses are to be issued to those holding diplomas from any incorporated college or to those who have passed an examination before the Board. There is very little reform here.

New Hospital and Dispensary in Brooklyn.—Ground will soon be broken for the new Eastern District Hospital and Dispensary, which is to be erected in South Third Street, Brooklyn.

Scarlet-Fever at Jersey Heights.—Scarlet fever has for a number of years prevailed extensively at Jersey Heights, and seems to be endemic there. There is an unusually large number of cases at present.

Priority given to Doctors' Bills.—Captain John H. Chamberlayne has introduced a bill into the Virginia Legislature, of which the following is a portion:

"Where the assets of the decedent in the hands of his personal representatives, after the payment of funeral expenses, *claims for physicians' fees for services rendered during the last illness of the decedent*, and druggists' accounts for articles furnished during the same period, and charges of administration, are not sufficient for the satisfaction of all demands against him, they shall be applied—first, to debts to the United States; secondly, taxes, levies, etc.; . . . thirdly, debts due as personal representative; . . . fourthly, all other demands ratably, except those in the next class; and, fifthly, voluntary obligations."

Medical Graduates of 1880.—The number of graduates from medical colleges this spring, as ascertained up to date, is as follows:—Medical College of University of New York, 200; Bellevue Hospital Medical College, 142; College of Physicians and Surgeons, 117; Jefferson Medical College, 196; Medical College of University of Pennsylvania, 104; Women's Medical College of Philadelphia, 14; Louisville Medical College, 56; Medical College of University of Louisville, 95; Louisville Hospital Medical School, 33; Rush Medical College, 144; Cincinnati College of Medicine and Surgery, 28; Miami Medical College, 46; Medical College of Ohio, 119; Medical College of University of Buffalo, 56; Detroit Medical College, 27; Iowa State Medical College, 22; Yale Medical College, 2; Medical College of Virginia, 20; Baltimore College of Physicians and Surgeons, 110; National Medical College, 12; Georgetown Medical College, 10. Total, 1,553.

A New State Medical Society in Tennessee.—The colored physicians of Tennessee have organized a State Medical Society; Dr. James M. Jamison has been elected President.

Discords.—The registrar of the Louisville Medical College is charged with double-dealing by the editor of the *Medical Herald*. The latter introduces affidavits into the *Louisville Medical News* to prove that the aforesaid registrar received a postal card addressed to the Dean of the Kentucky Medical School. Instead of turning over the communication to the proper officer, the registrar answered it himself, disparaging the Kentucky Medical School, and offering inducements to the prospective student to come to the Louisville Medical College. The registrar denies the truth of the story; meanwhile we have a newspaper war.

Diphtheria on Long Island.—There is so much diphtheria at Cypress Hills, L. I., that many of the inhabitants are becoming alarmed. The disease is confined principally to the vicinity.

The Thermometer in Trephining for Epilepsy.—According to M. Broca, in deciding the question of trephining in epilepsy from convulsions, etc., occurring in a patient who has a depression of the skull resulting from a previous fall or blow, the thermometer will settle our doubts. If the temperature is raised on the injured side, the effects are due to the lesion, and the depressed fragment must be raised; in the contrary case, the symptoms are not due to the lesion, and operative interference is contraindicated.

Dr. Christopher Tompkins has been elected Professor of Anatomy in the Medical College of Virginia, to fill the place made vacant by the resignation of Dr. F. D. Cunningham. Dr. Cunningham will give a practical course of lectures on diseases of the eye and ear.

Duration of Pregnancy in the Elephant.—On March 10th a female elephant, belonging to a circus in Philadelphia, gave birth to a baby which weighed

21½ pounds, and was thirty-five inches in height. Thus, according to the Concord News, is the first recorded instance of an elephant breeding while in captivity, in any country, and also the first on record in which the period of gestation has been accurately determined to be twenty-one months and a half. The elephant was owned by a male elephant at Concord, N. H., May 25, 1878. The facts concerning this, and concerning the early history of its pregnancy, appeared in the RECORD for March 22, 1879.

An Orthopædic Congress will be held at Milan in September next, after the International Public Health Congress at Turin.

A General Congress of Public Hygiene and Medicine will be held in Brussels at the Palace of the Academy, next August.

Dr. Copeman, of Norwich, England, recently died at the age of sixty. He will be remembered for his contributions to gynecology, and especially for the so-called "Copeman's method" of dilating the cervix for the cure of the vomiting of pregnancy.

Dr. Thos. Fairbank, Surgeon to the Queen and the Royal Household at Windsor, died on Feb. 26th, of aneurism of an artery of the brain. Dr. Fairbank was but thirty-seven years old at the time of his death. His professional career had been a brilliant one; he won many medals while a student, and at the age of twenty-three became surgeon to the queen, succeeding, at the same time, to a very large practice. He was engaged in this at the time of his death.

The Troubles of Medical Co-Education.—Dr. J. W. White was, a short time ago, brought up before the Board of Governors of the Philadelphia Hospital on charge of having used such indecent language in his venereal clinic as to oblige two female medical students to leave the amphitheatre. Dr. White succeeded the late Dr. Frank Maury as visiting surgeon to the Philadelphia Hospital, and he has been giving instruction in venereal diseases during the past winter. The Board of Governors, to whom the complaints were made, investigated the matter. They found that one of the complainants was a woman who was neither a student nor a physician, and who did not hear the alleged "indecent remarks" at all. Two female medical students testified that they were obliged to leave the amphitheatre on account of the character of the lecturer's remarks. All the other evidence went to show that Dr. White only used such expressions as were proper and necessary for the instruction of the students. The Board of Governors unanimously acquitted him of the charge. The matter gave rise to considerable comment in the local papers, and the whole thing was unfortunate and disagreeable. It seems as though the field of venereal diseases at least might be left alone, or studied alone by medical women.

Compound Fractures and Statistics of the Antiseptic Treatment.—Mr. T. Holmes has analyzed 203 cases of compound fractures that were treated in St. George's Hospital during the past twenty years. Leaving out 31 cases where immediate amputation was performed, he divides the remaining 162 into three groups. In 33, strict antiseptic measures were employed. Seven cases, or 21 per cent. died. Three of the deaths (2 pyæmia, 1 gangrene) were surgically preventable. Sixty cases were treated by sealing the wound with blood, dry lint, or collodion, with a mortality of 14 or 23 per cent.; 9 of the deaths were from pyæmia. The third set of 69 cases includes all those treated by other methods. Here the mortality was 19, or 27.5 per cent. There were 10 cases of pyæmia, 2 of erysipelas, and 2 of gangrene. These statistics, although comparatively favorable to Listerism, are absolutely unfavorable to St. George's Hospital. It seems as though there must be something wrong when 18.5 per cent. of the cases of compound fracture die from pyæmia.

Dr. Richardson's Legacy.—The choice wines which were left Dr. Richardson to be used for scientific purposes only, have finally been disposed of. They are turned over to the chemists, who will analyze their bouquets.

The University of Berlin has 3,598 matriculated students in the present winter session, a larger number than it has possessed at any time during the sixty-nine years of its existence. Of this number only 475 are medical students, while the Faculty of Law have 1,315, and the Philosophical Faculty 1,621 hearers. In addition to the matriculated students, there are 1,593 unmatriculated students in attendance on the various courses of lectures. America has 57 representatives among the matriculated pupils, 9 of them being students of medicine. The Medical Faculty consists of 8 professors, 12 assistant professors, and 16 private tutors.

The State Board of Health of California, as now constituted, consists of seven members, five being medical men. Of these, one is an eclectic by diploma, another a homœopath by profession. Their appointment at first aroused considerable excitement, for the regular profession created the board and now have a sort of claim upon it. In addition to this, many of the homœopaths are violently opposed to vaccination. There is, however, no quarrelling among the members as yet.

Selling American Medical Diplomas.—The Department of State has recently received official information that American medical diplomas are being sold in Berlin.

Answers to Correspondents.

The Thermo-cautery.—Subscriber, New Orleans, writes: "I have been using the thermo-cautery for the last two years, but latterly my instrument refuses to work. The liquid used, pure benzole, is the same as that with which it always worked, and is renewed each time. By raising the platinum to a red heat in a blow-pipe flame it works, but ceases to do so the moment the temperature cools below a low red. Does the platinum by use undergo a change preventing it from condensing the benzole vapor? If so, can anything be done to remedy it? I would like to know if other surgeons have met with similar results. If this be uniformly the case, it will materially detract from the usefulness of the instrument, as it is too expensive to be frequently renewed."

[The fault lies probably in the rubber of the bulb, or in one of its valves. The rubber wears out and may be easily replaced. A good deal of force to the current of vapor is necessary to keep up good combustion.—Ed.]

CLINICAL LECTURE UPON CASES OF GOITRE AND ATONIC DYSPEPSIA.

By BEVERLEY ROBINSON, M.D.,

LECTURER UPON CLINICAL MEDICINE AT THE BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

GENTLEMEN:—The first case I shall present to your consideration this afternoon is that of the woman before you, who is affected, as you perceive, with a large tumor of the neck. She is of about the middle age, a widow, has two children, does her own housework and some washing outside, and has always enjoyed excellent health. She was born in the province of Luxembourg. She has resided fifteen years in the United States, and the swelling began to be noticeable about five years previous to her arrival here. She comes to me through the courtesy of my friend, Dr. Frank Bosworth, asking to be relieved, if possible, of what to her is a distressing infirmity. Her tumor has not hitherto interfered with any of the important functions. She can swallow without difficulty, she has no dyspnœa, her voice remains unchanged; she is free from vertigo and headache, and there are no painful sensations in the neck, or the arms. Thus we recognize there are no unpleasant or dangerous pressure effects from the presence of this large, firm, lobulated mass. But what is it? Will any one among you tell me? One gentleman says it is a goitre. Now, I would like to know his reasons. He answers that it is so because it has reached its actual size slowly, and is hard. But may not this be said of a glandular tumor of this region. True; but, he replies, a glandular tumor would have a tendency to suppurate. Not necessarily, gentlemen; but then a glandular tumor would probably be conjoined with enlarged lymphatic ganglia elsewhere, and there would also be present other evidences of a lymphatic or strumous constitution. But might not this tumor be confounded with a cyst of the bursa over the thyroid cartilage? It might, but its situation is proof against this diagnosis. The enlargement of the thyroid bursa would be situated higher up in the neck. Moreover, this variety of tumor is rarely encountered. I have been in a position to have seen such cases for several years past, and thus far have only seen one, and you may all be in practice many years before seeing an example of the affection mentioned. Tumors of the thyroid gland are, on the contrary, not infrequently met with. As regards etiology, what caused this tumor? for we most of us recognize it to be a goitre, and we will not call this diagnosis in question any more. This patient was born and lived in a healthy locality in her youth. She drank rain-water, because no other potable water could be had. She has two children, and her confinements were natural. I might go on trying to find a sufficient cause for the development of this tumor of the thyroid gland, but I have already questioned her closely from this standpoint, and am unable to make out anything satisfactory. You know, doubtless, that such tumors are endemic in certain countries. In the valleys of Switzerland, more particularly, they are often encountered. "Crétins," as they are called, are the poorly developed creatures who are afflicted with them, and their growth is usually attributed to the fact that they drink habitually water which flows from the glaciers, and also the circumstance that the air they breathe contains little or no iodine. Again, painful or frequently repeated confinements have been instanced as efficient causes of such tumors. Manifestly, neither of these causes have been instrumental in occasioning what we notice in our patient. I will not employ any more time in pursuing the question of etiology, but will immediately consider the very important one of treatment. This patient has been told by a friend that her tumor could be taken out, and that some one at this college was the man to do the operation. Now, gentlemen, I greatly fear I am not the person she is in quest of. May a radical operation be performed in a similar case, and what are its chances of success? Undoubtedly it might be performed. It has already been performed more than once successfully, by eminent surgeons; and yet so distinguished an operator as Gross of Philadelphia does not hesitate to denounce it as unwarrantable.

This is, I believe, going too far, in view of our present knowledge. Radical extirpation of a goitrous tumor of this size must of necessity become a hazardous experiment, and one in fact which would endanger the life of my patient—and, is it justifiable? This woman is not a great sufferer. On the contrary, she has no inconvenience at all from this tumor, other than what pertains to her self-love. She dislikes excessively to be an object of criticism and idle curiosity, and hence seeks to have it removed. My advice to her is not to allow it to be operated upon; certainly not for the while. Now, what method of treatment shall I advise? Here I may stop a moment to say a word in regard to the different kinds of goitre. They are not all similar. Virchow has described three varieties: the simple variety, which consists essentially in the hypertrophy of the normal elements of glandular structure; the fibrous variety, in which the interlobular cellular tissue is greatly increased in amount, and which seems to exercise a sort of constricting power over a certain number of healthy lobules, and thus produces more or less secondary cystic degeneration; and a third variety, in which the vessels are very largely developed, and with which you are perhaps familiar when it is allied to an affection of the heart, prominence of the eyeballs, and a gradual wasting away of the health and strength of the patient. By this description I evidently have in my mind's eye the disease known as Graves' or Basedow's malady. To this division of Virchow, Dr. Morell Mackenzie, of London, has added two sub-varieties known as the fibro-cystic and fibro-nodular. Well, the patient before me is certainly not an example of the first or soft variety. If she were, her treatment would be very simple, and I should unhesitatingly recommend repeated applications of the blistering fluid of the British Pharmacopœia, or of the collodion cum cantharide of our own, and in this way I would expect that she would ultimately be wholly relieved of her actual cause of disfigurement. I place my hand over the tumor and I find no apparent pulsations. I examine the tumor carefully with my eyes and I notice no great development of superficial vessels. There is no heart trouble, no prominence of the eyes; this woman's general health is excellent. I at once eliminate Graves' disease. How about fibrous goitre? This tumor is firm, nodulated, and presents a very salient portion upon the median line, as to which I am doubtful whether or not it be a small cyst. I believe I would favor the existence of a cyst had not my patient informed

me that she had been punctured over this region not long ago by means of a hypodermic needle, and nothing but blood came out. Some among you may remember a remarkable case of the fibro-cystic kind that I had the honor of showing you at this clinic two winters ago. The woman's photograph before and after treatment I now pass around. This case was treated after the well-known method of Dr. Mackenzie Bruce, by means of tapping, and afterward the injection of a strong solution of tincture of iron, the object being to make a chronic abscess of the cyst. The iron injection is essential in similar cases, because there is considerable hemorrhage from the walls of the cyst after drawing off its contained sanguinolent and albuminous fluid. In this case I allude to many different treatments were undertaken—ergot was injected, caustic darts were introduced into the central and vegetating portion of the tumor, etc. The patient finally disappeared, having made an incomplete recovery.

In the case of my patient here to-day, I counsel, 1st, injections of tinct. iodinii comp., repeated once a week for many successive weeks. Upon each occasion from ten to twenty drops of the undiluted compound tincture should be employed. By such means I promise her partial relief from her large tumor. It will not cure her, but it will notably help her. Such is my own experience in similar cases; such, too, I believe is the experience of colleagues in the profession, well authorized to speak in like matters. If the iodine treatment does not succeed, I would advise, 2d, treatment by electrolysis; in other words, the introduction into the structure of this tumor of one or more surgical needles connected with the negative pole of an ordinary galvanic battery, while the sponge connected with the positive pole is held in the hand of the patient. The current from ten or more cells should be passed during fifteen or twenty minutes, and repeated upon several occasions, at intervals of a few days. In this way diminution of the tumor in size may be expected, owing to the chemical decomposition which will surely take place in its cell-elements. I have no personal experience in this matter, but have seen one very large growth of similar nature and location, in which electrolysis had obviously been of considerable value.

Not very long ago I was witness of an operation in one of the large city hospitals, in a case of enormously developed thyroid gland, in which the operator made use of the following plan: he first made a vertical incision over the bronchocele through the skin. He then separated the integument by careful dissection from the soft tissues beneath, and, after isolating the mass of the tumor as nearly as possible, he passed a platinum wire completely around its base, and after bringing the wire to a white heat by the aid of a galvanic battery, he proceeded to divide the tumor at its pedicle. I regret to add that this operation, although well conceived and executed, did not prove radical; a large portion of the bronchocele remained behind in situ, and a suppurating wound, which closed slowly and with some intercurrent accidents of septicemia, was a source of anxiety during several days. Still the operation appeared to me one that might be repeated, with better success, under more favorable conditions, and for this reason I have been led to mention it to you.

My second case is one of those which bespeaks the attention more, perhaps, of the practitioner than of the student of medicine, and yet we may even here find food for some practical remarks. She is a poor, sickly looking woman, who complains of occasional vomiting, distress over the epigastric region after taking food, and pains which are neuralgic in character and affect especially the lumbo-abdominal nerves. She is thirty-two years of age, and the mother of a pale, ailing, waxy looking, infant. Here, gentlemen, is a case of dyspepsia of dyspepsia of the atonic type allied with general depression of nerve-force and the signs of considerable anæmia. She came under my care after having run through quite a long list of symptomatic remedies, such as lime-water, solution of bismuth with cherry-laurel water, sulphate of iron mixture, Horsford's acid phosphates, pepsine and bismuth, and finally, a powder composed of cubebs, ipecac, soda, and bismuth. Surely she had already taken enough drugs to benefit her, and in fact she professed to have been benefited in a certain degree. When I saw her for the first time she had an occasional hacking cough which made her solicitous about her lungs. I found no physical signs of any pulmonary disorder, and after careful examination concluded that her cough was only another symptom of her dyspepsia, and as this symptom got better, so her cough would lessen or disappear entirely. In regard to diagnosis, I have fairly eliminated carcinoma of the stomach by reason of her age, the absence of any epigastric tumor, and of any chocolate-colored vomited matters or fæcal discharges. The pain she speaks of does not seem sufficient to make one suspect ulcer of the stomach, and she has never had any hematemesis. Moreover, she eats bread as readily as other solid substances, and has never remarked that milk seemed to suit her better than other fluids. I will only raise the question of chronic gastritis, at the suggestion of a member of the class, in order to dismiss it. There is no tenderness increased by pressure over the epigastric region, there is no febrile movement, and the tongue is coated with moderately thick white fur. It is not especially broad or flabby, and is not at all marked by the impression of the teeth along its margin. I gave this patient, during a few days, tablespoonful doses of mist. rhei et soda, and placed a large belladonna plaster over her epigastric region. She returned to me one week afterward, stating that she was slightly better, but suffered from a sort of gone feeling, or weakness in the region of the stomach. Her bowels remained constipated. I now gave her a small quantity of emulsion of cod-liver oil with saccharate of lime, to be taken in repeated doses of one to two drachms fifteen minutes after eating. I also prescribed the fluid extract of cascara sagrada for her costive bowels. To-day her motions are easy, and she has suffered less from stomachal pain and functional disorder than before during quite a long period. Now, gentlemen, look at this woman's tongue, and tell me, first, whether or not it is a true index of the condition of her stomach, and then what I must do to relieve her of what remains of her dyspeptic condition? I do not believe the tongue is always indicative of the state of the mucous membrane lining the stomach; but I am quite sure, in this instance, it shows that it would not take much ill-advised medication to set up even more irritative action than now exists in that organ. If we were merely to look at the general condition of this patient, almost any one would immediately affirm that she requires iron or quinine. But will her stomach bear either the one or the other at this time? I do not believe it will. I am confident that quinine would increase her actual difficulty, cause pain, increase of nausea, and attendant headache. One of Trousseau's dicta was, Don't give quinine when

your patient has a furred tongue; and for my part, I believe this great clinician was right. Nux vomica is what is needed in such cases, and given in a manner that I will mention presently. Iron salts are no better, under present circumstances, than quinine. Her stomach would not tolerate even the mildest of them. If this patient does not rapidly improve upon her present medication, I shall place a small fly-blister over her epigastrium, and give her tincture of nux vomica. At first I shall try her with five to ten drops diluted with water, immediately after eating. But if the remedy does not suit her in like doses, I will not abandon its use immediately. I will try her with very small doses of one drop or half a drop, or less still, and I shall hope thus to obtain effects which I may not obtain with the larger and more tangible doses. You must prepare yourselves, gentlemen, for a few seemingly heretical ideas. You might be inclined to call me homœopathic. I am not either homœopathist or allopathist in any narrow or restricted sense. I simply use remedies to produce certain wished-for results, and facts are more evidence to my mind than any number of well-constructed theories. Not long ago I was physician to a lady who was suffering from distressing dyspeptic symptoms. I had run through my own armamentarium with little or no good results. I called in consultation a very distinguished allopathic practitioner of this city. He advised the suppression of pepsine and bismuth powders I had been giving, and in their stead counselled the employment of very minute doses of nux. The counsel was followed, and the result was to me surprising, but, nevertheless, most beneficial to my patient. I am told by my professional friend, whose therapeutic acumen is undoubted, that he has been equally successful in many analogous cases. Doubt is the beginning of belief—the saying goes—and where I had great doubts, I am now disposed to believe. But here let me say a word about my use of cod-liver oil. Was it a rational prescription? I think it was. My patient wants fatty substances in a most assimilable form. Now, cod-liver oil in small quantities, and when well emulsified by means of an alkali, supplies that need. One must burn up hydrocarbons; and if one does not get them from the ingesta, they will be taken from the tissues of the economy, and that we wish in this instance to avoid. Moreover, theory apart, I can affirm that I know of no remedy which will tend to correct more effectually the feeling of epigastric weakness of which this patient complains, than the moderate use of cod-liver oil in nature or in the form of an emulsion. There is one form of gnawing at the stomach, of which I observed a case closely not long since, which is annoying, at times quite painful, and which appears to be caused by an unhealthy or undue secretion of gastric juice at a time when the stomach is partially empty, but does not, under ordinary circumstances, call for food. The instance I allude to is one in which the patient was seemingly very well in other respects; but, about one hour before lunch and dinner, began to suffer from these disagreeable sensations in the epigastrium. Thanks to the perspicacity of a medical friend, I was able to relieve the sufferer from his complaint by the use of the following prescription:

℞.	Potass. acetatis	ʒ ss.
	Tinct. nucis vom.	♏ ij.
	Infusi quassiæ	ad ʒ iij.

S. A teaspoonful, soon after meals, in a little water.

I presume this remedy acted in two ways: first, by stimulating the nerve-force of the stomach, and thus causing the orifices of the gastric tubules to contract; and second, by neutralizing any excess of gastric juice which was poured into the stomach during the digestive period. Doubtless, in consequence of this double effect produced, a morbid habit was broken up and the gastric glands only became active at their appropriate season, or when the stomach was normally irritated by healthy ingesta, both solid and fluid.

Original Communications.

REMARKS ON
RECTAL FEEDING IN DISEASE.

By WILLIAM WARREN POTTER, M.D.,

BATAVIA, N. Y.,

PHYSICIAN TO THE NEW YORK STATE INSTITUTION FOR THE BLIND.

[A Paper read at the meeting of the Medical Society of the State of New York, held February 3, 4, and 5, 1880.]

For a considerable period of time it has been well understood that nutritive aliments introduced into the body per rectum were capable of sustaining life almost indefinitely, even when unaided by the ordinary methods of ingestion. It is, however, a matter of considerable doubt whether the knowledge of this fact has been made as useful in the field of therapeutics as might have been reasonably expected from a method so potential, so simple, and withal so certain in its action.

Two causes, it appears to the writer, have operated in a large measure to narrow the field of usefulness of rectal alimentation in the management of disease, viz.: first, a want of proper confidence in the measure on the part of the profession; and second, a prejudice against it on the part of the laity.

The latter state of things is but a natural outgrowth of the former; so for both lamentable conditions we, ourselves, are responsible. If, therefore, the first-mentioned hindrance can be removed, the other obstacle falls to the ground as a matter of consequence.

It is confidently believed that in the intelligent discussion of methods of science and practice on all proper occasions, much can be done to strengthen our own hands on the one side, as well as to remove prejudice and doubt from the minds of the laity on the other.

The remarks which the writer is about to offer on the subject of rectal feeding, will only embody a few thoughts suggested by a somewhat limited clinical experience with the method, together with some ideas derived from a hasty glance at a portion of its recent literature.

Perhaps it were as well to begin with a narration of cases; yet, as nothing can be more wearisome to the listener, or dreary to the reader, I will be brief, limiting the record to four of my latest patients with whom the method has been employed.

Case I.—Mr. L——, aged fifty years, came under my observation May 24, 1879, suffering with chronic catarrhal bronchitis. After some months pharyngeal ulceration began, when dysphagia became a troublesome factor in the case. The blandest aliments, and even water, were now swallowed only with the greatest pain, and finally, buccal ingestion became impossible.

Rectal alimentation was substituted therefor on the 25th day of October, and was regularly kept up until the death of the patient, January 6, 1880. For seventy-four days the rectum was the main avenue of nutrition in the case, the only nourishment taken by the mouth during that period having been a few raw oysters occasionally, and less than three pints of cod-liver oil, except during the last few days of life, when milk-punch was thrown into the stomach through an œsophageal tube. When the rectal feeding was inaugurated the patient had taken very little food for a week, and death from exhaustion seemed imminent; but, from that moment, the strength and vitality improved so much as to give him hopes of ultimate recovery. The friends, however, were advised of the incurable nature of the malady, the disease having now degenerated into a well-marked form of broncho-pharyngeal phthisis.

The gratifying features of this case may be summed up as follows: that, by a well-organized and thorough plan of rectal alimentation and medication, the patient was rescued from impending death, and a two months' lease of life thereby obtained, thus enabling him to adjust important business interests which, without his personal attention, would have embarrassed his estate.

Case II.—Mrs. X——, aged 28 years; married July 25, 1879; consulted me October 30th for gravid nausea and inanition, having been for some time previously under the care of a homœopathic practitioner. The case presented a history of chronic gastric catarrh, extending back through a period of some years, to which was now superadded the excessive and uncontrollable nausea and vomiting of pregnancy. Examination by the touch and speculum discovered only the normal condition of a uterine body, say ten weeks pregnant. There was no erosion of the os; the cervical canal appeared healthy, and the parts were free from discharges. The position of the uterus was also normal, and the other pelvic organs healthy. All food, and even water, was now being rejected by the stomach, the retching and vomiting almost constant, as well as painful, and emaciation was marked. Rectal alimentation was, therefore, instituted November 2d, when all buccal ingestion was suspended. The potassic bromide was also given per rectum, according to the method of Prof. Busey,* which had the effect to so modify the nausea and vomiting that, by the 9th, small quantities of iced lime-water and milk were allowed per orem. For the next three or four days the patient's condition continued to improve so much that her husband felt warranted in postponing a consultation, which I had proposed, with an eminent obstetrician residing in a neighboring city. Finally, however, the rebellious stomach again began to reject everything, and on the 20th all stomachal ingestion was positively prohibited. Rectal alimentation and medication were steadily maintained for the ensuing fourteen days, to the exclusion of all other methods, and by this time the nausea and vomiting had nearly ceased.

In the meantime, however, the patient's mind became confused and wandering, although her physical condition seemed not to retrograde to any appreciable extent. On the 5th of December buccal ingestion was partially resumed, though only the blandest aliments were allowed, and these in small quantities, cautiously administered. Rectal alimentation was, moreover, still maintained as the chief dependence for nutrition. I should have mentioned that on the 25th of November, Dr. J. B. Cotes, a physician of large experience and undoubted skill, was invited to consult me in the case. He cordially approved of the plan which was being pursued, and advised its continuance as he did, also, at a later consultation. From the 5th to the 11th of December the condition of the patient remained apparently unchanged. She took small quantities of broth, lime-water and milk, barley water, etc., by the stomach, as well as beef essence, brandy, milk, and eggs by the rectum. Glairy mucus welled up from the stomach in greater or less quantities daily, from the commencement of my attendance, though without much retching or vomiting after December 5th. On the 11th of December I relinquished the care of the case to Dr Cotes for the succeeding ten days, during an absence from town. Meanwhile, another physician was associated with Dr. C., as counsel, and I am informed that this *gentleman*, who shall be nameless, for obvious reasons, indoctrinated some of the friends of the patient with the idea that the cerebral disturbance was caused by the rectal feeding, or the stomachal rest, or both—in short, that she had been starved at my hands. Be that as it may, somebody succeeded in so prejudicing the husband against the methods which I had employed, as to make it impossible for me to return to the case. The patient died on the 25th day of December, Dr. Cotes continuing in charge, and he informs me that rectal feeding was maintained to the last.

It is worthy of special remark that the potassium salt operated to control the hystero-neurotic† symptoms most effectually in this case, and, but for the fact that chronic gastric catarrh had so long preexisted, thus seriously complicating the pregnant sickness, I have no doubt that the rectal alimentation and medication would have proved successful. Moreover, in spite of all, life was prolonged much beyond any possible point, had the stomach alone been depended upon as an avenue of nutrition.

Case III.—Mrs. Z——, aged about 24 years, consulted me November 3, 1879. Her previous history disclosed a long-standing case of gastric catarrh. Present condition: emaciation well marked; stomach rejects all food, and even water often returns; eructation of glairy mucus constant and profuse. Examination per vaginam revealed the presence of a small ring-pessary, which the patient informed me she had worn for more than a year, on account of some supposed malposition of the uterus. The pessary was removed as being no longer required. The os uteri, as seen through the speculum, was healthy, though the cervical canal was filled with ropy mucus, while the endometrium was sensitive, and bled when gently touched with the probe. She had never borne children, and stated that she had never miscarried. It is proper to add that she had not lived with her husband for the past two years or more.

November 5th.—On my visit to-day I was shown more than two quarts of viscid, glairy mucus, unmixed with ingesta or other elements, which had been vomited during the previous night. I immediately commenced a systematic course of rectal feeding, prohibiting, at the same time, all stomachal alimentation. Under this plan the stomach soon became more quiet, and no desire for food per orem was expressed. Thirst, which was never extreme, was readily allayed by a goblet of water per rectum,

*Am. Jour. Med. Sciences, January, 1878, p. 140 et seq., and January, 1879, p. 112 et seq.

†Engelmann: Gynecological Trans., vol. ii., p. 518.

administered twice daily, together with occasional chips of ice per orem. The nourishment of the body, under this plan, was fairly maintained; but, at the end of three weeks, her mind, which had already, at times, exhibited confusion, now began to manifest symptoms of acute mania.

December 5th.—Small quantities of very bland aliments were now allowed by the stomach, cautiously administered, however; these were well retained, though rectal alimentation was still continued supplementary thereto.

December 10th.—Beef-essence, in teaspoonful doses, directed to be given per orem. This patient was, on December 11th, confided to the care of Dr. C. F. Rand for the next ten days, for the reason of my absence from town referred to in the previous case. While I was away the same practitioner, alluded to before, was invited to a consultation in the case, and he also visited the house daily for some days, as I am credibly informed, in the intervals of Dr. Rand's regular visitations. On my return I found that the friends of the patient had obtained the impression, in some way, that the cerebral disturbance had been produced by the methods which I had employed, viz.: rectal feeding and medication, and stomachal rest; whereupon my attendance ceased. I understand, however, at the present writing,* that rectal alimentation is still maintained in the case, and with slow but steady improvement.

Case IV.—Mr. W. H. P——, aged 57 years, consulted me November 10, 1879, for inanition and its consequent debility. Abdominal palpation revealed a tumor in the right hypochondrium, besides general tenderness on pressure over the entire region of the liver. There had been, for many months previously, general digestive disorder, with foul, gaseous eructations; moreover, the patient was now quite emaciated. I expressed the opinion that the symptoms pointed to malignant disease of the left lobe of the liver, although I did not, at that time, feel quite sure as to its true nature. He experienced so much distress after taking food, that I advised rest for the stomach for a time, and that rectal alimentation be substituted. In two days I was called and requested to assume charge of the case, the patient having been, for some months previously, under the observation of a homœopathic practitioner. Under perfect stomachal rest for a week, with rectal feeding regularly conducted, the stomachic condition so improved that buccal ingestion was cautiously resumed; only the blandest aliments, however, were allowed, supplemented with nutritive clysters. This plan has been steadily adhered to until the present time, with a gradual improvement in the stomach symptoms, much to the comfort of the patient; nevertheless, his physical condition does not change for the better. He is still greatly emaciated, and the tumor appears to increase in size, though very slowly.

Prof. James P. White, M.D., of Buffalo, N. Y., was invited to consult with me in the case, and did so on the 7th of January last. He concurred with me in diagnosis and treatment, and likewise gave an unfavorable prognosis.

I have briefly sketched these cases, in outline, for the purpose of basing thereupon some remarks germane to the general subject of rectal feeding in disease; and, for convenience, I have arranged what I shall have to say under three general heads, viz.:

I. Stomachal rest.

II. Methods and rationale of alimentation.

III. Conclusions.

I. First, then, of stomachal rest. A considerable experience and observation has convinced me that an essential factor in the employment of rectal feeding, especially in the severer forms of stomach disability, is absolute and unconditional rest for a time, for that organ, in so far as the introduction of ingesta is concerned. Moreover, I am not alone in this opinion, as I shall presently show. I am not unmindful of the fact that this will, oftentimes, appear to the friends of a patient as a stern, and possibly cruel mandate. Indeed, I have even heard physicians intimate as much, and say, when besought on the subject, "Oh, yes! always give some food by the stomach; a portion of it will stay and do some good;" and this, too, when everything was being tossed back as soon as swallowed. Nothing can be more harmful, in my view, than to torture an irritated and rebellious stomach in this manner, and nothing could be more reasonable than to apprehend injury from stomachal ingestion in such cases.

It cannot be denied that cases occur, now and then, where the stomach will not retain even the blandest aliments, either liquid or solid, and it needs no refinement of logic to prove that such a condition would only be aggravated by the gastric ingestion of any substance whatsoever. Would it not be far better to rest such a stomach until the disturbances shall have been sufficiently repaired to warrant the belief that the assimilative processes have, at least, been partially restored?

Says Leube, in writing upon chronic gastritis:* "After the diseased gastric mucous membrane has been, as it were, prepared for recovery by one of the methods just mentioned, the most important indication is *to preserve it from all irritation* which might interfere with the cure. This indication is only perfectly fulfilled when, for a considerable period, absolutely no food at all is received into the stomach, for even the blandest nourishment excites the activity of the affected mucous membrane, and in this way may disturb the healing process. In severe cases, therefore, it is always advisable to prevent entirely the reception of food by the mouth and to nourish the patient for some time entirely by the rectum."

Again, when writing upon cancer of the stomach,† the same author remarks: "If these regulations are ineffectual, it is well to give the stomach complete rest for a time by the employment of nourishing injections." This author makes further reference to the importance of stomachal rest for even a considerable time, when speaking of gastric ulcer, acute gastritis, and some other diseases of the alimentary canal. In the excessive and uncontrollable vomiting of pregnancy, a number of writers have of late directed attention to the importance of entire prohibition of stomachal alimentation as a remedial resource. Prof. Busey, in the papers already referred to, makes mention of its efficacy.

Prof. Henry F. Campbell, M.D., of Augusta, Ga., in a paper lately published‡ "On Rectal Alimentation, etc., in Pregnancy," bears testimony, in measured terms, to the necessity of rest for the stomach in gravid nausea and inanition. The writer of this article has also discussed the question, *inter alia*, of stomachal rest as an important factor in the successful management of the obstinate vomiting in pregnancy, in a paper which will be found in the *American Journal*

of Obstetrics for January, 1880. Did time permit, many other authorities might be cited whose opinions bear strongly upon the importance of prolonged stomachal rest in cases of severe disability of the upper portion of the digestive tract, but it would seem an excess of sentiment to dwell over much upon so simple and plain a question, where the propriety of the practice cannot be doubtful.

II.—We therefore pass to the second part of our discourse, viz., methods of alimentation, in which will also be discussed, to some extent, the rationale of the efficiency of rectal ingestion. Since it is desirable that the rectal food shall be a concentrated form of liquid nourishment, it would seem that the articles best adapted to the purpose are beef-essence, meat broths, milk, whipped cream, raw eggs, etc.

Dr. Nathan Bozeman, of New York, in a recent most valuable and instructive paper on ovariotomy,* recommends the employment of "mashed beef" in rectal feeding, which he thinks greatly exceeds in value any other form of animal nutriment generally made use of for this purpose. It is prepared by chopping say three pounds of fresh beef very finely, then mashing it in a wooden bowl with a pestle. A teacupful of cold water is now added and thoroughly incorporated with the mass. The whole is then strained through coarse crinoline, when it is ready for use. It can be kept in a cold place within a glass fruit jar, and should be warmed a little before being drawn into the syringe. For some time past I have made meat juice obtained in this way, the basis of rectal ingesta for patients requiring this method of nourishing, and can testify to its value and efficiency. I am often in the habit of adding to it some of the other articles mentioned, as well as arrowroot, animal jellies, the various condensed preparations or extracts of meat, etc. From four to eight ounces of food prepared in this way may be administered, say two to four times a day, according to the necessities of the case; and, should the rectum become irritated or intolerant of the clysters, the addition of a few drops of laudanum, or, still better, of Squibb's compound liquor of opium, will, speaking generally, arrest such a tendency. Brandy, quinine, and any other remedies needed, can be added to the nutrient injections, according to the requirements of each particular case. In cases where absolute stomachal rest is enjoined, it is well to give, per rectum, a goblet of water once or twice a day. This will have the effect to prevent or relieve thirst and dryness of the mouth, quite as effectually as if given per orem. In many diseases of the stomach and œsophagus, the supply of food and water must take place exclusively through the rectum.† Under this plan, however, rectal alimentation, medication, and stimulation can be gradually carried to the point of affording the greatest amount of nutrition and support. When it is judiciously and faithfully carried out, it furnishes a most precious way of restoring the functions of an irritable or diseased stomach, and is, in many instances, the *only* way in which that organ can be prepared for the ultimate reception of food and medicine.

The resumption of buccal ingestion must, however, be made under the most careful watching and with the greatest precautions; since too early resort to the stomach, in severe cases, for the introduction of either food or medicine into the system, is highly prejudicial to success, and oftentimes provokes irreparable mischief. Great caution should be observed, therefore, in selecting such articles, both of medicine and of food, as may be best adapted to the ends in view, and particularly in testing them with the strength or tolerance of the stomach.

With defibrinated blood as a rectal aliment I have no experience, but, on theoretical grounds, I should expect good results from its employment. It has been used by Dr. A. H. Smith, physician to St. Luke's Hospital, New York, in a large number of cases, and I understand that its therapeutical value has been clearly demonstrated by that observer.‡

More recently, Dr. F. L. Stewart, of New York, has brought to the notice of the profession a desiccated preparation of blood§ for rectal alimentation, which is now on trial at St. Luke's and other places. If the introduction of blood into the system per rectum should prove as certain and effectual in its action as claimed by its advocates, then will the days of blood-drinking and transfusion be numbered; since the former disgusts many patients, while the latter, even in the most skilful hands, is not unattended with danger. "But its injection per rectum is an easy and safe operation, which can be frequently repeated without risk of injury."‖

Says Dr. Stewart, in the paper already referred to: "Desiccated blood is therefore suggested for rectal alimentation, where the life powers are threatened by asthenia, due either to the loss of blood, loss of nerve-power, or both. It is indicated in all cases where, for any reason, digestion is impaired, in cachectic states from special constitutional poisons, and in all cases where impaired blood, nerves, or digestion give rise to the anæmic condition with its resulting general debility, hypochondriasis, or other functional disorder."

This brings us to a brief study of the rationale of the efficiency of rectal feeding in disease. What becomes of the aliments when placed in the rectum for purposes of nutrition? In what manner do they finally reach the blood in sufficient quantities to sustain life? Are they absorbed directly by the rectum or colon? Do the digestive fluids descend to meet them in the large intestine, and there prepare them for chylification and absorption? Or does the food ascend to the small intestine, where those digestive principles abound for its assimilation, and where, likewise, are found in abundance lacteals for chylous absorption?

These interesting questions have engaged the attention of physiologists for a considerable period of time; but it is possible, after all, that clinical observation may throw considerable light upon the subject, and, perhaps, aid materially in its final solution. The fact that proper food, timely and wisely placed in the rectum, does, somehow or another, furnish nutrition and support to the body, is quite beyond cavil; but if the *modus operandi* of rectal feeding, in accomplishing these important results, can be assuredly determined, a greater confidence will obtain for the method, and, as a consequence, its domain in the field of therapeutics will be greatly extended.

No doubt the failure of rectal ingestion to obtain the high therapeutical importance which, in the opinion of the writer, properly belongs to it, has

† Ziemssen, vol. viii., p. 127.

‡ I regret that I have not Dr. Smith's paper at hand. See, however, Archives of Medicine, vol. i., p. 113.

Prof. Busey of Washington, D. C., writes me January 24, 1880, that he has also used it with marked benefit, and corroborates all that Dr. Smith says of its value.

§ Medical Record, January 3, 1880, p. 11.

‖ Stewart, loc. cit.

been due, in a large measure, to the incredulity which exists in regard to the digestion, assimilation, and final absorption into the blood of aliments, when administered in this manner. It is well known that both rectum and colon are comparatively deficient in lacteal vessels; moreover, if these organs were so endowed, they do not possess the necessary digestive fluids for the disintegration, solution, and chylification of the alimentary matters so requisite to prepare them for absorption into, and final admixture with, the blood. Hence, some observers—notably Leube—deny the possibility of rectal nutrition unless the food has been first artificially digested. While it is highly probable that the rectum possesses the capacity, in a limited degree, to absorb medicines, water, and even aliments in thin solution, whence they are received into the portal circulation, and then distributed to the system after digestion by the liver; yet this avenue would seem entirely inadequate to furnish sufficient nutrition for the sustenance of life during any considerable period. If, therefore, the absorption of aliments by the rectum or colon was, alone, depended upon to sustain the vital powers during prolonged rectal feeding, it is more than likely that disappointment and failure would result. In discussing this question, Dr. Campbell remarks* as follows: "No physiologist of the present day, however fully impressed with the wonderful capabilities of venous and membranous absorption, can feel perfectly satisfied that these alone, and without the intervention of some other factor wanting in the rectum, can rationally and adequately account for the success and apparently perfect efficiency of rectal alimentation as reported in journals—and here and there in some works on practice."

The most reasonable explanation of the efficiency of rectal alimentation is, in the opinion of the writer, to be found in the recognition of the reversal of the normal peristaltic action of the intestinal tube, whereby the rectal pabulum is propelled upward from the rectum to the small intestine, where it meets the requisite juices for assimilation, and where, also, abound lacteals for its absorption into the blood. This newly-recognized function of the alimentary canal has been, by its discoverer, Dr. Campbell, very aptly termed "intestinal inhaustion;" moreover, he also claims that this phenomenon must invariably occur when rectal nutrition is accomplished.

Dr. Routh bears testimony to the retrostaltic action of the intestinal canal after rectal feeding, in the following paragraph, which I shall take the liberty of quoting from his book:† "Aliment in a fluid state is often absorbed in this way (*i. e.*, nutritive injections), as in the sad examples of adult persons intent on suicide, and who have cut their throats. In these persons, swallowing in the ordinary way has become impossible, yet they have been kept alive for six weeks by these injections. The same is true for cases where, from disease of the stomach, food could not be swallowed without provoking vomiting. Life in this manner has been prolonged till the irritation of the stomach has subsided, and food could be taken in the ordinary way. Even cod-liver oil may be absorbed, if given in an injection. Persons who have so taken it, have complained to me of *feeling the taste of it in their mouths for hours after.*‡

That the alimentary canal frequently performs retrostaltic acts in its different sections, under conditions of irritation or morbid disturbance, is a fact of daily observation. In citing examples of this sectional inhaustion of the digestive tract, I adopt, in the main, the admirable description of Dr. Campbell.*

"I. 'Gagging' is an action of the faucial muscles which reverses that part of the act of deglutition in which they are concerned.

"II. Vomiting, regurgitation, rumination (Copeland-Pavy) and several acts of this class concern both the œsophagus and the stomach. The contents, both solid and fluid, ascend, being forced up into the mouth and out of it.

"III. The familiar phenomenon of the ascent of bile into the stomach, indicates inhaustion between these two portions of the alimentary canal.

"IV. Chylous vomiting (Pavy) is inhaustion from the small intestine, the result of a reversal of peristalsis.

"V. The stercoraceous vomiting in ileus and in strangulated hernia, and in a few other conditions of serious intestinal disturbance, in which the matters are fluid, semi-fluid, and solid, tells its own history, and we know the journey it has taken, and that it must have passed through the ileo-cæcal valve. . . .

"VI. The ascent of fæces under restraint of the sphincter ani, in which the solid mass . . . . ascends above the sigmoid flexure" into the colon, where it remains for some time, if the desire to evacuate the rectum is resisted; and this desire is only again provoked upon its redescent.

"We have seen, then," says Dr. Campbell, "that every section of the intestinal canal is at times subject . . . to inhaust, or receive from below the contents of the section continuous with it. That which is so familiarly and demonstrably true, as pertaining to one and all the parts of this alimentary canal, may certainly, under similar circumstances, be predicated as pertaining to the whole. Then this upward movement, continuously maintained from the rectum to the small intestine, is what I would designate as the intestinal inhaustion subservient to rectal alimentation."

The permeability of the entire alimentary canal by enema has been demonstrated over and over again by numerous observers. In the fifteenth century, Guaynerius related the story of a man who vomited a suppository which had been previously placed in his rectum.†

J. Mathias de Gradibus (Venice ed. of his work, 1502) relates the case of a girl twelve years old, suffering from ileus, who not only vomited fæcal matters, but afterward clysters were rejected by the mouth shortly after they were introduced into the rectum. This state of things lasted for three days, during which time suppositories introduced into the rectum were vomited in like manner.‡ J. Optheus reports a case (cited with others by Senneritus to prove that ileus is not due to obstruction, but to reversal of the normal peristaltic action of the intestine) in which a piece of tallow candle used as a suppository was vomited shortly after its introduction.§

More recently, Dr. Robert Battey, of Rome, Ga., has demonstrated a similar permeability of the alimentary canal. In a paper presented to the American Medical Association in June, 1878, an abstract of which appeared in the *Virginia Med. Monthly*, vol. v., p. 551, the author states that in March, 1873,

* Loc. cit., p. 282.

§ Ibid.

while giving a large injection of soap and water to a patient, she recognized the taste of soap in her mouth. In January, 1874, he established the feasibility of injecting fluids into the rectum of a cadaver until they escaped by the mouth.

Experiments had been previously made (1845) to the same effect by Alfred Hall, and reported to the Medico-Chirurgical Society of Glasgow.*

Dr. Arnott is cited by James Scott ("Commentaries on the Use and Necessity of Lavements, etc.," London, 1829, as having written: "From an erroneous opinion that what has been called the valve of the cæcum acts as a perfect valve, allowing passage *downward* only, few practitioners have ventured to order much liquid to be injected, for fear of overstretching or bursting the lower part of the intestine; and the possibility of relieving disease *above* the supposed valve has scarcely been contemplated. It is now ascertained, however, that fluid may be safely injected, even until it reaches the stomach.†

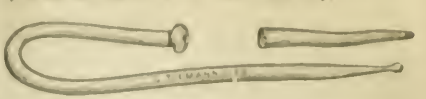
It would, therefore, appear that the permeability of the entire alimentary canal by enema has been clearly established through undoubted testimony.

I have taken some pains to study the phenomena clinically which have occurred in my own cases during the process of rectal feeding, through a careful questioning of the patients, and likewise by observations made in persons at the time of rectal ingestion. Soon after the aliments are injected a gurgling sound may generally be heard, and some intestinal commotion may also be observed. Moreover, the patients themselves, when questioned upon that point, have invariably informed me that they can "feel the injection going upward in the bowels" while the rumbling is going on. After the cessation of the commotion they have experienced no fear of the loss of the clysters. In some instances they have complained of tasting the aliments not long after their injection.

Experimental research on the lower animals, so far as made, goes to support the view that intestinal inhaustion occurs when aliments are placed in the rectum; and, if further experiments and observations should confirm those already made in regard to the retrostaltic action of the intestinal tube as an important factor in promoting the accomplishment of nutrition in rectal feeding, its rationale will be so simplified that all doubts as to its efficiency will fall to the ground.

Rectal alimentation will then take rank as a foremost therapeutical measure in all disabilities of the digestive tract, whether of reflex or structural origin, where stomachal ingestion is harmful or impossible; and it will likewise become an important agent in their intelligent management.

One word more before passing to the final section of this paper. I have observed that, now and then, the rectum becomes so irritated by the frequent use of the syringe as to jeopardize the success of the method by an occasional loss of the pabulum. To overcome this difficulty I have of late, in prolonged rectal feeding, been in the habit of introducing the clysters through a Wales' rectum bougie, previously carried into the rectum, and even past the sigmoid flexure. These bougies are made of pure, soft rubber, are quite flexible, and are tunnelled longitudinally, thus readily admitting the syringe nozzle. They are, in fact, most complete rectal-feeding tubes through which the nutritive injections can be easily propelled. The subjoined cut gives a tolerably good idea of these instruments, which are manufactured by Messrs. Tiemann & Co., New York City.



CONCLUSIONS.

The principles which this paper seeks to enforce may be formulated as follows:

I.—That rectal alimentation is a valuable agent, may, even an indispensable factor, oftentimes, in the management of all cases of disability of the upper portions of the digestive tract when, from any cause, stomachal ingestion becomes harmful or impossible.

II.—That stomachal rest, in so far as the entire prohibition of buccal ingestion can make it so, is a condition precedent to success in all the severer maladies for which rectal feeding becomes necessary. There cannot be the slightest doubt in regard to the adequacy of nutritive injections, to sustain life and maintain the nourishment of the body, wholly unassisted by the ordinary methods of ingestion, for a considerable period (from three months to five years), as attested by well-authenticated cases of record.

III.—"That rectal nutrition requires rather an explanation of its *rationale* than a demonstration of its truth."*

IV.—That in a more enlightened understanding of its value and certainty of action on the part of the profession, rectal alimentation and medication will obtain a wider range of therapeutical usefulness than it has heretofore occupied. Limited in the past, speaking generally, to the severer forms of chronic diseases of the stomach and œsophagus, I cannot doubt that they will, in the near future, become of vast service in the management of acute disease when, from any cause, the stomach becomes intractable and rebellious.

Example.—In October last I was treating a case of typhoid fever which, by the twenty-first day, became so critical that all hopes of recovery were abandoned by the friends of the patient. The case was rendered particularly desperate by the fact that the stomach now declined to further retain anything—water, food, or medicine. At this juncture, while collapse was threatened, I suspended all attempts at ingestion by the stomach, and gave injections of beef-essence, milk, brandy, ammonia, quinine, etc. This plan was steadily maintained for five days, when buccal ingestion was gradually and cautiously resumed, from which time everything progressed favorably; convalescence was promptly established, and the patient is now quite strong and well. There cannot be the slightest doubt, not only in my own mind, but also in the minds of others who saw the case, that success was due to the timely abandonment of the stomach, and the employment of rectal alimentation and medication.

V.—That the rationale of rectal nutrition is not satisfactorily explained in the absorption of the aliments by the rectum or colon alone; nor by means of the artificial digestion of the food previous to its injection, after the method of Leube; nor by the vicarious secretion of the digestion juices, according to Flint; nor by the attraction downward of the diges-

* Monthly Jour. Med. Sciences, vol. v., 1846, p. 1.

† See foot-note, loc. cit.

* Campbell, loc. cit.

tive fluids of the stomach and small intestine, until the alimentary mass is met and rectal digestion is accomplished, also an ingenious proposition of Flint. But I am persuaded that the adequacy of rectal feeding, in supplying nutrition and support to the body, can be fully accounted for in the recognition of the retrostaltic action of the intestinal tube—the "intestinal inhaustion" of Campbell—whereby the pabulum ascends to the small intestine, meeting there those digestive prineiples so necessary for its assimilation and chylification, preparatory to its admixture with the blood. Here, also, are found in abundance the lacteal vessels for the absorption of the chylous emulsion, ready to perform their part in the vital constructive process, whereby blood is made for the repair of the wasted and worn-out tissues, and for the building of such new ones as are demanded by the economy. Furthermore, that in this manner digestion is as certainly accomplished as though the food came by way of the mouth instead of the rectum.

VI.—That a timely and systematic employment of rectal alimentation and stomachal rest, in cases where the stomach is so disabled as to render the ordinary methods of ingestion harmful or impossible, is demanded alike by reasons scientific and humanitarian; and no person, except the most ignorant or malicious, could for a moment call it starvation. But, on the other hand, rectal alimentation, medication, and stimulation can be carried up to the point of affording the greatest amount of nutrition and support, and that wholly unassisted by any other means of ingestion.

VII.—That, in many forms of disease, stomachal ingestion is positively harmful, even though *all* food may not be immediately rejected. Such as is retained oftentimes undergoes decomposition, producing thereby fermentation, irritation, and distress, rendering it unfit for the purposes of nutrition; and, finally, the stomach expels the offending contents undigested. In such cases digestion is so disturbed as to render stomachal alimentation positively harmful—nay, even impossible; and its entire prohibition becomes at once a therapeutical factor of the greatest import.

VIII.—And, finally, that food sent upward through a healthy avenue, in good and sufficient quantities, will contribute with vastly greater certainty to the nutrition and support of the body, than when it reaches the absorbents through a diseased and disordered digestive tract, with its juices chemically at fault, and all its functions rendered morbid by pre-existing reflex or organic maladies.

FOUR CASES OF UNUSUAL DISLOCATION AT THE ELBOW-JOINT.

By ERSKINE MASON, M.D.,

SURGEON TO BELLEVUE AND ROOSEVELT HOSPITALS, NEW YORK.

Case I.—Dislocation of radius and ulna outward.

While making my visit at the Roosevelt Hospital, February 22, 1876, a boy twelve years of age was brought in the ward, having but a few moments before fallen from some rocks in the vicinity of the hospital, complaining of an injury to his left elbow-joint. The distance he fell, or how he struck, we could not ascertain from him, though the palm of the left hand being covered with dirt, while the other hand was comparatively clean, seemed to indicate that the force of the blow was received on the left hand while the arm was extended. The limb was in a slightly flexed position, though it could be flexed without difficulty. Upon examination of the elbow-joint a complete dislocation of both radius and ulna *outwards* was readily discovered. No swelling having as yet taken place, the relative position of the bones were quite apparent. The ulna was completely outside down, a little upward and resting, upon the external condyle of the humerus, while the head of the radius could be felt to rotate just beneath the integument, which was so tense that it seemed it must soon rupture, while the undue prominence of the internal condyle was strongly characteristic. Though complaining of pain in the joint, reduction was readily obtained without ether by extension and counter-extension, while pressure was made over the radius. The limb was put up in an angular splint, and in a few days passive motion was used. He left the hospital in a few weeks, regaining perfect use of the limb.

Case II.—Dislocation of radius and ulna outward.

On the afternoon of December 14, 1879, I saw, in consultation with Dr. J. H. Dew, a little girl seven years of age, who, on the morning of the same day, while climbing up to a closet, had fallen a distance of about four feet, and received a dislocation of her right elbow. We could gather no information as to what part of the limb had been struck in the fall. Upon examination, the limb was found a little flexed, with the forearm somewhat pronated. Scarcely any swelling had as yet occurred, and it was at once perceived that she had dislocated both bones completely outward, the olecranon resting upon the external condyle, and drawn upward about half an inch; the head of the radius could be distinctly felt under the integument, which was not drawn so tightly over it as in the preceding case; the undue prominence of the internal condyle was strikingly marked. Under ether flexion and extension were readily made, and the forearm felt as if but loosely attached to the arm. The reduction was readily accomplished (under ether) by the doctor making strong traction upon the forearm while I made counter-extension from the arm. Continuing this extension for a few moments flexion was made at the same time pressure was exerted against the radius, and the bones glided into position. Careful examination was made for fracture, but none detected.

Case III.—Dislocation of the ulna backward, and the radius forward and outward (left arm).

This case I saw in consultation with Dr. Whybrew eighteen days after the receipt of injury. The patient was a strong muscular man 28 years of age, by occupation a fireman on board of a steamboat. The accident was produced by a fall down-stairs while intoxicated, and, regarding the case as one of "sprained joint," had not placed himself under medical care till the day before I saw him. The limb was somewhat swollen, and there was some inclination of the tissues around the upper portion of the radius. The limb was nearly straight, and would admit of but slight flexion. Upon examination it was readily perceived that the ulna was dislocated backward while the radius was found thrown upward, resting upon the outer portion of the humerus. I could not positively determine as to the presence of a fracture, though felt disposed to the belief that a portion of the external condyle had been chipped off; though no bony crepitus could be elicited. Considerable pain was experienced upon pressure over the head of the radius, and

on the external condyle; this led me to the idea of fracture.

Under ether I made many and prolonged attempts at reduction, using extension and counterextension, strong pressure upon the head of the radius, flexion, rotation and supination, with the result of reducing the ulna into position, but only partially restoring the radius to place. Flexion finally could be made at a little more than right angles, the head of the radius gliding more to the outer side of the humerus. At one time we had so far reduced it as nearly to cause the finger to touch the shoulder, but it did not remain so. The final result of this case I am unable to relate, as three days after the reduction Dr. Whybrew informs me that he, the patient, left the city, and he has not heard from him since.

CASE IV.—DISLOCATION OF THE RADIUS AND ULNA BACKWARD, WITH SECONDARY DISLOCATION OF THE RADIUS BACKWARD AND OUTWARD, OCCURRING SHORTLY AFTER THE REDUCTION OF BOTH BONES.

In January, 1876, a man, 37 years of age, entered my service at Bellevue Hospital with the history of having received a fall two weeks before, and injured his right elbow. What portion of the body struck the ground he could not tell. No treatment had been resorted to, except the use of some liniment. Upon examination it was apparent that both radius and ulna were dislocated backward. Under ether reduction was readily effected; and the limb confined by a bandage. On the evening of the same day, while dressing the limb, my house-surgeon, Dr. Kearny, thought he noticed that the radius had slipped out of place again. I found that this had indeed occurred, and that the bone was projecting backward and outward, caused no doubt by his violence while coming from under the influence of ether. So great was the swelling which followed, that evaporating lotions were applied till February 5th. Eight days after the first reduction, when at my clinic, I reduced the bone by extension and pressure made against the head of the radius downward and forward, then flexing the limb. There was no fracture detected; the limb was confined in position, and when the patient left the hospital he could move the joint freely.

These four cases of dislocation are of interest owing to the infrequency with which they have been met with. In regard to the first two varieties, I have had the opportunity of seeing four examples. The first case was that of a lad 17 years of age, in the wards of one of my colleagues at Bellevue Hospital, whose case was reported in the MEDICAL RECORD for October 9, 1875; another was an old dislocation in a man that I saw through the courtesy of Dr. Frank H. Hamilton. It will be noticed that three of these cases occurred in quite young subjects, and I believe this has been the case in the majority of those reported. Hitherto, all the recorded cases, according to Hamilton (Fractures and Dislocations, 1875), have been but thirteen in number.

In reference to the third case we find no mention made of this variety of dislocation in some of our standard text-books. According to Gross, not more than five or six cases have been reported. Erichsen mentions having met with two cases in hospital practice. To produce such a dislocation, the limb would appear to have been flexed and the forearm severely twisted when the force of the fall was received upon the palm.

The fourth case, where the radius becomes displaced backward, is no doubt usually attended with fracture, but in this case I feel sure that such was not the case. That considerable laceration of the ligaments would be necessary to permit of such an injury without fracture is evident upon reflecting how strongly this joint is protected. That such injury to ligaments in this case existed, I think was evident, and I feel convinced that the displacement was due to violence of the patient in coming from the influence of ether and the means employed to restrain him.

A CASE OF CONDYLOTOMY FOR GENU VALGUM.

By CHARLES T. POORE, M.D.,

SURGEON TO SAINT MARY'S FREE HOSPITAL FOR CHILDREN, NEW YORK.

MICHAEL R——, aged four and a half, was admitted into Saint Mary's Free Hospital for Children, October, 1879, with genu valgum to a marked degree, in both of his limbs. Patient is a rachitic child. The internal condyles are on a lower plane than the external. There is no abnormal curvature of the femur or tibia, nor is there any hypertrophy of its inner head. He has worn braces, but has derived no benefit from them. There is some talipes valgus.

Figure 1 is from a photograph taken at the time of admission.

FIG. 1.

November 1st.—Patient etherized, and the following operation was done on the right limb. The leg being strongly flexed, a longitudinal incision was made two and a half inches above, and on a line with the tubercle, for the insertion of the tendon of the adductor magnus, directly down to the bone, so as to strike on the ridge of bone running from the linea aspera to the internal condyle. Into this incision a chisel three-eighths of an inch wide was passed, and rotated so as to be at right angles to the long axis of the femur, and the condyle was divided in a direction downward, outward, and backward, in a line corresponding to one drawn from the symphysis pubis to a point midway between the two condyles, when the limbs are parallel. The direction of the chisel was from time to time changed forward and backward, in order that the condyle might be freely separated from the femur, as far as the articular

cartilage. The limb was then extended, and the tibia bent inward, toward the median line, until the internal condyle was felt to yield and slide up, so that its lower border was on same plane with that of the external, the long axis of the tibia corresponding to that of the femur. During the chiselling, there was quite free venous hemorrhage.

A long splint, consisting of two pieces of zinc, one moulded to the thigh, and the other to the leg, united by an iron bar bent outward at the knee-joint, so as to leave that uncovered and provided with a foot-piece, was applied on the outer side of the limb, so as to hold it in an extended and corrected position. Lister's gauze was applied over the wound, secured by a tightly-applied bandage. Patient put to bed, and ice applied over the joint.

November 7th.—There has been no elevation of temperature, nor any pain since the operation. Dressings removed, and the limb put up in a plaster-of-Paris splint. Wound reduced to a small ulcer. There has been no suppuration.

November 8th.—A similar operation was done on the left femur. Hemorrhage during the section was about the same as at the first operation.

November 9th.—There has been considerable oozing coming through the dressings, so that they had to be removed last evening, and a compress, secured with a tightly-applied bandage, was put on. There

Fig. 2.

has been no further oozing. Temperature at 3 P.M. to-day suddenly rose to 102°, but by 6 o'clock had gone back to normal. There was no pain nor anything about the wound to account for this elevation.

November 14th.—Splint removed from the left limb, and plaster-of-Paris bandage applied. Wound about healed.

November 19th.—Plaster splint removed from the right limb; union seems firm.

December 3d.—Plaster splint removed from the left limb. The correction seems perfect. The malleoli can be made to touch. There is no stiffness about either joint.

December 13th.—Patient walking about. The right limb still showed some deformity. I do not think that I corrected enough; it is also half an inch longer than the left.

January, 1880.—Patient to-day went home.

Figure 2 is from a photograph taken two months after he began to use his limbs.

These operations were not done antiseptically, but a solution of carbolic acid was freely used during the performance.

The above described operation is known as Reeves's, the section is made in the same line as Ogston's, but there is not as much disturbance of the soft parts, and the joint is not necessarily entered by the cutting instrument.

There was not the slightest effusion or pain in either joint after the operation.

There is considerable projection of the internal condyle inward, due, I think, to its increased breadth, from the sliding up of the wedged-shaped section, the base being downward.

The limbs have not changed since the operation; the patient has been using them for more than two months. In standing he can place the malleoli in contact.

A NEW OPERATION FOR SYMBLEPHARON AND PERMANENT CURE.

By E. MACFARLAN, M.D.,

SURGEON TO EYE AND EAR DEPARTMENT, HARLEM DISPENSARY, N. Y.

H. O——, a butcher, while dressing a sheep received a wound which penetrated through the left lower lid, about four lines from the inner canthus, into the outer half of the eyeball, and embraced the retrotarsal fold. The resulting symblepharon was very extensive, consequently the movements of the eyeball were very limited. This annoying condition, together with the consciousness of an unsightly deformity, rendered my patient very desirous to have an operation performed which might afford some hope of a permanent cure.

Now, the experience of all engaged in ophthalmic surgery is, that symblepharon is one of the most intractable affections that we are called upon to treat; and the reason why is, because of the difficulty to prevent reunion after an attempted removal of the symblepharon. To accomplish a cure, then, it is obvious that the opposing surfaces must be kept from contact during the treatment.

Some surgeons claim good results from mechanical contrivances placed between the lids. Others, more recently, have had undoubted success by transplantation. But the case in hand suggested to my mind the possibility of effecting a permanent cure by a new and very simple method, of which the following is a description: 1. The symblepharon was dissected from the lid, retrotarsal fold, and the globe. 2. A pin was passed through the integument of the lower lid, about midway between the tarsal margin and the edge of the orbit. 3. A second pin was passed through the integument of the cheek, about three-quarters of an inch below the edge of the orbit. (Only a small portion of either pin was allowed to project from the point of entrance and exit.) 4. A thread of coarse ligature silk was now passed over the projecting ends of the lid pin, and the lid drawn down by it to the extent of producing a temporary ectropium. The thread was then twisted around both pins several times in the figure-of-eight form, and tied securely below the cheek pin.

Remarks.—By the use of the pins it will be seen an enforced separation of the lid from the eyeball was maintained, by which I was enabled to watch and control undue granulation, and thereby facilitate conjunctival repair.

At the expiration of ten days I found the repair

complete, and removed the pins; and when the pin-wounds were healed, discharged my patient permanently cured of symblepharon. I saw him several months afterward, and had the satisfaction to learn that there never had been the slightest indication of a return of the affection.

Progress of Medical Science.

Treatment of Prurigo with Pilocarpine.—Prof. Simon, of Breslau, states that he has employed pilocarpin in a number of cases of prurigo, and has found it to be a very efficient remedy for that disease. In cases of adults he usually administered the drug subcutaneously, injecting every day fifteen minims of a two per cent. solution, or a little over a third of a grain at a dose. Internally, he generally used a syrup of jaborandi, prepared by percolating fifteen ounces of boiling water through three ounces of jaborandi leaves, and adding eighteen ounces of sugar to the filtrate. Of this syrup the dose for adults was one or two tablespoonfuls, for large children two teaspoonfuls, and for small children one teaspoonful. After the administration of the drug, the patient was always wrapped up in blankets, and left in them for two or three hours. Under this treatment, even patients suffering from advanced forms of prurigo usually began at once to sweat profusely, and a favorable effect on the malady was almost always manifested rapidly. The intense itching was greatly relieved or even stopped entirely by the first dose; this effect was evidently due to the softening effect of the perspiration on the hard, dry skin. The exanthem rapidly diminished, the fresh spots of prurigo were much less numerous, and as the patients scratched themselves very little or not at all, the skin became progressively smoother. The swelling of the inguinal glands went down without any local treatment, and the deep furrows in the skin caused by the growth of the papillæ became shallower. Complete involution was obtained in mild cases in about fourteen days, and in severe cases in three or four weeks. In very inveterate cases the treatment had to be continued somewhat longer. In a large number of his cases, Prof. Simon used nothing but the pilocarpine or jaborandi, but in others he combined local treatment with it, and was convinced that the cure was hastened thereby. The local treatment in these last cases consisted in smearing the affected parts with tar, or painting them with oleum rusci, followed by a warm bath of two or three hours' duration. Relapses occurred in the cases treated in the above manner, but they seemed to be milder than usual.

Hebra, as is well known, regards prurigo as an incurable disease. Prof. Simon, on the other hand, believes that it is only incurable after the patients have passed a certain age, which he places at four years. Before that age he believes that even advanced cases of the disease can often be cured. He speaks of the difficulty of diagnosticating the affection from urticaria papulosa, a very common and readily curable complaint of early childhood. Prurigo is an exceedingly rare disease in America and England, but in Vienna, Breslau, and Berlin it forms about two per cent. of all cases of skin diseases treated in the hospitals.

Schnitz has reported two cases in which a growth of hair appeared on bald spots after the administration of pilocarpine, and Scholler states that he has seen the hair reproduced on a bald spot on a rabbit after two injections of pilocarpine. One of Simon's cases of prurigo was affected also with alopecia areata; the prurigo was cured, but the alopecia was entirely unaffected by the treatment. Simon reports, however, one case of complete alopecia in which he administered twenty injections of pilocarpine. The patient, a woman, thirty years of age, had absolutely lost all the hair of the body, even to the wool-hair, but a few weeks after the treatment the wool hair had reappeared over the entire body. In psoriasis and eczema, pilocarpine proved utterly useless, and in one case of pemphigus foliaceus, in which it was tried, it acted very unsatisfactorily, producing redness and tenderness of the skin. *Berliner klin. Wochen.*, No. 49, 1879.

Surgical Statistics.—Mr. Spence's article on Surgical Statistics, which appeared in the *British Medical Journal*, January 24th, and of which an abstract was published in the Record of March 13th, has called forth two replies in the *Journal* of February 14th, one from Mr. Lister himself, the other from Mr. W. Watson Cheyne, Surgical Registrar, King's College Hospital. Mr. Lister criticises the period from which Mr. Spence's statistics were derived, as long antedating his own, and suggests that the choice may possibly have been prompted by the exceptionally fortunate results obtained during that period. That these results were exceptionally fortunate, Mr. Spence's later statistics are adduced to prove. The statistics published by Mr. Lister were taken from 1871, when the antiseptic spray and gauze were first introduced, to 1877, when Mr. Lister left the Edinburgh Infirmary, and included all the cases operated upon in that institution in which strict antiseptic precautions were used. In Mr. Spence's tables the amputations mentioned were performed for disease; with the exception of three successful secondary operations, all the other secondary, and all the primary operations were excluded. Mr. Lister then analyzes the individual cases, and, comparing the similar ones in each table, claims a better showing for his own than for Mr. Spence's. In reply to the question relating to tumors of the breast, Mr. Lister says that during this period (1871 to 1877) he had thirty-eight such cases, of which two died, one from erysipelas, and one from septicæmia; but these were the only two deaths from blood-poisoning occurring among the operations performed antiseptically. The septicæmia was attributed to a failure in the proper application of the dressing, due to the carelessness of one of the assistants. But this one instance of septicæmia and not a single example of pyæmia occurred among 553 major operations, a multitude of minor ones, and a host of injuries varying from trivial ones, to compound fractures and wounds of joints.

The period selected by Mr. Spence was objected to by Mr. Cheyne for the same reasons as adduced by Mr. Lister, and a record of Mr. Spence's practice from October, 1872, to April, 1878, with the exception of the winter of 1874–75, was compiled by Mr. Cheyne from various publications in different journals. As this period corresponds in greater part to that during which Mr. Lister's results were obtained, it gives, it is claimed, a much fairer comparison. During this period there were 331 major operations with 58 deaths, a percentage mortality of 17.5, as contrasted with Mr. Lister's percentage mortality of

5.1. Much difficulty is experienced in attempting to ascertain the number of deaths from blood-poisoning: in 16 out of the 58 deaths, the cause is not definitely stated; of the remaining 42, 8 deaths are assigned to septic poisoning, while in several causes such as the following are mentioned: "irritative fever," "unhealthy action of the wound," "diarrhœa and vomiting" (in several cases), "uræmia, although without any marked symptoms," "hemorrhage, generally in the form of uncontrollable oozing," etc. The major amputations during these years numbered 97, of which 25 died, a percentage mortality of 25.7, as contrasted with Mr. Lister's mortality of 11.25 per cent. The claimed injustice of comparing the results of amputation for disease with those obtained in primary and secondary amputations is well illustrated in this table, in which Mr. Spence has a percentage mortality in primary amputations of 43.7; in secondary, 33.3. Although no definite information on the subject of blood-poisoning can be gathered from Mr. Spence's writings, a valuable record is published in Dr. Braidwood's work on *Pyæmia*, of the cases of this disease occurring in Mr. Spence's wards during the years 1859–65. It must be remembered that the 63 cases of major amputations for disease given in Mr. Spence's table occurred during the years 1860, 1861, 1862, and but one of these died of pyæmia. Dr. Braidwood's record of the six years, 1859–65, shows that of 227 major operations there were 43 deaths from pyæmia alone, leaving out of consideration septicæmia, erysipelas, and other forms of blood-poisoning. Of 44 primary amputations during these six years, 9 died of pyæmia, or 20.4 per cent.; of 113 secondary amputations (by which he probably means amputations for disease, and secondary to injury) 22 died from pyæmia, or 19.4 per cent. It is possible that many of these cases occurred immediately after the series of cases tabulated by Mr. Spence, but Mr. Cheyne expresses surprise that, if such were the case, these 63 cases alone should be produced and no mention made of many cases of pyæmia occurring immediately afterward.

Antiseptics in Cataract Extraction.—Following the example of Graefe, Mr. Simeon Snell has been testing the effects of antiseptics in ophthalmic surgery. The plan carried out by him in removing cataracts is the same as that recommended by Graefe. Shortly before the time of operation the eye was carefully washed out with a two per cent. carbolic solution, the eye then closed, and the external surface washed, and a sponge wetted with the carbolic solution laid over the closed eye until the operation. The instruments used were placed in absolute alcohol for a while, and then dried on lint or cotton-wool; the sponges were soaked in the carbolized solution. After the operation a pad of lint, wetted in a four per cent. solution of boracic acid, was applied, and covered with a piece of fine gutta-percha tissue; a simple pad of lint was applied over the sound eye, and a closely-fitting bandage was placed over all. Graefe changed the dressings every twenty-four hours, but Snell kept the lint constantly soaked by dropping the boracic acid solution upon it, and did not change the dressings for four days. The dressings were renewed for three or four days, and then discarded for a shade. Considerable pain was experienced on washing the eye, and the conjunctiva was so deeply injected and chemosed as to interfere seriously with the operation. On this account thymol was substituted for carbolic acid in the last operation, and these unfavorable results were entirely avoided. Eight cases have so far been treated in this manner, and the immediate results left little to be desired. Graefe stated that "the percentage of failures in the cases so treated was one and four-sevenths, while it varied from five to six in the cases operated upon before the adoption of the antiseptic plan." In an article on this subject, however, in a recent number of Knapp's *Archives of Ophthalmology and Otology*, the reviewer states that, "on a visit to Halle, he was authorized by the writer (Graefe) to add to his report that the recent results of extractions performed and treated in the same manner have been less favorable than before, showing an inordinate number of disastrous suppurative processes."—*The British Medical Journal*, Feb. 14, 1880.

On the Therapeutic Action of the Cortex Quebracho.—In No. 19 of the *Berliner klin. Wochen.* for 1879, Penzoldt published a very interesting paper on quebracho, in which he stated that he had obtained most striking and unexpected effects from that drug in different forms of dyspnœa, but that as a febrifuge it had failed in his hands. Dr. Berthold, of Dresden, has since then experimented with the remedy in fifteen cases of intense dyspnœa, with the following results: In a severe case of asthma convulsorum a teaspoonful of the tincture of quebracho gave speedy relief, and three doses at hourly intervals effected a complete cure. In a case of emphysema with asthma a teaspoonful of the tincture was administered every three hours; the dyspnœa did not yield until the third day, but the asthmatic attack was decidedly shortened by the remedy. In a case of emphysema complicated with pulmonary catarrh and pregnancy, the respiration fell in one day from forty-eight to thirty-two under the use of quebracho. In a case of pleurisy, and one of chronic pulmonary catarrh, the remedy caused no improvement at all in the dyspnœa. In a case of mitral insufficiency and stenosis, and in two cases of fatty heart, it exerted a very decided palliative action on the dyspnœa. Of six cases of phthisis with great dyspnœa, only two obtained any relief from the quebracho, but in these two cases the relief was very marked. In one of these cases of phthisis the diarrhœa stopped after the first dose of the remedy. Dr. Berthold has found the alcoholic extract of quebracho, that is, the resinous residue which remains after digestion, and is of course only soluble in alcohol, to be a very excellent remedy for diarrhœa. He administered it in five cases of acute and chronic intestinal catarrh with very prompt effect.

Dr. Picot, of Carlsruhe, writes that he tried the tincture of quebracho in three cases of dyspnœa, due respectively to catarrhal pneumonia, bronchial asthma, and valvular lesion, with very satisfactory effects. He also used it himself while doing some mountain climbing on his vacation, and found that it enabled him to climb with much greater ease and comfort—for instance, a certain expedition caused the pulse to rise from sixty-four to ninety-four, and the respiration from sixteen to forty-two, with a very unpleasant sensation of shortness of breath, but after a dose of half an ounce of the tincture the same ascent only caused the pulse to rise to eighty and the respiration to thirty. A corpulent man and a nervous woman, who suffered greatly from dyspnœa after moderately rapid walking on level ground, were able to take the same amount of exertion without distress after a dose of from two and a half to four drachms of quebracho. —*Berl. klin. Wochen.*, Dec. 29, 1879.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, April 10, 1880.

PAY-HOSPITALS, AND A POINT IN HOSPITAL MANAGEMENT.

In a work on pay-hospitals of the world,* recently written by Henry C. Burdett, the question of having in our hospitals rooms and wards where patients may be treated at certain fixed rates is discussed in a very thorough manner, with reference to securing improvements in this direction. In the matter of paying patients in hospitals, England is behind all other European countries. America will rank next above England. There is a particular need of examining the subject in these countries, therefore. The lack of paying wards in hospitals, on the one hand, encourages habits of improvidence and pauperism, and, on the other, it often prevents many people in moderate circumstances, as well as strangers or travellers, obtaining the best medical care and suitable surroundings. Nothing can be more unfortunate than to be sick in a boarding-house, apartment, or a hotel. Such a fate, however, is a necessity in England, and to a less extent in this country. The result of the present system is that only the very rich or the very poor get the best medical and surgical treatment.

The French long ago recognized the necessity of hospitals conducted on paying principles, and their *Maisons de Santé* have been very useful and successful institutions. As described by Mr. Burnett, they are in part under municipal and in part under private control. Their general arrangement is much like that of ordinary hospitals. There is a resident physician, with assistants, and a corps of visiting physicians and surgeons. The rooms and wards are divided generally into three grades, which differ in cost, and correspondingly in the matter of food and accommodation. The prices of board vary from seventy-five cents to several dollars a day. The patient can call in consultation any member of the visiting staffs of the Parisian hospitals, provided the resident physician is willing.

Similar institutions to the *Maisons de Santé* exist in Italy, Spain, and other European countries. They everywhere seem to supply a want and to be well patronized. In Germany it is customary for eminent medical men to own and conduct private hospitals of this kind, and more or less to advertise their institutions. Thus, Professor Volkmann, of Halle, has five of these "clinics," and over the door of each of them hangs his sign. This custom does not seem to be abused in Germany.

In our own country we have plenty of hospitals where the sick can go and be operated on or receive medical treatment, paying a respectable sum for the same. But with us, if a patient goes to a pay-ward he must of course be treated by the visiting staff; so that, if he had previously been under the care of one doctor, a change must be made. This is evidently unpleasant for the doctor, and it may be disagreeable to the patient. Then, on the other hand, the money paid by private patients all goes to the hospital, and none to the visiting staff. This is in many cases unfair. The money thus paid goes, of course, to the support of the indigent patients. But that part of it which is properly due to the visiting staff for professional services becomes virtually a contribution of that staff to the support of the hospital, which may be more than justice should demand.

In view of this state of affairs it has been suggested by Dr. Pront, of Brooklyn, that pay-patients in hospitals give the portion left, after paying for their board and accommodations, to such member of the visiting staff as they may elect, or even to an outside physician if they choose.

In regard to such a plan, we believe that it will not be practicable to any great extent in our present hospitals, since a good many of them need the money that pay-patients contribute. Neither would the plan of allowing pay-patients to call in outsiders be at all likely to succeed with most of our hospitals as now managed. A conflict with the various medical and executive authorities would be almost unavoidable if the system were introduced to any great extent. Our hospitals were not built, nor was their system of management organized, for such a plan.

Nevertheless, we recognize very strongly the need of *Maisons de Sante*—of places where physicians can send their patients, assured that they can have comfortable surroundings and careful nursing, and where the physician can follow his patient, and continue his course of treatment. Private institutions of this kind would undoubtedly thrive, and, if under responsible control, would be a great boon to the community. Their success has indeed been assured in this country, as shown by the Carney Hospital, near Boston, by the history of the old Washington City Infirmary, and by several other institutions which have more or less fully adopted this form of the pay-hospital system.

* PAY HOSPITALS AND PAY-WARDS THROUGHOUT THE WORLD. By Henry C. Burdett. London: J. & A. Churchill. 1879.

POST-GRADUATE STUDY AND THE NEW YORK ACADEMY OF MEDICINE.

In all of the New York medical schools a considerable proportion of the matriculates are doctors of medicine. They come on to New York after a few years of country practice, perhaps, desiring to break up the routine into which they have fallen; they wish to pick up the latest ideas in medicine and surgery, and to refurbish their therapeutic armory. The number of graduates engaged in this kind of study shows how much the need is felt of post-graduate instruction, and it was a wise and timely thought on the part of Dr. Yale to make this the text of his anniversary address before the New York Academy of Medicine. The rapid growth of this institution in numbers, its high professional standing, the ability of its members, and the excellent facilities afforded by its hall, all naturally suggested that it should lend its hand toward meeting this desire for post-graduate study and promoting the instruction of the profession in general.

The first and the simplest thing to do would be to institute a course of lectures. These should have a character much higher than that of the ordinary didactic lecture, or than the papers ordinarily read before medical societies. There should be kept in view the special object of the instruction of the general practitioner, as well as the promulgation of valuable original observations, and the earnest advocacy of whatever might tend to professional advancement.

It does not need argument to show the wisdom of establishing such a course. The Academy has members whose work in this direction would reflect the highest credit upon itself and the profession. It is unfortunate that in a city like New York we have not already had such courses established. The Harveian, Gulstonian, Lumleian, and other lecture courses delivered in London form some of the most valuable of the annual contributions to medicine, and are the very backbone of the London weekly journals.

Money is only needed in order that equally good courses be established here. We hope that an energetic movement to secure the necessary means may soon be inaugurated.

PROVIDENT DISPENSARIES IN LONDON.

The provident dispensary movement in London has lately received fresh impetus from the report of the Provisional Committee, appointed last June to arrange a plan for introducing it generally into the city. This committee, which embraced representatives of hospitals, dispensaries, friendly societies, charity organizations, and the profession in general, point out the well-known defects in the present dispensary and club systems. As a substitute, the plan they propose is not materially different from that of the provident dispensaries already established. It provides, however, for all the members of poor families, and it allows each family to select its own physician out of the dispensary medical staff. Provision for nursing, hospital treatment, and midwifery attendance is also made.

The committee say that one million of the people of London annually receive medical charity. They assume that one-half of these can become members of provident dispensaries; and it is thought that the establishment of fifty of such institutions throughout the city will furnish opportunities for all.

The club system of medical relief is now quite an extensive one, but it is unsatisfactory, because the medical attendance in this case does not include the whole family. It is believed that many of the clubs will reorganize on the provident system, and thus give it a great impetus.

The committee say that these dispensaries cannot prosper, if the just claims of the medical men on whose active exertions they depend, are not satisfied; and there ought, therefore, to be no uncertainty as to their fair remuneration. A proper care for preventing the abuse of this system is also recommended.

Altogether, the committee make a very good showing for the provident dispensary system, and there is a prospect that it will be introduced quite extensively into the English metropolis.

MEDICAL STUDENTS' CLUBS.

It is the complaint of the English medical student that he has but three places of resort—the college, the boarding-house, and the beer saloon. Taking this fact as the text, a correspondent of *The Students' Journal* writes quite bitterly of the neglect which the college authorities show toward the medical student, in every particular except that of his studies. No intercourse between pupil and teacher is cultivated; no provision for social intercourse and mutual help among the students themselves is made. In fact, they are left entirely to themselves, with no check from the faculty, until some fatal breach of discipline is committed, when the authorities arouse themselves and rusticate or expel the offenders.

This is the condition in most of the English medical schools, and there is something very similar to it in those of this country. We shall watch, therefore, with much interest, the discussion which is now going on in reference to securing a better state of affairs. Very little has been done, as yet, but in London a beginning is being made by the formation of Medical Club Unions. The purpose of these is to strengthen the influence of the medical students, and to promote unity and good-feeling among them. Whether they will accomplish any good must depend largely on their mode of organization and the spirit in which they are conducted. If the medical facul-

ties co-operate, or if the newly formed clubs teach these faculties to show a care for the students which is more paternal and not so exclusively didactic, as at present a great benefit will surely be secured. The medical student has strong social cravings, and he is at a time of life when these may easily lead him to acquiring bad habits and a low tone of thought. It is for the good of his future profession, as well as of himself, therefore, that he be watched and helped a little. We hope that the movement for the better care of the medical student may prove a successful one.

ECONOMY IN THE ADMINISTRATION OF THE PUBLIC CHARITIES.

A special meeting was held last week by the State Board of Charities to consider the possibility of reducing the expenses for charities. Fifty persons, representing twelve institutions of the city, were present. Mr. Theodore B. Bronson was made chairman. He stated that in 1865 the city appropriated for the Department of Public Charities and Correction $988,450; in 1880 the amount was $1,348,383. In addition to this the city appropriated $996,257 for various private institutions. Adding $342,573, the amount of the excise fund, we have a total of about $2,600,000, to be spent in 1880 on the city's dependent and criminal classes. This is at the rate of about $2.50 for each inhabitant of the city. In 1865 the total amount was $1,125,000, or about $1.50 per head. The increase is a striking one, and naturally provokes attention and alarm. Mr. Bronson called on the representatives of the various societies to give their views. All the representatives who responded deplored the facts as stated, but were positive that no retrenchment could be made in their own particular institution without great damage to the best interests of the city and of humanity. Mrs. Lowell protested against the incorporation of any more charitable societies, and thought that there were some in existence already which ought to be suppressed.

It was finally moved and voted that a committee be appointed, consisting of one member from each society, to consider the abuses of the per capita system. The meeting and discussion thus recorded were very timely, and it is only to be regretted that some more promising result was not effected by it. The appointment of an unwieldy committee of twelve, some of them from institutions which may themselves need reforming, does not give great encouragement. We hope for the best, however. This charity, which was once thought to be the divinest of virtues, seems to be becoming the genius of municipal pauperization.

A PHRENOLOGICAL SUPERINTENDENT.

We find a simplicity which is almost cherubic in the announcement by the superintendent of the Morristown Insane Asylum of his now matured views on the physiology of the brain. There are no doubts in his mind as to what is what in respect to this subject. Others may allow their energies to be wasted and their faculties blighted by modern experimental studies; but the distinguished alienist of New Jersey rises above this, and puts his trust in Dr Gall and George Combe.

The noble and neglected science of phrenology has captivated the mind of the superintendent. He sees in it a solution of all the problems of mental physiology and therapeutics, a deliverance from the crude work of modern neurologists, and a grand justification against the charge that asylum superintendents are not men of scientific education and training.

The trustees of the asylum receive the superintendent's statements with respect, and praise him for his erudition.

We believe that the Morristown Insane Asylum is a well-conducted institution, and is not much affected practically by the scientific vagaries of its superintendent; still, it is remarkable that a gentleman whose physiological views of the brain are based on the exploded theories of a past generation, should be at its head.

Reviews and Notices of Books.

How to Work with the Microscope. By Lionel S. Beale, F.R.S., etc. Fifth Edition. London: Harrison, Pall Mall. Philadelphia: Lindsay & Blakiston, 1880. 8vo, pp. 518.

The title of this work sufficiently indicates the scope of its author. From the appearance of the first edition in 1856 until the present, students of microscopy have looked upon the book as a trustworthy and practical guide in every variety of microscopical manipulation. As the science has expanded, and as its application has extended to the different departments of art, so has the work before us; and its fifth edition, which comprises a work of over five hundred pages, with hundreds of elegant illustrations, can be said to be fully up to date in all essential particulars. None better than the beginner can appreciate the difficulty of using his microscope properly and obtaining from it the best possible results, and none better than himself will appreciate the practical value of the several chapters that treat of the details of working the instrument. From a knowledge of the construction of the microscope, he is led to learn its use in the examination of different objects, the method of preparing the latter temporarily and permanently, the most approved methods of micro-photography, the best manner of making sections, of using injections, of staining tissues, of analyzing vegetable and animal tissues, and of employing micro-spectroscopy.

A distinguishing feature of the work is the large number of illustrations that it contains. By this means the reader has constantly before him methods of manipulation, forms of instruments, and arrangement of apparatus which it would be impossible to

describe to such advantage in the text. Even the most trivial points are illustrated—such, for instance, as the placing of microscopical covers in position, the dissection of insects under water with the arrangement of the magnifying power, etc. The remarks of the author on the use of the higher powers are particularly valuable to the advanced student as coming from one who has given the subject much practical attention, and who from extended experience is able to speak with authority. Altogether the work is the most complete one of its kind in any language, and is well calculated to supply the needs not only of the beginner, but the more advanced student. It is published in its usual unexceptionable style.

Transactions of the American Medical Association. Vol. XXX. Phila. 1879. 8vo, pp. 1028.

The volume recording the transactions of the last meeting of the American Medical Association is of the usual size and contains the usual number of papers. As a volume, it is not as interesting as some of its predecessors. The contents are as a whole not of that practical character which would make the work a valuable and useful one for the general practitioner. A greater part is given up to the papers of specialists, which are generally of a character that are of interest mainly to experts in the respective branches. The eye and the ear are particularly well represented; also, gynecology, skin disease, and lastly the treatment of spinal disease by the plaster-of-Paris jacket. The paper on the latter subject has its usual profusion of illustrations and occupies its usual number of pages. If this subject were entirely new, it would redeem the ordinary dulness of the volume. The papers on State Medicine are dry and to the last degree uninteresting to any save practical hygienists and members of health boards. The address of the president is on a very odd subject, and is treated in an oddly abstruse manner. The reader who plunges into its reading without due preparation, may be likened to the unthinking horse that rushes into battle. If at the end of the first half dozen pages he succeeds in mastering the situation, he can take courage and analyze the mysteries of life and death, of man's relation to animate and inanimate nature, and in the end he may congratulate himself that he has gained that true philosophy of our being which few are permitted to understand. The addresses on Practice of Medicine and Surgery are interesting and instructive; so also are the papers by Prof. Post of New York, Dr. Campbell of Augusta, Ga., Turnipseed of Columbia, S. C., and Marcy of Cambridge, Mass. The prize essay by Dr. McLane Hamilton is also a very creditable production, and presents the subject of primary and secondary degeneration of the spinal cord in a very instructive and practical light.

Notes of Hospital Practice. Part I. Philadelphia Hospitals. Selected and arranged by Samuel M. Miller, M.D. Philadelphia. 1879. 8vo, 137 pp.

The author has presented in a very practical form the views of most of the physicians and surgeons actively engaged in hospital practice in Philadelphia at the present time. Brief histories of cases of interest are given, together with the diagnosis and best modes of treatment for each. It is a book which will prove of great service both to the student and busy practitioner of medicine, containing as it does, in a condensed form, the latest opinions of men who are prominent specialists.

Paracentesis of the Pericardium. A Consideration of the Surgical Treatment of Pericardial Effusions. By John B. Roberts. With illustrations. Philadelphia: J. B. Lippincott & Co. 1880. 8vo, pp. 100.

After giving in detail the causes, symptoms, physical signs, diagnosis, and prognosis of pericardial effusions, the author discusses the various forms of treatment. In entering upon the subject of paracentesis, he goes fully into the history of the operation, together with the anatomy of the parts concerned, and the cases suitable for operation. He advocates the use of Potain's aspirator, because the vessel can be emptied of air before the trocar is introduced, and no shaking is produced by pumping after the pericardium has been perforated. After mentioning, and taking into consideration the various places adopted by various operators as the point of puncture, he comes to the conclusion that the fifth intercostal space, nearer the sixth than the fifth rib, to avoid wounding the intercostal artery, and from two to two and a quarter inches from the median line, is better than a point nearer the nipple, as in the latter situation the puncture may be made beyond the limits of the pericardium. Several minor details are entered into, after which follows a chapter on dangers to be encountered in the operation, treatment of complications, a table of cases, and the results of the operation.

Second Annual Report of the State Board of Health of the State of Connecticut, for the Fiscal Year ending November 30, 1879, with the Registration Report, 1878, relating to Returns of Births, Marriages, Deaths, and Divorces. Printed by order of the Legislature. Hartford. 1880. 8vo, pp. 84.

This report contains many suggestions to those interested in the matter of public health, a subject which at the present time is occupying the minds of so many of our public men. Those engaged in the formation of boards of health would do well to read the paper on the "Formation of Modern Boards of Health," by Professor W. H. Brewer. A brief resumé is given by Dr. O. Brown, of cases of "sickness from impure ice" occurring in the town of Washington. An able article is furnished by Prof. C. A. Lindsley, on "Sanitary and Unsanitary Conditions of the Soil," as also one on the much discussed subject of "School Hygiene," by Dr. C. W. Chamberlain. Other papers of value are published, and a report of the births, marriages, deaths, and divorces for 1878, together with the registration laws, concludes the volume.

Transactions of the American Ophthalmological Society. Fifteenth Annual Meeting, Newport, 1879. New York: Published by the Society. 1879. 8vo, pp. 106.

As usual, these "Transactions" contain much that is of interest in almost every branch of the specialty of ophthalmology. The first paper is by Dr. H. Knapp, "On the Operation of some Kinds of Complicated Cataract," who also furnishes another on "Tumor of the Optic Nerve." Dr. Haskett Derby contributes a valuable statistical article on "Influence on the Refraction of Four Years of College Life," in which some interesting facts are narrated. Next follows a paper on "Dacryocystitis in Nursing Infants," by C. J. Kipp. Dr. Noyes reports three cases of plastic operations at the inner canthus. The other papers

are by Drs. Webster, R. Dyer, G. C. Harlan, W. F. Norris, and others. There are some very good woodcuts presented in connection with the various papers, and the "Transactions" for 1879 compares favorably with those for other years.

TRANSACTIONS OF THE AMERICAN OTOLOGICAL SOCIETY. Twelfth Annual Meeting, Newport, R. I., July 24, 1879. Vol. II., Part 3. Boston: A. Williams & Co. 1879. 8vo, pp. 80.

A "Report on the Progress of Otology," from July 1, 1878, to July 1, 1879, by Drs. Vermyne and Webster, contains in a condensed form all that has been written in this department during the time mentioned. A digest of all the more important subjects is furnished, and is followed by a bibliography of the year. The papers are: a "Case of Ménière's Disease following Parotitis," by Dr. H. D. Noyes; "Contribution to the Pathology of the Temporal," by Dr. T. R. Pooley, also articles by Drs. Knapp, C. J. Blake, and Lucian Howe. This small volume is presented to the profession in octavo size, containing eighty pages of reading matter, and will, no doubt, be read with interest by those who wish to familiarize themselves with the latest advances in otology.

A TREATISE ON ORAL DEFORMITIES AS A BRANCH OF MECHANICAL SURGERY. By NORMAN W. KINGSLEY, M.D.S., D.D.S., President of the Board of Censors of the State of New York, late Dean of the New York College of Dentistry, etc., etc.; with over 350 Illustrations. New York: D. Appleton & Co. 1880. 8vo, pp. 541.

A CASUAL glance at this work might impress the reader with the idea that its contents were of more practical value to the dentist than to the general practitioner or surgeon. But, it is by no means a mere work on dentistry, although a practical knowledge of the latter art seems to be essential to the carrying out of the author's views regarding the correction of the different varieties of oral deformities of which he treats. In other words, the operations about the mouth for the corrections of the various deformities named are mechanical rather than in a strictly surgical sense operative.

The first part of the work considers the irregularities of the teeth, their causes, their association with general and special physical defects, notably with that of idiocy; their diagnosis, and lastly their treatment by mechanical means. Under the latter heading various apparatus are described. Appropriately following this chapter is one on the best methods of taking impressions of the mouth, while as a conclusion for this part of the work is an interesting recital of cases from practice, illustrating the principles of treatment previously laid down by the author.

But the really interesting part of the work, the one which is full of originality and which impresses the reader with the faithfulness of the author's work, the correctness of his observations, and the painstaking character of his conclusions, is that which treats of palatine defects. For a number of years our author has worked in this department with singular success, and now for the first time presents to his professional brethren the detailed results of such labors. It would be impossible in a reasonable space to follow him step by step through the different phases of the discussion of this part of his subject, and we must content ourselves with some general statements which will serve to give the reader an idea of the conclusions upon which his methods of practice are based. We may start with the idea that the failure of staphylorrhaphy is to be explained by the fact that a complete closure of the post-nasal orifice is not, as a rule, possible. This closure is absolutely necessary in order to eliminate the nasal intonation so common with patients suffering from the malformation in question. The author's observations to prove the part which the tongue and velum take in the articulation of the English vowels and consonants are of great physiological and pathological interest, and his conclusions seem to be legitimate and safe. What appears to be difficult to obtain by surgical operation in the way of closing the post-nasal opening is comparatively easy by artificial apparatus. The opening in the roof of the mouth in cleft palate is closed by a suitable plate, but to the latter is attached a soft rubber palate which is so adapted as to be acted upon by the rudimentary palatine muscles and in such a manner as to close the post-nasal opening at will. In most cases a special training is required, but the results of the latter are sometimes quite astonishing. In some instances the correction of the nasal twang is so complete that the patient's deformity may be effectually concealed. The cases from practice illustrating this point are of striking and practical interest.

We would be doing injustice to the work did not we make particular reference to the masterly chapter on the treatment of fractures of the lower jaw. The whole subject is so thoroughly studied that nothing is left to be desired by any surgeon who wishes to treat these fractures intelligently and successfully. The work as a whole bears marks of originality in every section, and impresses the reader with the painstaking efforts of the author to get at the truth and apply it in an ingenious and practical way to the wants of the general practitioner, the surgeon, and the dentist.

THE SPECTROSCOPE IN MEDICINE. By CHARLES A. MACMUNN, B.A., M.D., University of Dublin. With three Chromo-lithographic Plates of Physiological and Pathological Spectra, and thirteen Woodcuts. Philadelphia: Lindsay & Blakiston. 1880.

DR. MACMUNN states in his preface that "the spectroscope seems likely to be of almost as great use in medicine as it has already proved in terrestrial, solar, and stellar chemistry." This prediction may or may not come to be fulfilled. We will not attempt to dispute the possibility of such an event. For the present, however, even after having read the author's two hundred and seventy-nine pages of subject-matter, we fail to see the great practical usefulness of the spectroscope in medicine. There can be no question that some facts of physiological chemistry are easily demonstrable by this instrument. Hence, we believe that no well regulated laboratory should be without one. We further admit the importance of the spectroscope in certain pathological tests, and therefore the scientific investigator should be supplied with an instrument of this kind. But the practitioner will not, for these reasons, add a new ponderous apparatus, with various accessories, to his daily increasing stock of medical contrivances. Rather than provide himself with an expensive instrument which requires skilled practice for profitable manipulation, he will forego some of the undeniable advantages possessed by this method. We would not be understood to disparage the work done by the author. He has certainly with much industry collected all the main facts pertaining to his subject. Those who are interested in the subject will doubtless welcome this little volume as a convenient guide

to the spectroscopic examination of normal and pathological products.

THE REGIONAL TEMPERATURE OF THE HEAD. By J. S. LOMBARD, M.D. London: H. K. Lewis.

DR. LOMBARD is the adapter of a well-known physical form of mensuration to medical uses which involves the use of thermo-electric piles and the deflecting galvanometer. His apparatus, described several years ago, has been used by Hammond in this country for the detection of difference of temperature in the head. Broca, Gray, Schiff, and two or three Italian investigators have worked in the same direction—with surface thermometers, however. The work before us shows great patience and labor, and embodies a series of experiments made to determine the rise of temperature when the intellectual or emotional activity of the brain is excited. The variations are extremely delicate—so delicate, in fact, as to raise a doubt as to their practical value and the part played by outside influences; and for this reason we should be disposed to place more reliance upon the results obtained by the thermometer, which gives the indices of much more conspicuous changes. The book is one of great interest, however, and comes to us at a time most fortunate. Cerebral thermometry is in its infancy, and any aid in the development of such an important study is acceptable.

TRANSACTIONS OF THE VERMONT MEDICAL SOCIETY FOR 1879.

THE addresses of Dr. G. B. Bullard, President, opposing the germ theory, and of Dr. L. W. Bingham, Vice-President, favoring it, are readable articles, though they present nothing new. The latter details the armamentarium of Lister, and writes from the basis of Lister's and Volkmann's researches. This plan receives his attention at the Fletcher Hospital, at Burlington. Three of the ten articles of the volume are upon this mooted question. Dr. Draper, Superintendent of the Insane Asylum at Brattleboro, writes somewhat authoritatively on hysteria in insanity. Though an occasional writer, he is known as a careful observer. In the few positive cases of hysteria in the male, which he has watched, all of which were accompanied by the globus, masturbation or excessive venery was found to be the immediate precursor.

E. S. Peck, of New York, sends a paper on the etiology and treatment of chronic purulent inflammation of the middle ear. A table of 2,500 ear diseases is adduced, of which 600 are cases of chronic purulent discharge. The general practitioner, to whom scarlet fever ear-cases go quite as often as to the aurist, is cautioned against the promise to mothers and guardians, as dangerous as it is untrue, that such a discharge "will get well of itself." The danger of granulation tissue proceeding from the superior wall of the middle ear, and some unusual successes with the artificial drum-heads of Toynbee and Blake are detailed.

Dr. A. B. Somers, in a paper on the sympathetic eclampsia of children, notes some of the truisms of Alonzo Clark, Vogel, and Bouchut, and groups briefly a few instances of this infantile symptom, which were promptly relieved by gum-lancing, cathartics, and, finally, iodide and bromide of potassium. Dr. F. W. Goodell writes on irritable ulcer of the rectum, and Dr. C. W. B. Kidder on the surgical treatment of hemorrhoids.

The Secretary wisely devotes but ten pages to official business, while ninety are given up to selected papers. It occurs to us that the Vermont State Society does not bring out the talent of its best-known practitioners, and this volume is exceptionally small. For the year 1880, Professor S. W. Thayer is President, and Dr. S. S. Clark, St. Albans, continues as Secretary.

TRANSACTIONS OF THE MISSISSIPPI STATE MEDICAL ASSOCIATION. Vol. XXXII. 1879.

THE first half of this volume is occupied with addresses and poems to the memory of those physicians who died in the epidemic of 1878. This recognition of them is eminently appropriate and just. Eighteen physicians of Mississippi died during that summer, victims of the pestilence, and brief notices of their life and character are given. The poem by Dr. J. Dickson Bruns is a little crude and halting in its rhythm, but it is full of pathos, and, on the whole, has genuine merit.

The last half of the book is occupied with papers by the members of the society. These are, for the most part, short and on practical subjects. The "Spas of Mississippi," by Dr. L. Phares, gives a good account of the numerous mineral springs of that State. One of the longest contributions is by Dr. M. S. Craft, on "Surgical Diseases of the Rectum." A history of Intentional Anæsthesia is related by Dr. J. M. Taylor, and the credit of priority is given to Dr. Crawford W. Long. The notoriety and prominence which Southern physicians have been giving to Dr. C. Long in this matter does injustice, we believe, to Dr. Morton. "Ligation of the Femoral Artery," "Climato-Therapy of Phthisis," "New Remedies," "The Use of the Obstetric Forceps," and several short articles on surgical subjects, complete the book.

We cannot but criticise the taste of the printer in putting a double border around a scientific publication. This smacks too much of children's picture-books.

The officers of the society for 1880 are: President, Dr. E. P. Sale; four Vice-Presidents; Recording Secretary, Dr. Mort. Johnson, of Jackson; Corresponding Secretary, Dr. M. Craft, Jackson; Treasurer, Dr. E. K. Harrington.

TRANSACTIONS OF THE ILLINOIS STATE MEDICAL SOCIETY. Twenty-ninth Anniversary. May, 1879.

IN his opening address, the President, Dr. E. P. Cook, discusses a number of prominent medical topics. The proposed law for the commitment of the insane, resembling that of New York, is heartily endorsed, the adoption of the entire system is recommended, and remedies for the evils in medical education suggested.

A report on surgery is made by Dr. Jno. E. Owens. This includes a synopsis of the various additions to medical science during the past year, and is a valuable document.

A paper on "The Treatment of Fractures of the Femur" is contributed by Dr. C. Truesdale. Dr. T. has used for a number of years a triple inclined plane. With it he claims that shortening is not the rule, but the exception.

Dr. H. T. Gill, in a paper on the "Surgical Treatment of Croup," gives statistics of 106 cases of croup in which tracheotomy was performed; of these 28 recovered.

A report on obstetrics and one upon practical medicine and upon gynecology, contain much interesting matter. A paper entitled "The Chiropodist" has been already extensively published.

Dr. E. Bowyer read an article on "The Compensa-

tion of Medical Witnesses." In this he claimed that physicians have a moral and legal right to compensation as expert witnesses in coroner's cases and in court.

Reports on ophthalmology and otology complete the volume, which is above the average in the value of the matter it embodies.

Officers for 1880: President, Dr E. Dougalls, of Chicago; Secretary, Dr. T. D. Fitch; two vice presidents, treasurer, and assistant secretary.

TRANSACTIONS OF THE AMERICAN OPHTHALMOLOGICAL SOCIETY. Fifteenth Annual Meeting, Newport, 1879.

THE contents of this pamphlet embrace twenty articles, most of them quite short and well selected. It is noticeable that one-half the contributions come from New York City. A paper by Dr. Hasket Derby, on the "Influence on Refraction of Four Years of College Life," is well worthy of attention. He shows from careful examinations of classes in Amherst College that the percentage of emmetropia on entrance is 50.8; on graduation four years later, 36. The percentage of hypermetropia on admission is 5, on graduation 13.2; that of *myopia*, on admission, 44.2; on graduation, 50.8.

A paper showing much research is by Dr Henry D. Noyes, on "Statistics of Extractions of Cataract by the Flap Operation and by Von Graefe's Method." From a comparison of over 10,000 cases of each kind he shows that the percentage of loss by the old flap operation was about 17; that by Von Graefe's operation, 6.52 per cent. He concludes that an average loss of 6 per cent. is what is to be expected in Graefe's method when done in the most skilful manner.

TRANSACTIONS OF THE AMERICAN OTOLOGICAL SOCIETY. Twelfth Annual Meeting, Newport, 1879.

THESE transactions show the same prominence of New York City in the specialties as does the work of the Ophthalmological Society. Five out of the eight articles are by New York physicians. The report on the Progress of Otology, by Dr. J. J. B. Vermyne, of New Bedford, and Dr. D. Webster, of New York, is an admirable one. The articles are clear, concise, and exhaustive. Among the items of progress given are these: Dr. H. Knapp stated that over 6 per cent. of all cases of ear disease have had primary acute purulent inflammation of the middle ear; Politzer denies that his method of inflating the ear is liable to cause rupture of the drumhead; Von Tröltsch says that of the 38,489 deaf-mutes in Germany less than one-half are congenital, and that in one-fifth of the cases early treatment would have prevented the condition.

The other articles are: "A Case of Menière's Disease following Parotitis," by Dr. H. D. Noyes; a "Contribution to the Pathology of the Temporal Bone," by Dr. T. R. Pooley; a "Case of Trephining of the Mastoid in Acute Suppurative Otitis Media, with Rapid and Perfect Recovery," by Dr. H. Knapp; a "Case of Purulent Inflammation of the Middle Ear, with Facial Paralysis," by Dr. C. J. Blake; a "Case of Supernumerary Auricle," by Dr. H. Knapp; an article on the "Use of Permanganate of Potassa in Chronic Otorrhœa," by Dr. Lucien Howe.

OUTLINES OF THE PRACTICE OF MEDICINE, with Special Reference to the Prognosis and Treatment of Disease. With Appropriate Formulæ and Illustrations. By SAMUEL FENWICK, M.D. Philadelphia: Lindsay Blakiston. 1880.

DR. FENWICK is Lecturer on the Practice of Medicine at the London Hospital. He has also written a very excellent work on "Medical Diagnosis." He announces that the book before us is an attempt to remedy the present tendency in medical teaching, to adopt physical diagnosis as the basis for treatment, to the disparagement of those indications furnished by symptoms.

In carrying out this design, most of the space is devoted to therapeutics, etiological and symptomological. The subject is prefaced by two chapters on the general treatment of diseases. Very little exception can be taken to the suggestions and directions for treatment throughout the book, so far as they go. They are sensible, and evidently those of a man of experience. There is a very general neglect among medical teachers to give proper prominence to therapeutics; we can see that a book devoted expressly to this department, and written for students, may be of much service. This is all the good we can say of it, however. The book is too short, and the directions too brief and indefinite, to be of much value to the working practitioner, though helpful, perhaps, to students.

MINOR GYNECOLOGICAL OPERATIONS AND APPLIANCES, for the Use of Students. By J. HALLIDAY CROOM, M.B., etc. Edinburgh: E. & S. Livingstone. 8vo, pp. 106. 1879.

MR. CROOM divides his book into two parts: 1. Diagnostic, and 2. Therapeutic. Under these heads he gives directions regarding vaginal examinations, the use of specula, sounds, tents, etc.; also the methods of treating ordinary uterine affections. The book has several good illustrations, including some colored lithographs.

Correspondence.

LEPROSY IN JAPAN AND ITS TREATMENT WITH COPAIBA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Leprosy has undoubtedly existed in Japan from a very early period. Though more prevalent in certain districts, isolated cases are met with in all parts of the empire. Among medical men as well as the laity the general belief is in its hereditary transmission. So strongly is the whole mass of the people imbued with this notion that the most rigid scrutiny is instituted into the family history of both contracting parties before a marriage alliance is entered into. The effect has been to limit the prevalence of this horrible malady far more than any legal enactments such as are enforced in the Sandwich Islands could do. Having given considerable attention to the subject, and having had an opportunity of treating quite a large number of cases, I shall take an early opportunity to give a detailed account of my experience in its treatment.

At present I find the most effective remedy to be copaiba administered internally and by inunction. In the anæsthetic form of the disease, especially, it is a remedial agency of undoubted potency.

D. B. SIMMONS, M.D.

KEN HOSPITAL, YOKOHAMA, JAPAN,

TESTING PEPSINE.

To the Editor of The Medical Record.

Dear Sir:—A new so-called method of testing pepsine has been circulated among the medical and pharmaceutical professions, based upon the precipitating power of certain neutral salts, wherein the bulk of matter precipitated is assumed to indicate the comparative pepsine strength of various saccharated and other pepsines.

I think this process is calculated to mislead, and is based upon erroneous data.

True pepsine has not been, and probably never will be, isolated, as I think it cannot exist except in combination with animal matter, by which it is absorbed, and held ready for action whenever conditions are suitable.

In support of this view, V. Wittich has found that fibrin is capable of absorbing pepsine, and that the latter cannot then be washed out with water; it becomes active, however, as soon as it is brought into contact with diluted hydrochloric acid, and the combination is dissolved, peptone formed, and pepsine set free (reproduced?).

Ebstein and Grutzner have since confirmed this, and O. Nasse also agrees to the views of V. Wittich, but is of the opinion that the combination of fibrin and pepsine is not of a mechanical, but of a chemical character. He has found that coagulated albumen is capable of fixing pancreatine and amylum ptyaline in the same manner (*Ph. Centr.*, No. 40, 1874, p. 330).

If this be the case, pepsine, pancreatine, and allied principles are obtained when precipitated by chloride of sodium, in combination with, probably, the hydrochloric acid of the chloride of sodium, chloride of sodium, and animal matter. The precipitated matter is not pepsine, but simply holds it in proportions, which may be great or small, the amount of precipitated matter being no indication of the amount of pepsine present.

The error, therefore, it appears to me, consists in viewing this precipitated matter as pepsine, when it is only a vehicle; and no test can be considered reliable unless it involves absolute digestion.

Respectfully,

R. W. Gardner.

170 William St., New York, March 4, 1880.

ASPHYXIA IN THE NEW-BORN.

To the Editor of The Medical Record.

Dear Sir:—In the Record for Dec. 20, 1879, I gave the history of a case of profound asphyxia of a new-born infant, and what I ventured to call a new method of treatment for such a condition. At the time of giving this case to the profession I had tried this method on but one subject, and as it is said to be difficult to found a dynasty on *one* subject, so it might seem that a single case of asphyxia was not sufficient to test the value of a new method of resuscitation. It might be said, however, that a *test* case —a case where all the ordinary methods have failed and the new method succeeds—*is* a sufficient trial of a new method, and at once places it among the novelties that have a *raison d'être*. But additional trials of this method, by myself and others, have proved beyond doubt the value of this method.

The great importance of this subject of resuscitation of the new-born has induced me to bring these additional cases to the notice of the profession through your columns.

The following case occurred at the Maternity Hospital on Blackwell's Island, and the notes were furnished me by permission of the house physician, Dr. Farnham:

Kate K——, 19 years of age, primipara, came into lying-in room at 1 A.M., Dec. 14, 1879, complaining of little "teasing" pains. These continued during the whole of December 14th, and until 9 A.M., December 15th, when they became "bearing down" in character. At 10 A.M., December 15th, vertex presenting, os uteri no larger than a two-cent piece, and had a firm, wiry edge. From this time on the os dilated very slowly indeed, notwithstanding that the woman had severe bearing-down pains, and that the different methods of treatment for rigid os were faithfully employed; so that the first stage of labor was not completed until 7.30 P.M., December 15th, forty-two hours after labor commenced. As the second stage progressed slowly, and the woman was much exhausted, forceps were applied when the head had been arrested at the outlet of the pelvis about fifteen minutes, and the child was delivered at 8.45 P.M. The cord was immediately tied and cut. The color of the child was a dirty white, with almost black eyelids, ears, nose, lips, fingers, toes, and scalp, and the child gave no sign of life. The child was slapped on hips and buttocks with hands, and alternately with dry towels and with towels wet with ice-water. It was dipped into the hot-water bath, and had cold water dashed over it. Meantime Marshall Hall's method of artificial respiration was being performed. These various means of resuscitation were tried for fully fifteen minutes without restoring the first sign of animation.

Dr. Forest's method of resuscitation was then resorted to. The child was placed in a small bath-tub containing three to four inches of hot water (temperature about 100° F.). The child was held in the sitting posture, with the left hand of operator so placed on the child's back that the thumb and first finger supported and controlled the child's head; the second and third fingers were disposed over upper part of child's back, while the little finger extended down to lower part of dorsal portion of the spine behind. The right hand grasped both hands of the child. The movements were begun by the right hand carrying both hands of the child up, over, and back of child's head; then the thumb and forefinger of left hand allowed the head to fall backward, while the left little finger pressed up the dorsal portion of spine, producing a slight opisthotonos. This was the movement of extension. The arms of the child were now lowered upon its chest so that the right hand of operator, still grasping the child's hands, supported front of child's head and thorax. The child's body was then bent forward, supported by one hand in front and one behind, and a sudden pressure downward was given it, producing the same effect in forcing air from the lungs that a sudden, forcible sitting-down would have.

The movement of extension was then commenced again as described above, *i. e.*, the thorax fully extended, the head thrown back, and the arms carried above child's head.

As no air was heard to enter or leave the child's lungs as yet, though perhaps the child's lips were a trifle brighter in color, when the next movement of extension was being made, the mouth of operator was applied to the mouth of the child, and the lungs forcibly inflated by the breath of the operator; then, as the next movement of flexion was being completed, a slight bubbling of air from child's mouth and nose

could be heard. Then the third and fourth movements of extension and flexion were made. During the fifth the child's lungs were again forcibly dilated by breath from the operator.

After the movements, as above described, were kept up for about twenty minutes (the temperature of water meantime having been kept up by additions of hot water), the child was able to perform some irregular, feeble movements of respiration, which gradually became stronger and more frequent. But, as expiration was somewhat feeble and impeded with mucus in the larynx, the child was allowed to remain some time longer in the hot water, while assistance was given to the child by squeezing the lower part of the thorax during each voluntary effort at expiration. The movements of extension and flexion were kept up altogether for about thirty-five minutes. An assistant, who held the hips of the child to keep them from sliding about on the bottom of the bath-tub, dashed the water over the child's chest whenever it was exposed during the movements of extension. The child the following day seemed strong and well.

The following cases occurred in my own practice, during December, 1879:

Mary P——, aged 28 years, mother of three children. Taken in labor December 11th, 6 A.M. When I saw her at 9 A.M., the os was fully dilated and the membranes unruptured, child presenting by the breech. The pains, which had been strong, seemed to die away after my arrival. After waiting an hour, I ruptured the membranes and disengaged one foot. The pains came on strongly, and the child was born as far as the shoulders. The back of the child was posterior, while the neck of the child was so rotated that the occiput was toward the mother's right acetabulum. Both arms were above the head, the anterior arm carried around behind the occiput, and firmly wedged there. The disengagement of the arms occasioned much delay, and meantime pulsations in the cord had entirely ceased. After some five minutes' efforts, by rotating the body of the child, as recommended by Dr. Barnes in his "Obstetric Operations," I succeeded in disengaging the arm, and then easily delivered the head.

The child, when born, was badly asphyxiated; the fœtal heart could be felt with difficulty; no pulsation in cord; no sign of reflex action when my finger was introduced into the larynx, and the color of the child was a bluish white.

I called for a wooden pail, filled nearly half full of water, at a temperature of about 110°, and placed the child in this in the sitting posture. Then I commenced artificial respiration, as described in the case narrated above, and still more fully in my previous article. As in all the cases, while performing the movement of extension, I frequently placed my lips to the child's mouth, and inflated its lungs with my breath. Then, at the next movement of flexion, and for a few movements thereafter, air could be heard bubbling from child's mouth and nose. After about fifteen minutes' persistent effort, the child gave occasional spasmodic gasps, which gradually became more and more frequent. It was more than an hour before respiration was fully established. The child made a good recovery.

Case III.—Mary W——, aged 26, had one child, which "came cross-birth," and was killed during delivery.

On examination, found the os fully dilated, membranes unruptured, and child presenting by right shoulder, dorso-anterior. Gave chloroform, and by external manipulation partly turned the child, and then, rupturing the membranes, easily seized the left foot. Some delay occurred during the delivery of the arms and head, and the child was asphyxiated when born. Ten minutes' efforts at resuscitation with the hot water bath, and artificial respiration with the child in the sitting posture, gave the first signs of returning animation. The child made a complete recovery.

These three cases, and the one mentioned in my previous article, would seem sufficient to test this method of resuscitation. In two of these cases all the ordinary methods were tried, and failed before this method I have described was tried at all. As I said in my previous article, the value of this method of resuscitation consists in combining the very best method of artificial respiration with the very best, and in these cases only practical, stimulant to the circulation, namely, the continuous hot water bath. The first fills the lungs with air, while the second sets the blood in active circulation, so that it may become aerated in the lungs, and then be carried on to stimulate the nerve-centres of respiration and circulation. In a slight case of asphyxia, where the heart can be felt beating strongly, the hot water is not indicated, as artificial respiration alone will be sufficient. But in other cases, where the cardiac pulsations are but feebly felt, if felt at all—where stimulants to excite reflex action, such as flagellations, hot and cold douches, etc., fail to arouse animation, then this method described above may be resorted to with a well-grounded hope of success.

W. E. Forest, M.D.

168 Spring Street.

ASPIRATION FOR STRANGULATED HERNIA.

PROBABLY THE FIRST CASE IN WHICH IT WAS TRIED.

To the Editor of the Medical Record.

Sir:—I think I have discovered the first case where the gut was aspirated for strangulated hernia. I was called a few weeks ago to a man who had some difficulty in wearing a truss. He told me the following story:

Twenty-eight years ago he was troubled by his rupture getting down and called in his family physician for relief. The rupture could not be reduced. He told the doctor that all that was necessary was to plung something in and let out the air. The doctor went home for some medicines, which was several miles away. While gone, he made an instrument, plunged it into the gut, the tumor collapsed, and he went into the field haying at once with no trouble. I put no confidence in the story (for the best of people will lie on such subjects) until he produced the instrument. I saw at once that it would be serviceable as an aspirating needle. It is at least novel and ingenious. He says he made it in this way: First made a conical hole in a hard board, took a common large-sized needle and held it in the centre, run in around it melted pewter, when cold filed it into shape.

He says that he plunged it into the gut about three-fourths of an inch, and was relieved at once. I have the instrument in my possession. This was done twenty-eight years ago. I think this man, though a farmer, has a good claim for priority in aspirating for strangulated hernia.

Respectfully,

James Oliver, M.D.

Athol, Mass., March 17, 1880.

A NEW CAUSE FOR TUBERCULOUS DISEASE.

To the Editor of The Medical Record.

Sir :—The etiology of disease is being studied with a thoroughness very commendable. To the imaginative mind it would appear to be possible that the fons and origo of every disease will eventually be known, and the necessary means for prevention will be taken in due course. Since the promulgation of the germ theory a new light has been thrown upon the pathway of enthusiastic investigating etiologists. With his olfactories alive for sewer-gas and his microscope adjusted for bacteria, his procrustean tendencies are more and more satisfied the farther he proceeds; just the same as a pathologist who has no other name for a morbid growth, and calls it a sarcoma, so the searcher for the cause of disease speaks of the disease germ, and no one cares to go farther. And who can fail to be impressed with the learned essays that are being scattered broadcast over the land, and in which are the diagrams of pipes, traps, and sewer-mains from which the dreadful gas is shown to escape in all possible directions by means of artistically twisted arrows finding their way into every undesirable place imaginable? Generally speaking, the householder who is not afraid of the bills of the man who has a practical knowledge of traps, waste-pipes, etc., can keep his mind easy regarding the fruitful cause of innumerable diseases. But, although sewer-gas may be considered as the germ producing element of our age, the grandparent of *all* the ills of advanced civilization, it appears that we have not yet arrived at the end of the chapter. From the present lookout it would seem that there is to be an infecting germ for every special disease, and each germ is to have its special medium of attack. The latest investigation bearing on this point has been made in reference to the cause of phthisis. According to a certain German savant, it seems to be proven that a fruitful cause of phthisis is the drinking of the milk of tuberculous cows. The germs of the disease presumably pass from the milk of the tuberculous animal into the stomach of the victim, and so on, until the air-vesicles are reached, and phthisis results. One strong proof of this is that ten per cent. of the cows kept in towns are said to be diseased, and that persons with consumptive tendencies are fond of milk. There is, consequently, one chance in ten that the healthy and unsuspecting drinker may come across the milk of one of these diseased cows, and that the statistics of phthisis will rise accordingly. There does not seem to be a reasonable doubt concerning the connection between cause and effect, at least according to the germ theory, and the only practical way out of the difficulty would appear to be either to make every dairyman an auscultator or recommend each consumer to look after his own cow. If both of these is impossible, we must calmly wait for the disease to develop itself, and then be ready with the benzoate of soda.

S.

New York.

TRACHEOTOMY WITHOUT THE TUBE.

To the Editor of The Medical Record.

Sir :—In No. 3 of the Record, Dr. Mitivier, of Holyoke, wishes some one to give a description of a new mode of performing tracheotomy without a canula, mentioned in some former number of this journal. I do not recollect the proposals made in that contribution, and the number is not at my hands; but, having in several instances met with the same disastrous difficulties in the after-treatment of tracheotomy as referred to by Dr. Mitivier, which sometimes annihilated the anticipated success when least expected, I have some time ago contrived a little instrument to supplant that dangerous apparatus, the tube, resolved to use it whenever an opportunity should offer. This occurred a few weeks ago, and, the result being a very satisfactory one as to the working of the instrument, I beg leave to give you in short the description of the case, the instrument, and the *modus operandi*.

The case was one of severe diphtheria in a boy of seven years. When I first saw him, about the third day of the disease, thick, coherent membranes covered the arches of the palate and the posterior wall of the pharynx; the uvula also thickly coated, being swollen to the size of a large bean, and resting on the epiglottis. This state of things, at the outset of the disease, I always consider very ominous, because the local process, in spite of the most energetic treatment, almost invariably enters the larynx, and causes either stenosis or septicæmia, or immigration of the bacteria into the veins or the substance of the heart, with its consequences. My local treatment consists for the last eleven years in the hourly application of a solution of an iodide of phenole after this formula:

℞. Acid. carbol. cryst.,
Spir. vini..... āā 5.00
Tr. iodi..... ..... 5.00
Aquæ dest.,
Glycerini..... āā 5.00
M.

This gives a clear, brown mixture, which does not act as a caustic, but merely as an antiseptic. I apply it with a small sponge on a wire probang, or with a forceps, in order to remove at the same time all loosened membranes, even down into the larynx when necessary. This treatment, when early commenced and combined with antipyretic measures, usually succeeds in arresting the local process within five to eight days, and the patients recover. In this case it failed, for, although the fever was reduced to a normal temperature from the second day, the epiglottis became involved on the third, sticking up like an immovable piece of bone, and on the seventh tracheotomy was performed on account of complete stenosis of the larynx. I had my instrument ready for trial, but, the boy being extremely weak, I hastened to open the trachea before taking up the deep fascia. This caused a little hemorrhage, and at the same time my assistant took out the hook from the trachea, so that I had to feel my way with the finger. There was no time to lose, and, not being sure of the facility of introducing the new instrument without seeing, I inserted a silver tube under the guidance of the finger. The boy rose at once, breathed perfectly freely, and felt extremely comfortable after the preceding agony. As the respiration remained quite free, I thought best to leave the tube in its place, reserving the experiment for some other occasion. The case went on quite favorably till the third day, when, under complete loss of appetite, vomiting of blackish mucus set in, accompanied by blood-colored, slimy discharges from the bowels. There was also a slight rising of pulse and temperature, but not the least obstruction of the air-passages. On the fourth day I left him quite satisfied, as the tem-

peratare and pulse seemed normal, but was summoned an hour afterward by a message that he had suddenly died from suffocation. I found him alive, but very prostrated. The mother had resolutely torn out the inner tube, and, through the elastic catheter, according to her instructions, removed some bloody mucus, when the boy began to breathe again. While I was still occupied with him, a new fit of suffocation came on. I introduced the catheter down to the bifurcation without the least resistance, aspirated some mucus, but without avail. The child struggled for air, but none entered through the open tube, and I thought he would die under my hands. Without hesitation I tore out the whole tube, which was followed by a large piece of membrane and free respiration. Now, this piece of membrane, about two inches long, had apparently plugged up the lower opening of the tube without being able to enter it or go through, so that it was without any feeling of resistance pushed down by the catheter, and then thrown up again and arrested by the margin of the tube. Had I not been present, the child could not have escaped death by suffocation.

I now inserted my instrument, which I had left there for all emergencies. It slipped in, as it were, by itself, and was retained firmly by the walls of the trachea and the upper and lower margin of the wound. The boy did not feel the change in the wound, there was no stretching, no sensation of pain or discomfort, but very free and easy breathing through the oval-shaped opening. The instrument was, besides, secured by a tape round the neck like the tube.

From this moment the respiration was never embarrassed again, small pieces of membrane and mucus being thrown out occasionally without the least difficulty. The night passed quietly, but in the morning I found the pulse 36 per minute, T. 36° Cels. (96.8° F.). Stimulants, injections of ether and liquid ammonia were of no avail to raise the heart's action, and the boy died in the evening, apparently of paralysis of the heart, respiration remaining free and easy to the last moment. Out of several hundred cases this was the first I saw die of paralysis of the heart. But a week later another boy of four years, without stenosis, and while the local process was rapidly healing, died on the ninth day under precisely the same symptoms.

The instrument is very simple, and easily understood by the diagram, which shows it in its natural

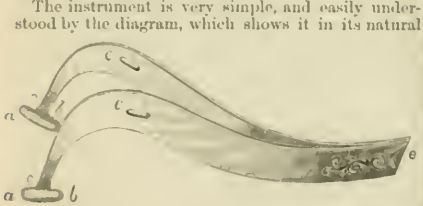

Fig. 1.

size (Fig. 1). It is made of German silver, and resembles a spring-forceps, the branches of which, about one millimetre in thickness, are just strong enough to hold the tracheal wound oval-shaped open, without stretching the tissues too forcibly. The two cross-bars, *a*, *b*, six millimetres long, are inside concave, outside convex, with rounded and flattened ends at *a* and *b*, so that, when the two branches meet, they form together a flattened, wedge-shaped little tube.

When the trachea is opened by a cut just as long as the cross-bar, or even a little longer, and still held by the hook, the "tracheo-diaspast" (as with a Greek term it might be called) is seized at *d* between thumb and index pressed together, so that the bars close, and the wedge-shaped end *a* introduced into the gaping wound, pushed upward until arrested at *c*, when the other end *b* will easily slip in at the lower edge of the wound. The wound forms then an oval opening; the bars are firmly held by pressing gently against the side-walls; but the whole instrument is to be pushed a very little downward, so that the two ends of the bars are covered by the upper and lower margin of the wound. Through the slot at *d* a tape goes round the neck from each side of the instrument to secure it still firmer in its place. The lower end *e* rests on the sternum.

The advantages of this instrument are:

1. The facility of introducing it.

2. The safety against the plugging-up of the trachea by membranes or clots, the passage being constantly free for anything to pass.

3. The easy access for medicated sprays, probangs, aspirators, etc. For cleansing the trachea, I had a sort of inverted brush constructed, a bunch of camel-hair fastened to a flexible wire, the hair turning upward (Fig. 2) so that it goes in very smoothly, while

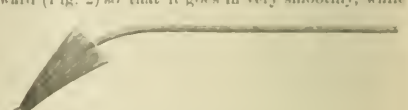

Fig. 2.

in withdrawing it the hair-brush spreads out to bring up anything loosely attached to the tracheal walls. It can also be saturated with medicated solutions.

To seize the trachea, I used a hook with a slit in its curvature (Fig. 3) for the direction of the scalpel

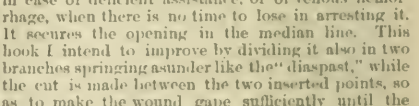

Fig. 3.

in case of deficient assistance, or of venous hemorrhage, when there is no time to lose in arresting it. It secures the opening in the median line. This hook I intend to improve by dividing it also in two branches springing asunder like the "diaspast," while the cut is made between the two inserted points, so as to make the wound gape sufficiently until the diaspast is inserted.

Respectfully yours,
C. G. Rolhe, M.D.

Altenburg, Germany, March, 1880.

Gratuitous Services to Clergymen.—In regard to charging the clergy for medical services, the following resolution was adopted at the meeting of the Allegan County, Mich., Medical Association, July 26, 1877:

"*Resolved*, That the custom of giving our professional services to clergymen and their families gratuitously is unjust to a large class of our patrons, whose incomes are much less than the average incomes of theirs, and that we will hereafter adopt the practice of charging them the same as others."

Obituary.

CHARLES A. ROBERTSON, M.D.,

ALBANY, N. Y.

Dr. Charles A. Robertson, the distinguished ophthalmologist of Albany, N. Y., died of empyema April 1, 1880, aged fifty-one years. He was born in Mobile, Alabama, in 1829, graduated at Harvard University in 1850, and from the Jefferson Medical College, Philadelphia, in 1853. After a residence of a year and a half abroad, studying with the masters of his specialty, he commenced practice in Boston, Mass., where he became connected with the Boston Eye Infirmary. He was surgeon of the 159th Regiment, N. Y. S. V., during the rebellion. After the war Dr. Robertson removed to Albany, where he resided the remainder of his life. He immediately took a foremost rank in his specialty, and patients came to him from every section of the State and country for advice and treatment. For many years he was surgeon in charge of diseases of the eye and ear at St. Peter's Hospital and the Albany Hospital, and also of the eye and ear relief located at Troy and Albany. For three years he was connected with the Troy Hospital, and was one of the founders of the American Ophthalmological Society and the American Otological Society. Dr. Robertson was a member of the State Medical Society and the Albany County Medical Society, of which he served as president two years ago. His literary abilities were of a high order, and he proved on many occasions that he was a man of deep learning in fields other than medicine and surgery.

His writings are quite numerous, and are of more than temporary value, among which are "Some Curious Reflex Phenomena after Injury of the Eye," July, 1870; "Review of Report of Last Illness of Dr. Alden March," January, 1870; "Medical Ethics and Medical Dissensions," January, 1871; "An Eye Case in the Courts," Dec., 1873; "Diagnosis of Diseases of the Eye," February, 1874; "Old Eyes Made New, or Injury from Eye Cups," February, 1875; and "Obituary of Dr. J. V. P. Quackenbush." Dr. Robertson was married in 1853 to Ellen A. Fuller, of Cambridge, Mass., but no children resulted from the union. He was elected president of the Young Men's Association in the spring of 1874, and served in that position throughout his term with ability and untiring energy, looking always to the best interests of that institution. He was also prominently connected with the Masonic fraternity, being a member of the Capital City Chapter, No. 242, R. A. M.; De Witt Clinton Council, No. 22, R. and S. M.; Temple Commandery, No. 2, K. T., and the several bodies of the Ancient and Accepted Scottish Rite. He was a man of strong social instincts, and, consequently, had hosts of warm friends. By his death Albany loses one of the brightest ornaments of the medical profession, and a public-spirited citizen. The remains will be taken to Boston, Mass., for interment in the Mount Auburn cemetery, where the family burial plot is situated.

The British Naval Medical Service has for some time needed reform. Recently a Royal Commission of seven has been appointed by the Government to investigate the matter, and report upon the measures needed.

New Instruments.

A NEW UTERINE DILATOR.

By A. ADY, M.D.,

WEST LIBERTY, IOWA.

In performing Ball's operation upon the flexed uterus, for the relief of that intractable form of dysmenorrhea which is due to those flexures and contraction of the cervix, I found the dilators in common use to work very imperfectly, and suggested to Messrs. Tiemann & Co. that they construct one that would have sufficient force with the blades opening parallel to each other, by the aid of two brackets moved by a screw through the handle. They soon manufactured the beautiful, neat, and efficient instrument represented by the above woodcut. I found instruments opening by one bracket, near the point, to be of sufficient force, but when open they were much wider at the point than anywhere else, and, in spite of the efforts of the operator, would ascend to the fundus of the uterus, and, in order to produce the proper dilatation, had to be dragged through the cervical canal by pulling upon the handle, a procedure that was likely to cause more or less laceration of the external os. Those wherein the brackets were set back some inches from the point, the blades would spring together at the point and slip out, unless they were serated, which increased the danger of laceration and unfitted the instrument for many other uses that the above dilator may be used for.

I have found it all that I could desire in dilating the flexed and contracted cervix uteri.

This instrument exerts great force with surprising ease to the operator. Those who have been in the habit of using any of the various dilators might easily produce laceration with this, but for the scale of figures on the handle, which give a sure index to the width the blades are opened.

A HANDY OPHTHALMOSCOPIC SCREEN.

By S. HEMINGWAY, M.D.,

EXAMINING PHYSICIAN TO DEPARTMENT OF CHARITIES AND CORRECTION, BELLEVUE HOSPITAL, NEW YORK.

The great difficulty experienced, at times, of making ophthalmoscopic examinations in hospital, and also in the physician's office, was the occasion of my devising the ophthalmoscopic screen, some years ago, while resident physician to the Epileptic and Paralytic Hospital, N. Y. In the former instance, if the patient is unable to leave the bed, the result of an examination with the ophthalmoscope, made after closing all the blinds in the ward, and with the unsteady light held by an assistant, is unsatisfactory to the physician and unpleasant to others in the ward;

and, in the latter instance, as a rule, the physician has no proper means, unless he is a specialist, of making these examinations, without the expense of a room, devoted expressly to the purpose. The expense of the screen is very small, and if used in an hospital it is adapted for the ordinary purposes of the ward screen when not used in making examinations. A common three-fold bed-screen of proper dimensions, with a removable slanting roof about six inches wide, a few yards of black paper muslin, and a lamp, complete the apparatus. The screen should be six and a half (6½) feet high; the middle fold six (6) feet wide, and the side folds each five (5) feet in width. The folds should each have three horizontal connecting pieces—at the top, centre, and near the bottom. For the arrangement of the light, the *middle* fold has a perpendicular piece of wood, of the same circumference as that composing the frame. This perpendicular piece *slides* between the top and centre cross-pieces, being neatly fastened to them by a loop of tin or iron at either end. This allows a sliding to the right or to the left. An ordinary lamp bracket, with a clamp that can be attached to the perpendicular piece, is made to slide up or down. The screen is made thus complex, in order to accommodate the light to any position—either up or down, to the right or to the left. The roof is made of light pine, painted black on its inner sides, and is used not only to protect the covering, but also to give solidity to the frame; it is not hinged to the frame, but is held in place by jaws formed of wood, fitting neatly at each corner, and they should hold the roof firmly in its place. The concluding portion is made from a few yards of black paper muslin, cut square at the top, to fit the roof, and long enough to fall to the floor, draping all four sides.

By hinging the connecting pieces, the frame can be folded lengthwise as well as sidewise, thus diminishing the space it would otherwise occupy when not in use. There is ample room for two persons inside the screen, and should protracted examinations be necessary, a valve-like opening for ventilation can be made by pasting a moderately large circular piece of pasteboard on the top of the muslin, and then by cutting the muslin *almost* completely around it. The adjustment of the screen around the head of a bed is so evident that it needs no explanation. The hospital bed being on an average three feet wide, there is an abundance of room.

I have the screen in use, and find it practicable, and also of great service in laryngoscopic and other examinations of a like nature.

115 East 39th Street, N. Y.

A GRADUATED PROBE.

By M. G. RAEFLE, M.D.,

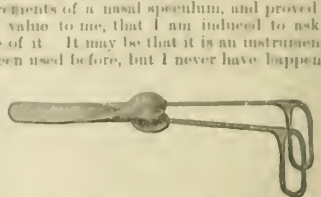
NEW YORK.

Feeling the necessity of procuring an instrument for the accurate measurement of wounds for medico-legal purposes, I made inquiries with that view, but found that no such instrument was made, with the exception of the ordinary rule. I therefore had constructed an instrument which seems to fulfil the indications I had in view. It is a simple probe, tipped like that of Nélaton, with flattened shank to enable graduation. It is made by Messrs. Tiemann & Co. of pliable material, and graduated to eight inches. Used as an ordinary probe, it enables the operator to measure at a glance the depth of a wound, an advantage which I hope will secure for it a permanent place in the armamentarium chirurgicum. It can be obtained at a very reasonable price.

A NEW NASAL SPECULUM.

By F. H. BOSWORTH, M.D.

This little instrument, which has been made for me by Mr. W. F. Ford, has fulfilled so perfectly all the requirements of a nasal speculum, and proved of so much value to me, that I am induced to ask your notice of it. It may be that it is an instrument that has been used before, but I never have happened to see it.



It is light and perfectly self retaining. It elevates the tip of the nose somewhat by the width of the blade, while at the same time it dilates the flexible portion of the nostril as far as the patient will tolerate it; and, finally, it is quite inexpensive.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from March 28 to April 3, 1880.

Brewer, J. W., Capt. and Asst.-Surgeon. The sick-leave granted him from A. G. O., Sept. 22, 1879, extended three months on surgeon's certificate of disability. S. O. 67. A. G. O., March 26, 1880.

DeWitt, C., Capt. and Asst.-Surgeon. To accompany Co. B., 20th Infy. from Fort Sidney, Neb., to Fort Niobrara, and report to the commanding officer thereat for duty. S. O. 26, Dept. of the Platte, March 26, 1880.

Moseley, E. B., Capt. and Asst.-Surgeon. Having relinquished remainder of leave of absence, relieved from duty with the Ute Expedition and assigned to duty at Fort Sidney, Neb. S. O. 26. C. S., Dept. of the Platte.

Medical Items and News.

Contagious Diseases — Weekly Statement. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending April 10, 1880.

April 3, 1880.	0	11	38	6	79	45	0	0

A Medical Vacancy.— Mr. M. B. Van Duser, editor of the *Long Island Traveller*, Southold, L. I., informs us that Dr. A. L. Sweet has removed from Southold, "leaving a good opening for an active

and competent physician and surgeon." It is to be hoped that there are still some young medical men not already engaged in active practice, who may respond to this invitation.

Effect of Chloral on the Eyes.—Dr. F. P. Stevens, of this city, writes: "Noticing another communication in your last issue concerning the effect of chloral upon the eyes, I will state that a case of 'cephalalgia periodica' recently came under my care, in which chloral was used during the paroxysms. The patient afterward complaining of pain in the eyes, upon examination I found the conjunctivæ moderately congested, and the lids considerably swollen. This condition gradually improved, but had not entirely disappeared when last seen, seven days afterward. I will also add, that some time since a patient objected to the use of chloral because of the 'pain in the eyes which it always produced.'"

The Bill to Increase the Efficiency of the United States Marine Hospital Service, now before Congress, has been reported on favorably by the Committee. On March 31st it was referred to the Committee of the Whole. This bill provides for an increase in the number of surgeons and passed assistant and assistant surgeons, so that there shall be thirteen of the first and twenty-five of the second and third class. This, with about thirty acting assistant surgeons, makes the whole force number about seventy. The bill further provides that there shall be no appointments to the service without a previous competitive examination, and that the appointments shall be made by the President, by and with the advice and consent of the Senate. The whole tenor of the bill is toward promoting the efficiency of the service and elevating it entirely out of political influences. It has been very generally indorsed by medical organizations and prominent medical men. The prospects of its passage are very good.

Pleuro-Pneumonia.—The State Legislature has appropriated $35,000 to carry on the work of stamping out pleuro-pneumonia.

A Serious Accident occurred to Dr. C. H. H. Sayre, son of Dr. Lewis A. Sayre, on the 5th instant. While walking rapidly into the Gilsey House he turned suddenly to go back to his coupe. His foot slipped, and he fell over the iron fence into the area between the hotel and the sidewalk, twenty feet below. He struck upon his knees. He was picked up unconscious, and found to have sustained a compound comminuted fracture of the left femur, about eight inches above the knee. The bones protruded so extensively that the ends had to be sawed off before the parts could be brought into apposition. Counter openings were then made, drainage tubes passed through the thigh, and the whole fixed in plaster-of-Paris, after Markoe's method. The operation lasted more than two hours.

The injury is a very serious one, but Dr. Sayre has a vigorous constitution, and his chances are thereby much increased. Dr. Sayre has shown much enthusiasm, energy, and skill since he entered the profession, and his accident will be widely regretted.

Medical and Surgical History of the War.—A dispatch from Washington, dated April 5th, states that the joint resolution directing that 10,000 copies of the "Medical and Surgical History of the War of the Rebellion" be printed was indefinitely postponed by the Senate.

The Milwaukee Test of the Thirtieth Dilution.—In December, 1878, the Milwaukee Homœopathic Academy of Medicine undertook to have a series of scientific tests of the thirtieth dilution of certain remedies. Several drugs were carefully prepared, diluted, and potentized strictly after the Hahnemannian method. Ten vials were then taken, the diluted drug put in one and sugar pellets only in the other. Sets of ten vials thus prepared were sent off to various physicians with the request that they test them and try to discover, by proper experiments, which vial held the drug. There was not a hearty response to this praiseworthy attempt at scientific investigation. Among thirteen reports, however, which we find tabulated in the St. Louis *Clinical Review*, in but one case was the right vial hit upon by the experimenter. In this one case there were but five vials from which to choose. Yet men with very considerable claims to intelligence will doubtless go on for many years to come prescribing the thirtieth dilution.

Battey's Operation in New York.—The operation for removal of the ovaries was performed on a patient in the New York Lunatic Asylum a short time ago. The patient was a young woman who had been insane for some time, but who had of late been suffering from attacks of catalepsy. It was thought that the insanity, or at least the cataleptic attacks, were due to some irritation of the ovaries, and their removal was undertaken by Dr. Montrose A. Pallen. Not much change in these organs was found. The patient died at the end of the third day.

A daily paper of this city, which is building up a reputation for scurrilities, learned of this occurrence, and published a long article misrepresenting and condemning the whole thing. The operation was skilfully performed, and the indications for it were quite as full as they ever are.

Battey's operation is still *sub judice*, however, its dangers are great, its promise of good always uncertain, and there is something repugnant in its unsexing a human being. The greatest care is therefore needed in diagnosing the proper cases, if there are such, for the operation.

A few months ago this operation, or something very near it, was performed in Bellevue Hospital. The patient died. It is to be hoped that both these cases will be reported.

Meetings of State Medical Societies.—The following State Medical Societies hold or have held meetings this month: Tennessee State Medical Society, at Knoxville, April 6th; Mississippi State Medical Society, at Vicksburg, April 7th; Alabama State Medical Society, at Huntsville, April 13th; Medico-Chirurgical Faculty of Maryland, at Baltimore, April 13th; South Carolina State Medical Society, at Columbia, April 20th; California State Medical Society, at San Francisco, April 21st; Georgia State Medical Society, at Augusta, April 26th.

Physicians to make Examinations for Color-blindness.—A circular has just been issued by the Secretary of the Treasury modifying the regulations relating to the examinations for color-blindness. It states that in view of the expense and hardships likely to accrue to pilots living at points remote from stations of the Marine Hospital Service in visiting such stations for the purpose of being examined for color-blindness, the regulations are altered so as to permit pilots to be examined by any respectable resident physician. Such physician can sign a certificate to the fact that the pilot is (or is not) color-blind. This certificate will then be taken to the local steamboat inspector, who will make out the pilot's license, or not, according to its reading. This

arrangement, however, does not apply to the applicants for original licenses.

As there are probably more than four thousand pilots in various parts of the State, it may be well to remind physicians that the best method of making examinations is that of Holmgren. A pile of worsteds, of various colors and shades of the same color, is placed before the person to be examined. A skein of worsted of a particular color is then selected and placed on one side, the examinee is then required to pick out all the worsteds which have any shade of this particular color. If he does this successfully, another color is selected and matched in the same way. It is generally sufficient to match two colors. Green and red are the ones oftenest used.

Crystal Anniversary Dinner of the East River Medical Association of the City of New York.—The fifteenth annual dinner of this association took place at Delmonico's March 30, 1880, and was in every respect a successful occasion. Seventeen physicians, with their wives, were present.

The members of this association claim that those who take part with them in the trials of life should also share in its joys, and so from year to year they invite the wives of members as honored guests.

The following were the regular toasts of the evening, with their respective respondents: The College of Physicians and Surgeons, by Dr. D. E. McSweeney; The Bellevue Medical College, by Dr. Martin Burke; The University Medical College, by Dr. P. J. Lynch; The Academy of Medicine, by Dr. Truman Nichols; The County Medical Society, by Dr. R. A. Barry; The East River Medical Association, by Dr. N. S. Roberts; The Ladies, by Dr. J. R. Taylor; Our Anniversary, by Dr. Henry E. Crampton.

Each lady received, at the close of the dinner, a richly engraved toilet bottle of finest cut-glass, filled with cologne, as a memento of the occasion.

The following are the officers of the association: President, Dr. N. S. Roberts; Vice-Presidents, Drs. J. R. Taylor and T. C. Finnell; Recording Secretary, Dr. Wm. J. Purcell; Corresponding Secretary, Dr. Henry E. Crampton; Treasurer, Dr. Veranus Morse; Trustees, Drs. John Burke, Daniel E. McSweeney, Truman Nichols, Alex. S. Hunter, Robert A. Barry, Patrick J. Lynch.

Traumatic Achromatopsia.—At a recent meeting of the Paris Société de Chirurgie, a case of traumatic achromatopsia was related. A colonel, æt. 25, was wounded by a ball in the temporal region; he had all the symptoms of a fracture of the cranium, almost complete loss of memory, and achromatopsia, which lasted for two years. During this time he could distinguish only white, black, and gray. The faculty of distinguishing colors returned successively after the discharge of small splinters of bone by the primary wound.

Professor Pettenkofer, of the University of Munich, has been given the Bavarian Royal Order of the Crown, for his researches in chemical hygiene and allied subjects.

Sir Thomas Watson was eighty-eight years old on the 7th ult.

A New French Pharmacopeia.—The French Minister of Public Instruction has appointed a commission to prepare a new edition of the Codex, or official formulary of medicinal and pharmaceutical preparations. The last edition was issued in 1867. We notice on the commission the names of Bouchardat, Hayem, Regnault, Vulpian, and Milne-Edwards.

The Fish Cultural Conventions—The Propagation of Oysters—Nutritive Value of Fish.—A number of papers of considerable scientific interest were read before the American Fish Cultural Association, which met in this city on the 30th and 31st ult. Prominent among these was an article on the propagation of the oyster, by Dr W. K. Brook, of Johns Hopkins University. The manner in which this propagation takes place had never before, he said, been thoroughly understood. Through studies made by him last summer, however, great light was thrown upon the subject. He found that the American oysters do not breed their young in the shell, as has been supposed, and that consequently the eggs can be impregnated artificially. An average oyster contains from six to nine million eggs, and one of large size may contain fifty millions. The plan pursued in fertilizing these eggs is to chop the male and female oyster up together, thus the fluids are mixed and the impregnation is made complete. The process of development immediately begins and goes on so rapidly that a change may be noted every fifteen seconds. In a very few hours the embryo is sufficiently formed to swim in the water. The shells at first are very small, and are not adjacent to each other. They grow very rapidly, closing down over the sides, and finally unite and form the hinge. In the short time of twenty-four hours the young oyster is able to take food, and from three days to a week it attains perfect form. During its early life it is a swimming animal. The oyster is able to reproduce his species at the end of a year's growth, and it is marketable at the age of three years.

A paper was read by Professor W. O. Atwater, of Wesleyan University, giving the results of chemical analyses of different species of fish, made by him. The flesh of the cod, he said, was only one-sixteenth solid matter, while that of the salmon was one-third solid. A comparison of the analyses made showed that the mackerel contained 17 per cent. of solid matter—the rest being water; halibut (lean), 20.6, shad 35, salmon 33.5, and bluefish 21.9. Taking medium beef as a standard of 100, the nutritious value of lean beef would be 91; fat beef, 112; fat pork, 116; cow's milk, 24; butter, 124; fresh codfish, 68; shad, 99; salmon, 101; and dried cod, 346.

Ovariotomy in the Sixth Month of Pregnancy without Interruption to Gestation.—Dr. Alfred L. Galabin reports in the *British Medical Journal* a case of ovariotomy, performed in the sixth month of pregnancy. The tumor was very large, and held eight pints of fluid. The operation, which lasted one hour and a quarter, was performed antiseptically. The woman had an attack of phlegmasia dolens on the fifteenth day, but otherwise did well, and was delivered of her child at full term. This is the only case of its kind ever reported.

The Royal Victoria Hospital at Netley caught fire on the 4th ult., and had a narrow escape from total destruction. The fire was, however, extinguished, after it had injured several wards. Some of the books of the library and a number of pathological specimens were lost.

Mrs. Ernest Hart, in the *London Medical Record*, punctures the theories of Dr. Norris in regard to an invisible or third corpuscular element in the blood.

Veterinary Colleges.—Prof. A. Liautard informs us that there are three veterinary colleges which are authorized by law to issue diplomas, instead of one college, as stated in a previous issue.

Original Lectures.

A LECTURE ON COCCYGODYNIA.

Delivered in Chicago Medical College,

By EDWARD W. JENKS, M.D., LL.D.,

PROFESSOR OF MEDICAL AND SURGICAL DISEASES OF WOMEN, AND OF CLINICAL GYNECOLOGY.

(Reported for The Medical Record.)

Your attention will be directed to-day to a disease of which little has been written, and yet an affection which may be met with by every practising physician, although not very frequently by any. The disease is known as coccygodynia, coccyodynia, coccygalgia, or coccyalgia, and is an affection which seems to be peculiar to women. I am prompted to discuss the subject at some length now, as one of the patients of our clinic presents pronounced symptoms of the disease.

This patient has been treated for uterine disease—a not uncommon occurrence—as coccygodynia has many symptoms, which are frequently attributed to, or are sometimes associated with, either uterine or rectal disorders. She complains of pain in the coccyx when sitting upon a hard seat, that the pain is aggravated by coughing, sneezing, or defecation. A physical examination of the pelvis and pelvic organs having been made, we find all of her pains were aggravated in attempting to move the coccyx. The bones are not inflamed, necrosed, or apparently diseased in any way. When they are in a condition of perfect rest, there is no pain, but when moved by my hand, or by the contraction of muscles having a coccygeal attachment, or by change of posture, the sufferings are severe. Without dwelling at present upon this particular case, I desire to direct your attention to a general consideration of the disease designated as coccygodynia.

About twenty-five years ago, Sir James Y. Simpson directed the attention of the profession, in one of his public lectures, to a peculiar form of disease of the coccyx, which had heretofore had no place in medical nomenclature, which he called coccygodynia. Since then this affection has been known as coccygodynia, coccyodynia, coccygalgia, and coccyalgia.

The lectures of Simpson on diseases of women were begun twenty-two years ago, in the *London Medical Gazette and Times*, and continued to be published in that journal for the following two years.

These lectures were first published in the United States in 1863. In one of his clinical lectures, Prof. Simpson directed the attention of his class to a case of disease in the hospital, saying, "you will find, I believe, no description of it in any book." He further stated that he purposed subjecting the patient to an operation on account of her disease, such as, so far as he was aware, had never been performed before, or, as he qualified his remark, "at least under similar circumstances."

Although Simpson was the first to give a significant name to this affection, an American surgeon of distinction was the first to recognize its existence, as well as operate for it.

The late Dr. J. C. Nott, of New York, but then a resident of Mobile, Ala., was the first to describe this disease in 1844, under the name of "neuralgia of the coccyx." He published the history of two cases in the *New Orleans Medical Journal*, one in 1844, and the other later, in which the symptoms were fully given. In each case the bones of the coccyx were extirpated, resulting in the complete relief of the suffering patients.

In consequence, Dr. Nott received many complimentary letters from prominent members of the profession, among which was one from Professor Charles Meigs, of Philadelphia, who attached great importance to the pathology and treatment of the disease brought to notice by Dr. Nott. It is related that the latter gentleman, in return for the complimentary remarks by Prof. Meigs, sent to him the two extirpated bones, which were annually exhibited by Prof. Meigs to his classes, as long as he continued to lecture in Jefferson College.

It was strange, that notwithstanding the publicity given to the papers of Dr. Nott, they failed to attract sufficient notice to become known to Simpson, and until quite recently there has been no allusion to the disease under consideration in the majority of the text-books upon either surgery or diseases of women.

The name first given to the disorder by Simpson, of coccygodynia, was dropped for a time, and it was generally designated "coccyodynia." In the clinical lectures of Prof. Simpson, published in 1863, the term "coccyodynia" is employed, but in the posthumous work of Professor Simpson, edited by his nephew,* coccygodynia is the word again made use of. It has also been adopted into the nomenclature of Robert Barnes,† and many of the leading European gynecologists.

Coccygodynia is, etymologically, the correct term, rather than coccyodynia, coccygalgia, or coccyalgia, to designate this disease, the literal meaning of which is "pain in the coccyx." The name "coccygodynia" does not in the least define the pathology of the affection, it simply means "pain in the coccyx," as we speak of pleurodynia or mastodynia, to designate pain in the side or breast.

This disorder consists of a peculiar state of the coccyx, or the muscles attached to it, rendering their contraction and the movements of the bone very painful, presenting a condition analogous to vaginismus, or fissure of the anus, when disease causes painful contractions of the constrictor vaginæ, or sphincter ani muscles.

Coccygodynia is not infrequent, as many cases have been observed since the attention of the profession has been called to it by surgeons who had seen it previously without regarding it as a special disorder.

The most marked peculiarity of coccygodynia is the sensitiveness and pain about the coccyx when there is movement of the bone, or pressure upon it. Most of the patients affected by it are obliged to sit on one hip, or with one side resting upon a chair, and the dread of causing pain to the sensitive part makes them awkward and miserable; they dread sitting down, and the erect posture, putting some of the muscles upon the stretch, causes pain, and thus many patients, able neither to sit nor stand with comfort, become bedridden, and, as a consequence of the supersensitiveness of the coccygeal region, are compelled to so support their persons with cushions, that no pressure is allowed upon the painful part. A deep inspiration, coughing, sneezing, or any sudden muscular movement, causes excruciating pain. Again, there are other cases where the symptoms are

* Clinical Lectures on Diseases of Women, by Sir James Y. Simpson, Bart. Edited by Alexander R. Simpson, M.D., etc., New York, 1872.

† A Clinical History of the Medical and Surgical Diseases of Women, by Robert Barnes, M.D., etc. Philadelphia, 1878.

not so aggravated; some, when walking, will have pain with every step, while others can walk without any painful sensation. Others, again, feel most pain when the bowels are evacuated, or under any circumstances in which the sphincter, or levator ani, or the ischio-coccygeal muscles are called into action. The pain in some instances is not acute, whereas in others it becomes perfectly intolerable.

As the disease has symptoms which are frequently attributable to, or even sometimes associated with uterine or rectal disease, patients treated without obtaining the expected relief from their suffering and trouble despair of being cured, lose faith in therapeutics, and expect, but all in vain, that the menopause will end their chronic discomfort. In this connection the mention of the menopause is significant of one peculiarity of this disorder, and that is the fact that it seems to be found only in women. Men may have inflammation or necrosis of the coccyx from traumatic causes, being analogous to coccygodynia, but the disease under consideration, upon the authority of the limited number of observers, when induced by traumatism, seems to be from the class of injuries to which the pelves of women alone are liable. It is an important fact that the disease frequently manifests itself from other causes than traumatic, as many cases occur where there is not the least indication of injury, inflammation, or any form of disease of the bone itself.

Drs. Simpson and Nott have found the disease exclusively among women; and Thomas, Barnes, Courty, Nonat, Gallard, Le Blond, Sinéty, and other recent authors, include this disease in their several works upon gynecology.

We have the most convincing proof that the pain of this disease is due to the action of muscles attached to the coccyx, and this development is a necessary consequence of the greater size of the female pelvis. Then, again, as already stated, the pelves of women are subject to injuries to which the pelves of men are not liable. Dr. Simpson says that it is by no means very easy to understand why the action of particular muscles should be attended with the production of pain in particular instances. It may be that the disease is confined to the tendons of the muscles, or the portion of the coccyx from which they spring; or possibly, certain muscles, during their action, may bring the bone in contact with a supersensitive nerve or some inflamed structure, and thus give rise to the painful sensation.

Dr. Nott, in a paper which was published in the *American Journal of Obstetrics* (vol. i., No. 3), and read by him before the New York Obstetrical Society, on Coccygodynia, spoke of an article taken from Virchow's *Archives of Pathology* (1860, vol. xviii.), on the "Glandula Coccygea of Man," in which an account is given of a small gland, usually about the size of a hempseed, situated on the anterior surface of the end of the coccyx, connected with filaments of the ganglion impar of the sympathetic nerve, and with the small branches of the arteria sacralis media, between the levator ani and the posterior end of the sphincter externus. The gland is rich in nerves derived from the terminal branches of the sympathetic, which form microscopic net-works perforating the stroma, and are occasionally seen connected with ganglion cells. The writer says: "Although the function of the organ is at present unknown, it is already of great interest to the pathologist because it is not only the seat of the so-called coccodynia but also of the hygromata cystica perinealea." "Upon what observation," adds Dr. Nott, "rests the assertion that coccalgia or coccygodynia is caused by this gland I am not informed." Harnes also calls attention to the article just mentioned, and adds of the glandula coccygea: "When we consider its highly vascular and nervous elements and its position, we can hardly doubt that in some cases it may be the seat of coccygodynia." Other writers seem to attach no importance to the "glandula coccygea" as connected with this disorder.

It is well to bear in mind the anatomy of the parts, in order to have a better understanding not only of the phenomena attending the affection, but of its pathology. There are attached to the coccyx, the greater and lesser sacro-sciatic ligaments, the ischio-coccygeus, the sphincter ani, and levator ani muscles, and some of the fibres of the gluteï muscles.

Certain movements of the body, as defecation, rising from the sitting posture, walking, etc., bring these muscles into activity, and it is a well-known law that where any chronic irritation is brought to bear upon a muscle, there follows a tendency to spasmodic contraction, and acute pain is produced whenever an effort is made to elongate the contracted muscle.

I have alluded to the analogy between the disease under consideration and fissure of the anus and vaginismus. In these latter affections, irritation in the region of the muscles causes painful contractions.

I am convinced, from cases coming under my observation, that the characteristic pain of coccygodynia is, in some cases at least, produced in the same way. Now we know that we can overcome the spasmodic contraction of vaginismus and fissure of the anus, by anæsthetizing the subject. I observed in one case, very markedly, that an attempt to examine a grumbling coccyx without an anæsthetic, caused the point to be drawn forward, and the muscles attached were made very tense, the contraction being accompanied by excruciating pain. The administration of ether caused the muscles to be relaxed, when the coccyx became exceedingly movable. Now, there is no pain in vaginismus or in fissure of the anus, when there is perfect rest of the parts, neither is there in coccygodynia; but, owing to the number of muscles attached to the coccyx, a slight movement of the body produces pain, because the movement involves their action.

This leads me to speak of the causes of this disorder. It need not be due exclusively to any injuries received during the process of parturition, for we find it among those who have never borne children, and even in the young and unmarried. Among the assignable causes, other than child-bearing, are direct injury inflicted upon the coccyx by blows or falls, certain forms of exercise, as riding on horseback, or undue exercise of any kind, exposure to cold, and other climatic influences. I am myself convinced, from observation in several instances, that vaginismus, or fissure of the anus, or any source of irritation to the muscles included in the vaginal, perineal, or coccygeal region, may lead to this affection. Courty alludes to the local influence of cold in causing the disease, and cites one case caused by the patient's habit of sleeping in bed with her "seat applied against the wall." Simpson and Scanzoni have observed the disease many times where the subjects had recently been in childbed. In nine cases mentioned by Scanzoni, the coccygeal pain was manifest immediately after the application of forceps.

As previously mentioned, there are some symp-

toms attending coccygodynia similar to those found in uterine diseases, hence the danger among a class of diagnosticians who class all troubles of women under the one head of uterine disorders, of mistaking one for the other, and of attributing the sufferings, of which they complain, to the sympathetic pain of affections of the womb.

Barnes,* writing of coccygodynia, states positively that he has "traced it to retroflexion of the uterus."

Nonat† says, that with one of his patients this pain was caused by the introduction of a large vaginal speculum. Nonat is of the opinion that coccygodynia "presents two forms differing by the nature and by the location of pain." Sometimes this pain has its seat specially in the sacro-coccygeal articulation, and then it may be of a rheumatic origin, or from a traumatic cause. He says that in the first it usually proceeds from exposure to cold, whereas in the latter it is usually provoked by some exterior violence, as by a blow, a fall, an exaggerated distention of the articulation by the head of a fœtus, forceps, or speculum. This author believes that sometimes the affection is of a nervous nature, and offers all the characters of neuralgia. It is then, especially, that it is to be ranked along with the neuralgic complication of uterine and peri-uterine affections.

Nonat, who has written but little that is valueless, expresses himself so positively and clearly on certain points regarding coccygodynia, that I quote further from him, not literally, but substantially in the abstract as follows: "When the coccygodynia is articular or sacro-coccygeal, it is augmented by pressure upon this point, by movements of the extremities of the coccyx, and by all changes of position a little '*brusque*.' It is also increased by a sitting position, and by efforts at defecation. The pain is of a lancinating character, and extends to neighboring parts.

"It can exist independently of all uterine or peri-uterine affections, but if present coincidently with one of these affections, it does not receive any modifications by their treatment.

"The neuralgic variety of coccygodynia does not occupy any seat as exclusive or as limited as the articular. The pain is more extended and more diffuse, extending to the parts near to the coccyx, sacrum, in the ano-perineal region, and in the direction of lumbar and sacral nerves. It is lancinating, and produces an hyperæsthesia of all of the skin in the sacro-coccygeal region; it is sometimes intermittent, while at other times it presents alternately remittences and exacerbations.

"These exacerbations are sometimes of extreme violence, they coincide more often with fluxionary and inflammatory recrudescence, which are themselves produced in uterine, or periuterine affections, particularly at menstrual epochs."

Neuralgic coccygodynia coexists, or alternates, sometimes with other neuralgic pains.

When coccygodynia is associated with disorder of the uterus or its annexes, it follows often a parallel progress with these diseases; increasing or diminishing with them, receiving a favorable influence from their treatment, and sometimes cured with them.

In some cases, however, the coccygeal pain is rebellious, and persists long after the uterine or periuterine disorder has disappeared. It then demands treatment for itself. Nonat seems to have devoted more space in his work than any other French writer has done to the consideration of this disorder. One of the very latest* volumes by a French author on "Diseases of Women," which, by the by, is an excellent work in many respects, devotes less than two pages to the subject of coccygodynia. In this chapter its pathological anatomy is disposed of in five lines, as follows: "There has evidently been described under this same title affections of variable nature. It is thus that there has been found lesions of the periosteum, or of the sacro-coccygeal articulation, an abnormal mobility, or an increased length of the coccyx."

With the exception of this remarkable clause, there is nothing on the subject, by this author, but what has appeared many times before.

A careful physical examination enables one to differentiate coccygodynia from any of the other disorders to which the region is liable. As a rule a valuable diagnostic sign is the extreme mobility, especially under the influence of anæsthetics of the supersensitive portion of the bone drawn forward by muscular action.

And now let us turn from the causes and the diagnosis of this disease to speak briefly of its treatment.

Cases of coccygodynia which arise from climatic causes may be similar to cases of myalgia in any of the other muscular structures of the body, will be of rather an acute type, and yield to very much the same treatment as is employed in myalgia.

Chronic cases of a mild character will sometimes yield to epispastics or mild blistering, and anodynes administered either by the mouth or rectum.

The hypodermic injection of morphia over the coccyx may overcome the irritability and painfulness of the muscles, and possibly effect a cure. But if the case does not improve in a short time under some of these modes of treatment we must have recourse to surgical art.

So far as my own experience has extended, I agree with the majority of those whose observations of the disease are on record, that in well-marked cases medicine is of but little avail.

Hence, we can understand why patients, deeming their disorder incurable, refuse to have further medical attendance. On the other hand it will not do to leave the disease to nature, as patients gradually become worn-out with pain, and while waiting for nature's tardy reparation, their vigor diminishes, oftentimes the chief reason being their inability to take any kind of exercise.

Courty, writing on the treatment of this affection, begins by the statement that "a cure is difficult to obtain." In illustration of this assertion he adds that in twenty-four cases observed by Scanzoni, ten only were terminated by cure, in nine there was simply amelioration; in the remaining five the definite results were unknown. The treatment employed was extremely varied, including leeches, blisters, belladonna, aconite, chloroform, morphine, etc.†

It would seem from this, that he relied only on medication, and did not, in a single instance, have recourse to surgical measures.

Courty further states that Hörschelmann of St. Petersburg, "obtained, in 1862, two cures, thanks to aconite," but both were children. This portion of the chapter concludes with the assertion that Simpson, who has seen all these means fail, first proposed the subcutaneous separation of the coccyx from its

† Maladies de l'uterus, etc., par A. Courty, Prof. etc., Paris, 1872.

muscular attachments, and when this does not effect a cure he does not hesitate to remove a part, or the whole of the coccyx.

The divisions of the disease by Nonat have a practical bearing upon its treatment that should not be lost sight of.

I took the position several years ago, in a published paper on the subject of this lecture, that the disease is not neuralgic, and that the majority of cases require surgical treatment only.* There was at that time but little literature relating to coccygodynia, and the conclusions regarding it were based almost exclusively on my own observations. Increased observation and knowledge leads me to believe that these *may be* typical cases of articular and neuralgic coccygodynia, and that medical treatment, to be intelligently directed, must depend on their differential diagnosis. Further, in every instance therapeutic means should be given a full and fair trial before having recourse to any kind of surgical operation. I say this on the authority of reliable observers, rather than from my own observation; the truth being, that while I have had some patients cured by the administration and local application of remedies, the majority of my patients with coccygodynia have been benefited only through surgical interference. It is taught that the treatment should be different in one variety than in the other. For instance: in the articular form it is important that the patient should repose in the horizontal position in bed, thus securing immobility of the pelvis.†

Each topical application of opium, or belladonna plaster, or chloral liniment, may often prove of service, but when the pain is severe more potent remedies are required, such as the hypodermic injection of morphine, or atropine, or a combination of the two.

In the neuralgic coccygodynia, according to Nonat,‡ "if the disorder does not yield to the treatment directed to the uterine or perinterine affection, with which it is so frequently complicated, it should then be treated as a simple neuralgia;" the use of topical applications are about the same as mentioned in connection with the articular form; hypodermic injection of morphine, or atropine, are essential in this disorder; rectal suppositories of opium and belladonna may be used with great advantage. I have myself prescribed, with good results, particularly when the coccygeal pain was aggravated by defecation, suppositories of extract of stramonium. If the coccygodynia is of an intermittent character, our principal therapeutic reliance is quinine, which should be freely and persistently administered.

Nonat says that two cases treated by him, where all the means just mentioned had failed, he succeeded in curing by the use of the actual cautery applied over all of the painful region. This author, who seems to have given medical therapeutics a fair and impartial trial, also concludes that the refractory cases that do not yield to treatment should be operated upon after the method proposed by Simpson.

I have spoken somewhat at length on the medical treatment of this disease, for the purpose of informing you how much you can reasonably expect from medication, and also to show you by what process of reasoning experienced gynæcologists have come to the conclusion that while in some instances medical treatment will effect cures, there is a limit to it where surgical aid must be sought, and through which radical cures can alone be effected.

There are two operations possible for the cure of this painful disorder, neither of which are attended with any great risk to the patient. The first I shall mention is a subcutaneous operation, originated by Simpson, which has for its object "the complete separation from the coccyx of the muscular and tendinous fibres that are in connection with it," upon a principle somewhat similar to common operations for fissure of the anus and for vaginismus. To effect this, a tenotomy knife may be passed underneath the skin at the inferior portion of the coccyx, then turned flat upon the bone, and all the muscular and tendinous attachments severed, first upon one side and then on the other, as far up as the sacro-coccygeal articulation. The operation is quickly and easily performed, attended with but little pain or loss of blood, and by this simple proceeding patients are not unfrequently instantly relieved from their sufferings, and permanently cured.

Simpson relates one case of a lady who had long suffered from coccygodynia, where, while he was performing this operation, the slender knife broke deep in the tissues.

He told the patient of it, and she at once raised herself up, alarmed to hear of the calamity; "but," he adds, "before I had done telling her of what had happened, she had time, in sitting up, to discover that she had been cured of her disease, and, rejoiced at the discovery, quickly replied: 'Oh! never mind, my pain is gone—let the knife remain;' and there, for aught I know, it remains to-day."

The other operation is the extirpation of part or the whole of the coccyx. In very fleshy women the proceeding just mentioned is not easily performed, and in the case of patients where the subcutaneous operation may have relieved for a time, but not permanently cured, amputation of the coccyx should be resorted to, as it effects a radical cure.

There are certain conditions where I would perform the latter operation instead of prefacing it by the former, as when we have reason to think the bone is diseased, and in such cases, as with one of my own, where the coccyx was extremely painful and movable, and with the point drawn forward by the action of the muscles, so that the mobile portion was about at a right angle to the remaining part, acting as a foreign body and as a constant irritant. I also deem it better to remove the bone when it is both supersensitive and anchylosed, which, however, is an exceptional condition.

The mode of operating for amputation of the coccyx is as follows: Anæsthetize the patient, and place her upon her right side, that the index finger of the left hand may be introduced into the rectum to press the coccyx backward, and as a guide during the progress of the operation.

Cutting down to the bone with a scalpel, it can be further separated from its attachments by means of scissors, or a knife, as we may choose, and selecting the location where amputation is to be made, we can then disarticulate at the joint, or follow the mode of Simpson, who used the bone-forceps and cut the bone without reference to joints.

By one of the procedures mentioned, namely, separation or amputation, we can confidently expect a cure; and as neither is attended with danger, we are also able to class these operations among the satisfactory ones of surgery.

I cannot conclude without giving you two important points relating to amputation, which were taught

---

* Coccygodynia. A paper read before the Mich. State Med. Soc., June 12, 1873. By Edward W. Jenks, M.D., etc.

† Nonat, op. citat., p. 1620.

‡ Op. citat., p. 1020.

me by my earliest operations, as follows: 1st. In case you amputate the bone by means of cutting forceps, remember that the bone of the stump should be "rounded off," so that there will be no sharp points to prick and annoy the patient whenever the skin of that region is made tense. In one patient I operated upon, where the removal of the bones of the coccyx put an end to a long period of suffering in every respect, except the one just named, a second operation became a necessity.

2d. I believe that disarticulation is the better plan; and if you decide to operate by this mode, remember that in case there is articular cartilage on the stump, it should not be allowed to remain intact; on the contrary, you should cut away thin slices of the cartilage, by reason of which the process of healing will be quickened and made more perfect.

Original Communications.

TREATMENT OF SUBACUTE AND CHRONIC GOUT.

By ALEXANDER HADDEN, M.D.,

VISITING PHYSICIAN TO THE PRESBYTERIAN HOSPITAL, NEW YORK.

Gout is an affection which seems to be as old as civilization itself. Nearly all the physicians of the early periods of medical science, who have left any records, have made mention of it. The descriptions of it given by Hippocrates, Galen, Celsus, and others of their respective times, show clearly that they understood the disease as well as did those of a later date, as Sydenham, Wollaston, Boerhaave, etc., and with the exception of the contributions made by modern chemistry and microscopy, their knowledge of the subject was fully equal to that of the physicians of our own time. Among the most prominent of these last who have written upon the subject and whose names are familiar to the profession, may be mentioned Garrod, Todd, Watson, and Budd.

By universal consent, the presence of uric acid in the blood and urine, where it exists in the form of urate of soda, and the deposits of the same in the joints, has now become a diagnostic sign, one which pre-eminently distinguishes gout from all diseases of a kindred nature. I will therefore make direct reference to this fact as a cardinal point in the treatment of the malady. Certain circumstances, together with the treatment of a number of cases, with well-demonstrated results, have lately shown to my mind conclusively, that some things usually set forth as the prominent causes of gout, are only apparently such, and this, because of their intimate association with the real causes; I refer now to a diet embracing a large proportion of flesh meats and other articles containing a large amount of the nitrogenous and albuminous principles.

Heretofore all authors who have written upon gout have united in classing foods of the character named as among the chief factors in the production of this disease; hence in their treatment of it such have been, to a great extent, excluded from the dietary of the patient. Now, free livers, as a general rule, are large consumers of animal food, as well as of wine, beer, etc.; and leading at the same time, perhaps, inactive lives. Whether it was the association of the meat diet with these other conditions that led to this conclusion, thus attributing to one cause what was in reality due to another, I cannot say; but the fact is as stated.

Dr. Garrod, in his remarks upon the causes of gout, seems to be somewhat in doubt when speaking of the effects of various kinds of food upon different animals. He instances the tortoise, feeding exclusively upon lettuce, and excreting the urates in greater proportion than the dog which feeds upon animal food. Sir Thomas Watson, also, is not quite clear when treating of the causes of gout. He mentions the case of butchers who are rarely afflicted with the disease, though, as might be expected, great consumers of the commodity in which they deal. Men and women of sedentary habits, according to him, are not especially apt to suffer from gout, while, on the other hand, the huntsman, a free liver, but taking an abundance of exercise in the open air, does so suffer.

Dr. Budd seems to be more positive in his opinions as to the causes of gout. He speaks of the ballasters of the Thames who drink excessively of malt liquors, and who almost universally suffer from this malady, although taking a large amount of out-door exercise.

Dr. H. Bentley Todd, in an article on gout in the London *Journal of the Medical Sciences*, for Dec., 1843, recommends, in a very cautious way, the employment of a moderate amount of animal food in the treatment of this disease, discarding, at the same time, all vegetables having saccharine properties, or which might be prone to acetous fermentation in the stomach and duodenum; and thinks that a diet of this kind, embracing a fair proportion of animal food, and regulated as to quantity, would be the one most conducive to the establishment of a healthy digestion. This author—I may here remark—is the only one, so far as my reading extends, who does not assign flesh food as a cause of gout, and show a disposition to exclude it from the bill of fare in the treatment of this disease.

In regard to the different theories that have been from time to time enunciated by medical men in regard to the pathology of gout, they are too numerous to dwell upon here; but the cases which I shall present, will bring out some new facts, or at least some facts not hitherto observed, in the treatment of this malady.

Case I.—D. B. P——, æt. 50; native of the U. S.; married; by profession lawyer; residence, Brooklyn, N. Y.; came into my service at the Presbyterian Hospital Dec. 1, 1879, having been a helpless sufferer from gout for eighteen months previously. He had been, when in health, a man of fine physique, tough and rugged, descended from a long-lived ancestry, both parents dying at advanced ages, and giving no hereditary history of the affection in question. He had been a free liver, and though not intemperate, had yet indulged freely in almost all kinds of alcoholic beverages. When he came under my care his condition was as follows: Feet and hands very much swollen, especially the joints of the fingers, which were also deformed by gouty deposits; the joints of the toes the same; the knees, shoulders, and elbows also swollen, so that he was unable to move either arms or hands. Almost every joint in the body was stiff and painful; even the temporo-maxillary articulations were stiff and painful to the degree that he could not open his mouth sufficiently to take food, except such as had been reduced to a fluid or semi-fluid state. He was confined to bed and unable to move even a finger. Was in fact totally helpless, and had besides, severe gouty conjunctivitis. The heart's action was feeble, but no organic change had

yet taken place. Kidneys healthy: no evidence of albumen or casts. Large quantities of the urates of soda were eliminated by these organs. Lungs large and healthy, and brain clear. He suffered at times from intestinal flatus, and at times from diarrhœa, alternating with constipation. It was, in fine, a typical case of an advanced stage of gout. The patient had been subjected to all the ordinary and well known methods of treatment usually employed in such cases, but without anything more than very temporary relief. The disease was thought to be in a progressive state, and the case regarded as hopeless.

On December 8, 1879, patient was put upon the following treatment: a diet consisting almost wholly of animal and albuminous foods, with such vegetables as contained neither amylaceous nor saccharine principles, such as white turnip, spinach, leeks, celery, raw cabbage, onions, both raw and cooked, potatoes sliced thin and fried crisp, gluten bread toasted. All stimulants, both alcoholic and malt liquors, were withheld. When diarrhœa was present a sufficient amount of opium was given to control it. The exhibition of salicylate of soda, which the patient had been taking previously, was continued in small doses several times a day, so far as to relieve any occasional rise of temperature, and check any fermentation of food that might take place, but not with a view to cure the disease. The wrists and hands were encased in plaster-of Paris, so as to prevent all muscular movements. Under this treatment the patient began slowly to improve. The urates disappeared from his urine, he became free from pain, was soon able to sit up the greater part of the day, and finally he became able to walk. At this writing, March 15, improvement still continues.

Case II.—Rev. Charles P——, æt. 57; native of the U. S.; married; by profession; a teacher was a case of hereditary gout, several of the patient's ancestors and near relatives having suffered from the disease. Since 1848 he has himself been subject to attacks of the malady, which were sometimes attended with great cerebral disturbance, causing him to lie upon one occasion for three weeks unconscious. These attacks became more frequent and of longer duration until, in the autumn of 1875, he became a confirmed invalid, and has so remained up to the time of his coming under my care. He would be sometimes, as he himself states, bright and cheerful; but most of the time he was unable to attend to the duties of his profession, or even to walk. In the spring of 1879 he experienced some mitigation of his sufferings; but in September of that year, although residing in a district of country famous for its salubrity, he was taken down with chills and fever, which continued for three weeks, and from this time he never left his bed until he set out for the Presbyterian Hospital, New York, where he arrived December 6th, and I saw him for the first time on the 7th.

In this case, as in No. 1, nearly all the joints of the body, both large and small, were inflamed, swollen, and painful. He had lost all appetite, food had become distasteful; his digestion was much disordered; there was borborygmus, great and frequent evolutions of gas, and the bowels were obstinately constipated. The circulation was feeble, 42–45, and intermittent. He had been rapidly losing flesh and strength, and the condition of his nervous system was such that he could endure neither light nor sound. He had been living mostly upon farinaceous food, fruits and milk. He had taken all the remedies usually prescribed in such cases, and also stimulants, both spirituous and malt, but all without benefit.

He was first ordered a cathartic pill of compound calocynth, in order to clear his bowels. He was then put upon salicylic acid and ordered to take bicarbonate of potash, gr. xx., at bed time, to make him sleep. On December 8th he was put upon the meat and non-amylaceous and non-saccharine diet, with a bill of fare substantially the same as that ordered for Case No. 1. On this treatment, by January 10, 1880, one month from its commencement, the urine of the patient, which had been at first acid, now became neutral, and the urates had wholly disappeared. By the 18th, the urine showed an alkaline reaction. The deposits in the joints were now rapidly disappearing, the patient was free from pain and going about the hospital, and on the days going outside to walk. Improvement still continued up to 1st March, when he left the hospital on a visit to his friends.

Case III.—S. J——, æt. 22, native of the U. S., single; conductor on horse-cars. Two years ago had an attack of gout in right foot, which continued for two months, and was followed by pain and swelling in the right knee and hip. Both hands were also slightly swollen and somewhat stiff. No distortion, however, had yet taken place in any of the joints. These conditions continued with intermissions up to the time of his admission. On January 8th, he was put upon the meat and non-amylaceous and non-saccharine diet, and ordered to take salicylate of soda. Improvement in patient's condition was soon manifest, the urates disappeared from his urine, his hands became quite supple; but as he was discharged for insubordination on the 26th, having been in the hospital only a little over three weeks, the time was too short to show the full effects of the treatment; but so far as the case had progressed, the same favorable results were seen as in the preceding cases.

Case IV.—M. G——, æt. 35, native of Ireland; married; by occupation housekeeper. Has had trouble with her feet for the last five years, interfering very materially with locomotion. About six weeks previous to admission her feet became œdematous and the ankle-joints very tender. The knees became involved subsequently, and finally the wrist and elbow. All these joints were swollen and tender, but never red. At the same time she was taken sick with flatulence and pain at the epigastrium; symptoms all pointing plainly to a case of gout.

On December 6th, she was ordered to be put on the flesh and non-amylaceous and non-saccharine diet, and the fingers of the right hand to be put in a plaster-of-Paris bandage. In this case, as in the others, the urates disappeared from the urine, and the specific gravity steadily increased from 1012 1015, then to 1018, and finally to 1020, and the patient's general health showed manifest improvement. On the 26th, the diet was again changed to one purely vegetable. Although the effect was not at once seen in the urine, it was immediately apparent in the general health of the patient. The tone of the system was evidently lowered. But on the 5th of the following month, twelve days after the change to a vegetable diet had been made, the urates reappeared in the urine, when she was again put upon the animal diet. The patient left the hospital a few days afterward, discharged at her own request; so that I have no means of knowing the final result. The history of this case is given in this connection, simply because it illustrates so well the effect of the meat and albuminous diet in causing the urates to disappear from

the urine; and then again the result from the employment of a vegetable diet in causing their reappearance in large quantities.

I would call especial attention to this method of putting gouty patients upon a diet of strictly animal and albuminous foods, together with such vegetables as are destitute of amylaceous and saccharine properties; for that is the central fact in the above plan of treatment. It may be noticed too, that in the treatment of these cases none of the usual medicinal agents have been employed, with the exception of salicylate of soda, and such others as were from time to time indicated for the correction of merely temporary conditions.

As has already been shown, gout may be produced under many and various conditions and circumstances: either where there is a hereditary predisposition to the malady, or without; under circumstances of active exertion, or where persons have led sedentary lives; where there has been use and even abuse of the stronger alcoholic beverages, or where the subject has been strictly temperate, even abstinent. Under each or all of the above conditions, persons may have the gout or may escape it entirely. But while this is the case, it is a settled fact that those who live largely upon animal food are less liable to the disease than others; while, according to Dr. Gubler of Paris, who has recently been making extensive researches into diseases of the blood-vessels, those living upon an exclusively vegetable diet, as do many of the French peasantry, and more notably the monks of La Trappe, are peculiarly subject to chalky or calcareous deposits in the arteries. The same is true of animals and birds as well. Siedamgrotzki states that gouty deposits take place in the pigeon; also in the turkey under domestication, and in the common barnyard fowl. In further confirmation of this we have the testimony of Mr. Wm. A. Conklin, Director of the Zoological Garden in Central Park, New York, who, in reply to my inquiry, affirms that it is only the herbivorous and granivorous animals and birds that are subject to such deposits, while the carnivora escape them entirely. This fact alone might, I should think, indicate the point of departure in the treatment of this disease.

Might it not be too, that in the case of animals and birds, as also in the case of the human subject, feeding upon too exclusive a diet of vegetable food, abounding in amylaceous and saccharine elements, under certain conditions a species of fermentation is set up, resulting in certain chemical changes somewhat analogous to the fermentation of vegetable matter out of the body, whereby certain gases are evolved and certain properties generated? For example, the fermentation by which wine and beer are produced.

ABSCESS OF THE ANTRUM, WITH CHRONIC DISCHARGE.

Treatment and Cure by Use of a New Drainage-Tube.

By W. F. DUNCAN, M.D.,

NEW YORK.

The patient, a lady, aged about fifty-eight, came to me for treatment of an offensive discharge from the antrum and nasal catarrh, in December, 1878. She then gave the following history: "She had always enjoyed moderately good health until the year 1869, when a constant earache and pain in the upper jaw on the right side, occurred; the pain was increased on going out in the cold air, even in a closed carriage. Nothing gave any relief, and the pain was endured as a chronic neuralgia. In 1873, a dentist, who was called in to extract the second right molar tooth, discovered a fistula, through which a little matter exuded, leading to the antrum. About this time a disagreeable matter began to run from the right nostril, and the whole of the right side of the face felt sore and painful. The dentist kept open the fistula by strong injections of iodine, zinc, etc., which came out of the nose. After nine weeks, acting on the advice of a distinguished surgeon, it was allowed to heal. The severe pain, which had been modified but not entirely relieved when the fistula was open, immediately returned when it was closed. Nothing was done from this time until April, 1878, except to syringe the nostril, which constantly discharged pus.

Again, a dentist was visited on account of pain in the teeth of the lower jaw on the same side. He found the aching teeth to be sound, but discovered the disease of the antrum, and drew two molar teeth from the upper jaw and opened a large passage to that cavity. It apparently healed again in two weeks, and the old pain came back. Another surgeon being consulted, made an examination of the nose for tumor, but discovered nothing but "congestion." A third dentist being visited, reopened the antrum, probed it, injected iodine, etc., and the discharge increased. He introduced a solid, hard rubber plug, which he wired to the bicuspid tooth, and directed it to be removed daily and the cavity to be washed. Again, a surgeon was called on, who advised making with a stout drill and gouge, a large opening through the alveolar process into the sinus, prognosticating serious future trouble unless the operation was done." She then came to my office for examination, December, 1878. I prescribed a wash, a solution of salicylate of soda, and spray to be used daily, and suggested a means of cure without an operation. After the first visit I saw nothing of my patient for six weeks, when she returned for treatment. Examination of the antrum with the probe failed to reveal any dead bone, which she had been told might exist. The opening through the alveolar process was about the size of a crow's quill. A small counter-opening into the middle meatus of the nose existed, which I enlarged at once by the forcible introduction of a strong right-angled probe. The inspection of the nares by means of a speculum and strong light showed a mass of sticky, whitish secretion filling the whole of the right side, and, when this was washed away, a polypoid thickening of the middle turbinate bone appeared. The right nares was unaffected.

The parts were thoroughly cleansed daily with syringing through the antrum, and an astringent spray was used to relieve the inflammation. After the lapse of a week I had constructed a silver tube $\frac{3}{4}$ in. long, $\frac{1}{17}$ in. in diameter, with a flange at one end, to which was soldered an arm, $\frac{1}{2}$ in. long, of malleable silver; the sides of the tube were perforated with holes. I introduced the tube into the antrum, tying the arm to the bicuspid tooth to keep it in position; the object being to establish a permanent drainage, and carry off all the foul pus which before had been allowed to accumulate in the sinus, and to make use of the two openings to thoroughly cleanse the diseased surface. The patient assisted the cure very greatly by taking a mouthful of carbolized water, and forcibly ejecting it through the antrum into the right nares and thence into a vessel. She repeated this operation frequently, and thus prevented

pus from collecting in the sinus. Sprays of nitrate of silver, zinc, ferric alum, etc., were used at intervals of a few days. The face-ache and ear-ache at once disappeared, and the discharge gradually grew less until the present time, when it is imperceptible; the patient became stronger, and now, after fourteen months' treatment, pronounces herself well. She still wears the tube because it occasions no inconvenience, and she fears to remove it lest it will cause the disease to return. Examination of the parts shows them to be in a healthy condition, with the exception of a slight thickening of the mucous membrane of the turbinate bone.

29 West Forty-Second Street, New York

HYDRONEPHROSIS OF TRAUMATIC ORIGIN.

By J. L. HICKS, M.D.,

Flushing, N. Y.

The discussion of hydronephrosis in a recent number of the Record suggests a case of that disease of traumatic origin which came under my notice last summer, an account of which I transcribe from my note-book.

On the evening of August 1, 1879, I was asked by Dr. Burne to see with him P. C., eleven years of age, a spare, rather badly nourished boy, but who, up to the present time, had enjoyed fair health. Three weeks previously he had been kicked by a horse, the blow falling upon the abdomen upon the right side, and as nearly as could be ascertained below the level of the umbilicus. He dropped upon his knees, and then fell forward unconscious. He soon revived, and was carried home apparently very weak, but not suffering much pain. The following day there was a little pain and tenderness in the abdomen over the seat of the blow, but no swelling or tympanites, and no fever, but occasional nausea after eating. He said, however, that he could not lie comfortably on the left side. The bowels had moved, and continued thereafter to move as usual every day. The morning following the injury he had passed a large quantity of pure blood from the bladder; this was followed by vesical tenesmus and the passage of urine *guttatim*, and finally by a large and free flow of water unmixed with blood. The boy after this was tolerably comfortable, and moved about to a limited extent, passing a fair amount of water with ease and regularity. Some pain, however, persisted over the seat of the injury.

On the day that I first saw him there had been some increase of pain, and he had remained in bed; warm compresses had been applied, and I believe he had had a little opium. On examination I found his pulse accelerated without increase of temperature or other evidence of constitutional disturbance. There was a sharply-defined, circumscribed, fluctuating, tense swelling on the right side of the abdomen about six inches in diameter, evidently originating below the abdominal walls, unaccompanied by œdema of the subtegumentary tissues, or the brawny feel and appearance usually associated with an acute abscess. With the view of learning something more of the nature of this tumor, I thrust the needle of a hypodermic syringe into its summit and withdrew a syringeful of a clear, colorless, limpid fluid, having a faintly alkaline reaction and no perceptible odor. With the doctor's concurrence I then introduced the middle-sized needle of an aspirator, and withdrew a little more than two pints of a clear, pale yellowish fluid, to the great relief of the patient, who now found himself able to lie indifferently on either side, and who, after the application of a compress and bander, enjoyed a quiet night's sleep.

The aspirated fluid had a sp. gr. of 1010, was feebly alkaline, contained a small amount of albumen and a considerable amount of sodium chloride. There was a slight precipitate, but no change of color, with sulphuric and hydrochloric acid.

Urine drawn from the bladder immediately previous to the above tapping was strikingly similar in appearance to the tapped fluid, but gave an acid reaction and had a sp. gr. of 1020. Precip. by heat redissolved by nitric acid and changing to brown with slight effervescence. Precipitate by nitrate of silver not redissolved by nitric acid or ammonia.

August 5th.—The fluid has accumulated again, and the tumor seems even larger than at first. As the patient lies in bed the flank seems prominent and overhanging, and he complains a good deal of pain which he defines as centering at a point as nearly as possible over the middle of Poupart's ligament. His pulse was a little quick, expression anxious, but there is no elevation of temperature. Aspirated the collection of fluid and drew off two quarts with great relief to pain. This fluid resembled that first drawn off. Sp. gr. 1008; light yellow alkaline; same chemical characters as before. It contains merely a trace of urea. Microscopic appearances for the most part negative, presenting neither epithelium of any kind, crystalline deposit, or blood elements. The only thing noticeable were aggregations of granules (bacteria), presenting movements in mass, and not resolvable by the highest powers available (one-tenth). The urine passed at the same time was light yellow, acid; sp. gr. 1016; somewhat more translucent than the other fluid; chemically similar to that first examined. Quantitative analysis gave 7.224 grains of urea to the ounce. The microscope exhibited vesical epithelium, but no crystalline deposits. Ordered tr. cinch. co. and syr. ferri iod.

August 8th.—The patient has been free from pain until to-day. Appetite much improved, and general condition good. The distention has now, however, become painful and he desires relief. Two quarts of fluid were drawn off which differed in no essential particular from that previously examined.

August 25th.—Since previous date there has been no reaccumulation of the fluid that I can ascertain. On two occasions I called at his house, but on each he was away from home. His parents say he was doing as well as possible. To-day I sent for him to come to my office. He appeared remarkably well, and had evidently gained flesh. All traces of the fluid collection had passed away. He states that after the last tapping he began to pass and still passes a much larger quantity of urine than before. A specimen, procured and examined at the time, was as colorless as water. Sp. gr. 1008, feebly acid, and slightly albuminous.

September 18th.—Called at the office. Has been away in the country for a few weeks. Looks remarkably well. Nothing observable to sight, or palpation about the abdomen. Says he is passing two quarts and a half pint of fluid in twenty-four hours. Since last date he has gone on well. The polyuria has diminished, and he is apparently enjoying as good health as before the injury.

Cases of the kind just narrated, though quite rare,

have been occasionally reported; two or three notably similar, but with ultimate disastrous results, are described in Holmes' System of Surgery. Hydronephrosis, resulting from disease of the kidney and urinary tract, associated with cysts of the kidney, or dilatation of the ureter from obstruction, progressive or sudden, has been studied through a sufficient number of cases to render its pathology quite familiar. Cases, however, of traumatic origin, involving a probable rupture of the ureter or kidney, and causing large and rapidly accumulating collections of fluid in the subperitoneal connective tissue, not accompanied or succeeded by inflammation and suppuration, and not associated with evidence of marked constitutional disturbance, are certainly not only rare but perplexing. The rapid and copious secretion of fluid by the kidney on the injured side, may be accounted for by a reflex irritation starting from the seat of the injury, which, in turn, may be conservative by determining a much less irritating quality of fluid infiltrated through the loose tissues, and so admit the formation of a protective cyst. The peculiarly bland character of the fluid found in such collections, differing so markedly as it does from the fluid drawn from the bladder, and which may be inferred to come from the kidney on the uninjured side, may, it seems to me, be more reasonably accounted for upon this hypothesis than upon the supposition that normal urine was first extravasated, and the crystalloid elements subsequently reabsorbed. The amount of urea in the cystic fluid is always small, but traces of it can usually be found. Cooper, Rose, and Spencer Wells are said to have met with cases in which there was no urea. Such fluid, if from cysts of a chronic character, would doubtless point to a process of reabsorption. Still it is hardly conceivable that normal urine escaping into the tissues from a ruptured ureter or kidney, could fail to set up the same active, diffuse, and destructive inflammation that is set up when extravasation takes place from a ruptured bladder or urethra.

The favorable issue in the above case would seem to point decidedly to the importance of prompt and persistent evacuation of collections of fluid succeeding such injuries whenever they may be recognized.

Reports of Hospitals.

NEW YORK HOSPITAL—OUT-PATIENT DEPARTMENT.

SERVICE OF DR. L. DUNCAN BULKLEY,

ATTENDING PHYSICIAN FOR DISEASES OF THE SKIN.

SERPIGINOUS TUBERCULAR SYPHILIDE OF THE SCAPULAR REGION, WITHOUT PREVIOUS HISTORY OF SYPHILIS OR ANY OTHER MANIFESTATION OF THE DISEASE.

THE patient was a female, thirty-four years of age, and of a perfectly healthy general appearance. There was no history of any affection of the skin whatever previous to that from which she was suffering. She had been married for fifteen years, and had had one miscarriage (at three months) not long after her marriage. Since that she had had five healthy children, three of which were still living, the other two having both died of acute diseases. She denied ever having had any of the symptoms of syphilis, and said that her husband had always enjoyed good health.

Eight months ago the present trouble made its appearance, and the first thing that she noticed was a small pimple near the lower border of the right scapula, which was quite protuberant, and covered with a white crust. This soon began to increase in area, and it has continued to spread ever since. The lesion was at first dry, but afterward became moist, and crusts would form over it from time to time, although many poultices and various lotions had been applied to it. It was always somewhat painful, but usually more so when the patient first got up in the morning than at any other time; and the pain was naturally increased by movements of the arm. Almost from the first appearance of the affection she had been under homœopathic treatment.

On taking a view of the lesion at a little distance, it was found apparently of an oval shape; but, examined more closely, it was seen to be more like a double crescent in outline. It was about three inches in length and two and a half inches in width, situated over the lower portion of the right side of the scapula, and extending in an oblique direction around toward the right axilla. In the centre there was a patch of a dark purplish color; around this there was a zone of cicatricial tissue, lighter in color; and, outside of all, a border of ulcerating surface. This presented a general raw appearance, which was, no doubt, due in great part to the fact that the patient was in the habit of washing it several times every day. If it had been allowed to crust over, it would have presented a very different appearance. On inspecting the central portion, it was found that the part had entirely healed, and was now covered with good epidermis. The circle of ulceration was of a somewhat inflammatory character, but was also seen to be composed in part of a new deposit which was non-inflammatory. There was no other lesion of any kind whatever on any part of the body.

In arriving at a diagnosis, Dr. Bulkley said it would be well first to exclude a number of affections for which this might possibly be mistaken. It could not be either eczema or psoriasis, because there was ulceration present, and the characteristic appearances of these diseases were wanting. For the same reasons, as well as on account of the fact that there was only one patch of diseased surface, it could not be a parasitic disorder, such as one of the forms of tinea. It might possibly be mistaken for epithelioma or some other form of carcinomatous disease; but it lacked the hardened edges and other features of such. There was the most danger of all, however, in confounding it with lupus. In the first place, the patient was still in the period of life when lupus almost always occurs, although she had nearly reached its termination. Then, erythematous lupus had the characteristic of extending peripherally as the lesion here was doing, and this form of lupus was sometimes seen quite late in life. But the strong point against such a supposition was the presence of ulceration, which does not occur in lupus erythematosus. The development had been too rapid for lupus: and, moreover, in true lupus there were always a number of outlying tubercles, the edges were irregular, and seldom, if ever, was one patch found alone, as in this case.

So, by a process of exclusion the diagnosis of specific trouble could be arrived at. But, in addition, there were certain characteristics of the lesion which pointed out unmistakably its syphilitic origin, such as the peculiar curving outlines of the growth. Then, the location was a point that should be taken into account, and Dr. Bulkley said that he had seen

a number of syphilitic lesions in this situation. The reason for it was probably the irritation produced by the top of the corsets, as well as that which the part received when the patient was leaning back or lying in bed.

In such a case as this it was difficult to say why the lesion should be present without any previous history, or any present evidences whatever, of syphilis. It was simply one of those anomalous instances which were met with from time to time, and the occurrence of which had not as yet been satisfactorily explained. It was a fact, however, that such lesions without previous syphilitic history were much more frequently found in females than in males, and it seemed probable that in them the immunity from the ordinary effects of syphilis was attributable, as a general rule, to very great activity of the organs concerned in child-bearing, which absorbed the energies of the system to such an extent that the cutaneous surface was almost entirely spared from invasion by the disease. In women the early stages of syphilis were sometimes passed through without any external evidence whatever of the presence of the affection; and in the case in question there had been no history of anything connected with it except this one late syphilide. Some might be inclined to doubt, therefore, that the lesion was of this nature; but Dr. Bulkley was of the opinion that the treatment which he proposed to adopt would show beyond all question that such was its character. Here the appropriate treatment was that called for in the later forms of syphilis, and the patient would consequently be placed upon small doses of the biniodide of mercury, in connection with the iodide of potassium. In addition, she would be ordered iron and such other tonics as her general health seemed to require. The reason that the affection had lasted so long, Dr. Bulkley thought, was because its true nature had not been recognized, and it had been treated almost entirely by means of local applications.

The only local treatment that he would recommend here would be simply the wearing of cotton batting over the part, which might be changed from time to time; although it was important that, when the patient washed the lesion, she should not remove the shreds of cotton adhering to it.

The subsequent history of this case was that the lesion yielded with remarkable rapidity. Within two weeks the ulcerated surface was about healed. She then neglected treatment for a while, being occupied with a sick person, and was again exhibited with the surface at the edge ulcerated and covered with thick, adherent crusts. Again the lesion yielded promptly to the mixed treatment, and she remains well.

LUPUS VULGARIS.

A case of true lupus was shown in a woman forty years of age, who had been under Dr. Bulkley's care for three years. This disease, although more frequently met with in Europe, is considered a comparatively rare one in this country, and Dr. Bulkley remarked that, personally, he did not see, perhaps, more than one or two instances of it in every thousand cases of skin disease that came under his notice in public and private practice. As before remarked, it was emphatically an affection of early life—that is to say, as regards the period of its origin, though it not infrequently continued until old age. It was very rare for it to appear after the age of thirty. In this case it commenced when the patient was fourteen. It made its appearance just on the side of the nose, from which point it spread until it had involved the whole face and ears, and extended for some distance down the neck, while there were also some isolated lesions upon the trunk.

Since the disease first began, the patient had been subjected to almost every conceivable method of treatment at the hands of many physicians. Thus, she had been salivated sixty four times (though never by Dr. Bulkley), had taken calomel for four years, had been painted with tincture of iodine for two years, and had been placed on the use of arsenic, in accordance with the practice of Mr. Hunt, for one year. When Dr. Bulkley first saw the patient, three years ago, the disease occupied the same area as at present, with the exception that there had, in the meanwhile, been a trifling increase at its margin. During the three years there had been very marked improvement in the condition of the parts. Thus, the lips and cheeks now presented none of that succulent and swollen appearance which had characterized them when he first saw the case, and cicatrization had been progressing in an excellent manner. It was this which had encouraged both himself and the patient to persevere steadily in the treatment, and attention was called to the numerous little white points and lines of cicatrization, which were regarded as so hopeful a sign. Last year the thickened and infiltrated lips had been twice the size that they are at present.

The treatment had been somewhat varied during this period. No very active local measures had been attempted, because of the patient's weakened condition, and the great difficulty of properly carrying it out in an out-patient. The disease was arrested first by the internal use of phosphorus in Thompson's solution. Then this seemed to lose effect, and for a while she improved much on the mixed treatment of syphilis.

Still, the previous ravages of the disease were painfully evident in the marked ectropion seen in the lower lids of both eyes, and in the destruction of the ala of the nose. About two years ago it had attacked the larynx, producing the change of voice now noticeable, and this was the case of lupus of the larynx which Dr. George Lefferts had reported in the *American Journal of the Medical Sciences* several months since. The irritation now caused by the lupous deposit in the larynx is now so great that she is greatly disturbed by a cough, which is gradually exhausting her. The air-passages are being treated by Dr Lefferts locally, with a measure of relief; but the prognosis of the case is very bad, and little or no hope of recovery can be entertained.

Dr. Bulkley spoke particularly of the absence of great ulceration in lupus, and stated that it was not apt to occur in this disease except at points where there was some special invitation inducing it. One of the principal characteristics of the disease, however, was scaling, the minute scales being arranged somewhat in the manner of thatching, and always firmly attached to the integument upon one side. Succulent, pulpy tubercles were also another feature of the affection, and some of these could still be seen under the right ear, and in little outlying patches upon the neck in this case, though they were much less marked than they had been a year ago. They were so soft that they could be dug out with the point of a pencil with the greatest ease. Lupus was a disease of the *cutis vera*, and its lesions were found to consist of a soft, small-celled deposit. In order that a cure might be effected, the all-important point was that cicatrization should take place.

FAVUS.

A case of favus was shown in a girl eight years of age, whose brother had been under treatment for the same disease for some time, at the Demilt Dispensary. It presented an exception to the general rule, in the fact that no scabs were to be found upon the scalp. This was due to a special cause, however. When first seen the child was found to be affected with phtheiriasis, and, in order to get rid of the lice, the hair had been kept soaked with kerosene for twenty-four hours (Dr. Bulkley's ordinary treatment in such cases). Hence, the crusts had all been dislodged, and almost all traces of the more serious disease obliterated. If the case had first come under observation at this time, the favus might perhaps have escaped detection, though its presence ought at least to have been suspected. It was not unfrequently the case, said Dr. Bulkley, that patients were brought to him in which special care was necessary in making a diagnosis, since they had already been under good treatment for a time, and many signs of the real nature of the disease present had thus disappeared.

On making a careful examination here, there were found three little red patches on the scalp, which were devoid of hair. These could not be due to simple eczema, for this does not destroy the hair, while in *alopecia areata* the patches, instead of being more highly colored, were whiter than the normal skin. Hence, notwithstanding the absence of the characteristic crusts, there was good reason for ascribing the trouble, in all probability, to favus.

Some might consider that, the crusts having all disappeared, the case was in a fair way of recovery; but Dr. Bulkley pointed out the erroneousness of this view, and also stated that the chronicity of a great many cases of favus was in reality due to this error of supposing the disease cured when there were no longer any crusts to be seen. It was a grave mistake, because the pathological process was still going on at the roots of the disease just the same as before. It was altogether probable that in a week the crusts would appear again in this case, and it would not be safe to dismiss it until every hair that had been or was likely to be affected had been epilated.

The disease was due to the growth in the epidermal cells of the vegetable parasite, achorion Schoenleinii, and this followed down the root-sheaths of the hairs, which were but involutions of the outer layers of the skin. If, now, the eruption were all swept from the surface, still there might be any quantity of the spores and mycelium of the parasite along the hair and within its structure, beneath the skin; and if this were left alone, it certainly would germinate and produce the ontward lesions outwardly recognized again and again.

URTICARIA PAPULOSA.

The patient, who was a boy, five years old, had been perfectly healthy up to two years ago, when the present eruption appeared. It had been treated for several months past by another physician, with arsenic internally and the application of spiritus saponis alkalinus externally. The affection was seen to be located on both upper extremities (extending from the ends of the fingers to the elbows), upon the back and buttocks, on the outsides of the thighs, and all over the legs; while the face was almost, and the trunk entirely free from it. It consisted of very numerous hard papules, and numerous scratch-marks were present. It was ascertained that the patient scratched himself very much, especially at night.

The case at first sight strongly suggested one of scabies, and in some respects the eruption on the extremities resembled it so strongly as to lead to a very careful study of its features.

Although there were two younger children in the family, neither of them had taken the disease, and the mother also remained free from it. If, as had been supposed by some, it were a case of scabies, Dr. Bulkley remarked that that disease would not exist in this isolated way without other members of the family getting it, although it was possible for scabies to be found under such circumstances; as, for instance, if the affected child had been in a public institution in which the disease existed, or visiting away from home for some time, and had only just returned. Therefore, he remarked, that it was not always safe to place too much reliance on absence of the disease in those around the patient. Occasionally also we find those who do not take the disease when exposed to it.

There were other things to be looked at, however, besides this. If scabies were present we should find somewhere about the hands or wrists the little furrows of the *acarus scabiei*, which is one of the diagnostic points of the affection. These minute black lines, made up of little dots (the eggs and faces of the female insect) and looking like bits of sewing-silk beneath the skin, Dr. Bulkley said, were only to be found in one plate representing scabies, and that was the admirable one from Dr. Duhring's atlas, which was passed around. In scabies these furrows were not invariably to be found in adults, but in children they were almost always present. They were generally to be found located between the fingers, but in the case under notice none of them were visible. Indeed, there was no eruption whatever between the fingers, neither was the eruption nearly as marked about the creases of the wrists, and no furrows could be discovered there, as is ordinarily the case in scabies. There was none of it at the root of the toes and between them, as is always seen in that disease in children.

A careful examination was also made of the two other locations where the furrows of the acarus are most likely to be found, viz., the soft part of the ankle beneath the external malleolus, and the penis; but no trace of furrows could be found. Altogether, therefore, scabies was to be excluded in this case, and one additional reason for doing this was because there was some of the eruption on the face, which is very rarely the case in that disease. The lesions also were more thickly set on the arms and legs, and the papules much larger and harder than seen in scabies, and no vesicles could be found.

It was easier, however, to exclude scabies, Dr. Bulkley remarked, than to decide just what the affection was. There were some of the lesions of eczema present, and yet it certainly was not that disease. It had not attacked the flexor surfaces at all. The disease which this case most resembles is papular urticaria, although the character of the hard, shot-like papules scattered all over the ends of the limbs and on the extensor surfaces of the thighs differs from what we ordinarily look for in urticaria. But the congestion which produces the wheal in urticaria may, and often does, go on to form a plastic exudation in the form of a papule, and these, which were small at first, have, by long duration and scratching, been changed into the larger rounded papules seen here so abundantly.

Some time ago Mr. Hutchinson, of London, described a disease to which he gave the rather ridiculous name of *varicella prurigo*, and Dr. Bulkley stated that the present case corresponded to the cases of that disease which had been shown him in London last year. It was a very obstinate affection, and it was almost always worse in winter than in summer. It very frequently dated back to an attack of varicella, although not always. This boy had had varicella, and this appeared to follow it. He did not believe in any causal connection other than that common to all exanthematous diseases, which appear to weaken the skin and to render it rather more prone to such affections.

Dr. Bulkley hardly knew by what name to call the eruption in the present case, as it was difficult to find any one term that perfectly described its character. Some thought it to be lichen, while others would designate it as *strophulus pruriginosus*. He would rather hold to the diagnosis of papular urticaria.

The treatment consisted in the use of alkaline baths and subsequent inunction with carbolated cosmoline (gr. v. ad ʒ i.), and the internal administration of the syrup of the hypophosphite of soda, lime, and iron. The case was presented again a few weeks later very much improved, and shortly after was brought almost entirely relieved of the cutaneous disease.

TREATMENT OF SCABIES.

If the disease had been scabies, Dr. Bulkley said, he would have employed the following ointment:

℞. Sulphur..... ʒ i.
Styracis ..... ʒ ij.
Ung. adipis ..... ʒ i.
M.

The patient should first be washed thoroughly with yellow soap, and then have the above applied constantly for two or three days and nights. It was possible to cure scabies here as quickly as it is done in Paris, and Dr. Bulkley mentioned one case of his own in which the complete cure had been made in thirty-one hours.

Progress of Medical Science.

THE ANTISEPTIC THEORY IN OVARIOTOMY.—Mr. Lawson Tait recently read a paper before the Royal Medical and Chirurgical Society, in which he analyzed one hundred cases of ovariotomy, and endeavored to extract from them some indication of the value of antiseptics in this operation. In doing this he made the method of recovery in his patients the criterion of the value of the system, the basis of the antiseptic claim being that it prevented septic poisoning, or fever—the usual cause of death in ovariotomy. The antiseptic system, therefore, should uniformly facilitate recovery, as, in non-antiseptic cases, the germs would enter the peritoneum, and theoretically produce fever in every case. The presence, then, of a marked difference between the pulse and temperature curves of the cases treated antiseptically and those not so, in favor of a less febrile course of recovery in the former, would go toward establishing Mr. Lister's views. If there were no difference, the question remained where it was; but if a difference were found in the other direction, then the germ theory would probably fade away from professional acceptance. Details were then given of the system of pulse and temperature observations which he had taken by trained nurses for ten days succeeding ovariotomy. More value was attached to the pulse than to the temperature curves, as a rise in the former more certainly indicated something wrong. The temperature rose uniformly at night during recovery, while the pulse did not rise after the fourth night, in cases ending badly, however, while the temperature did not rise much, the pulse rose continuously. The non-antiseptic cases had a better pulse curve than the antiseptic, and their time of recovery was one day shorter. Judging from both temperature and pulse curves, the non-antiseptic method, with the short ligature, gave a better and shorter recovery than any other; the nocturnal acceleration of temperature in the antiseptic cases being caused by the suppuration due to the irritating effects of the gauze dressings. Mr. Tait had found more satisfactory results from dry lint dressings. His conclusion was that the Listerian method had no paramount influence in the course of the case; it could not be actually said to delay recovery, but it certainly did not facilitate it. He still employs the antiseptic precautions during operation.

In the discussion on the paper Mr. Spencer Wells defended the antiseptic method. His conclusion was that the use of antiseptics enabled the intraperitoneal method of dealing with the pedicle to be carried out without septic results. He agreed with Mr. Tait as to the advantage of dry dressings, for which he used thymol. He attached more importance to the variations of the temperature than to those of the pulse, as the latter is never affected by accidental influences. Since he adopted the antiseptic method the temperature had been markedly lower, seldom rising over 100°, and the use of the ice-cap had become very rare. Dr. Mathews Duncan said that in St. Bartholomew's Hospital, before the adoption of the spray, ovariotomy had been very unsuccessful, but that since its adoption Mr. Thomas Smith had operated in twelve cases with only one death (from injury of the liver). Dr. Thomas Keith had also had seventy recoveries in succession since he began to use the spray. Mr. Knowsley Thornton found that, as a rule, there was no fever after antiseptic ovariotomy, and when it occurred he suspected neglect on the part of the nurses. He agreed with Mr. Tait, that the wounds did not heal so well under the protective; he now simply applied carbolic gauze, leaving it a week or more, and he did not remember seeing any pus in his last seventy or eighty cases. The wound in ovariotomy ought always to be healed by the ninth or tenth day.—*British Medical Journal*, Feb. 14, 1880.

ACUTE MENSTRUAL GOITRE.—At the meeting of the Surgical Society of Ireland on January 16th, Prof. Bennett reported two cases which he regarded as examples of acute menstrual goitre, an affection of which but little is known, and which Virchow refuses even to admit into the class of goitres. The first patient, a girl sixteen years of age, was admitted into hospital suffering from intense dyspnœa, which was evidently due to a large bronchocele. Laryngoscopic examination showed the mucous membrane of the larynx to be livid but not swollen, and excluded the possibility of a foreign body or spasm. The attacks of dyspnœa had begun about a year before, and the neck had increased in size irregularly since then. The patient was fully developed, but an abortive attempt at menstruation six months previously had been the only sign of the establishment of the

menstrual function. On her admission to the hospital emetics and hot fomentations were tried without benefit, and as the case was urgent, laryngotomy was then performed. The trachea could not be reached below the tumor, because it extended very low down, completely filling the supra-sternal notch. The tumor presented none of the characters of a vascular bronchocele, and no vessel of importance was encountered in the dissection. After dividing the cricoid cartilage and the membrane, it was found necessary to divide the trachea for some distance behind the tumor by means of a probe-pointed bistoury introduced into the tube, before air could enter the lungs. A large tracheotomy tube was then introduced, and for two hours the patient was comfortable, when the dyspnœa again returned. The tube was then removed, and a large prostatic catheter was passed into the trachea and down toward the chest, meeting some slight obstruction on the way. As its point passed down beyond this, the air entered with a rush, and all was well again. A full-sized tracheotomy tube was then made with the length and curve of the portion of the catheter in the trachea, and the patient wore it constantly. It was found that the tube had to be 5⅜ inches long, in order to pass the constriction which impeded respiration. After the introduction of the new tube the dyspnœa did not recur, and the patient, after a short time, improved in health and began to menstruate regularly. At the same time the bronchocele diminished markedly in size, the circumference of the neck over the tumor falling from 15¾ inches to 12½ inches. Two attempts were made at long intervals to close the tracheal wound, but each time a recurrence of the dyspnœa made it necessary to reopen the wound and reintroduce the tube. The patient is now in perfect health, general and menstrual, and without visible goitre. The necessity for wearing the tube is probably due to the deformity of the trachea, which prevents the escape of mucus from the bronchi.

The second patient, a healthy girl, sixteen years of age, was admitted to the hospital suffering from a very prominent goitre. She stated that she had first observed it six weeks previously, about the time of the first signs of the menstrual discharge. She suffered from paroxysms of dyspnœa, but her ordinary breathing was easy, and her voice natural. Seven weeks later, she was suddenly seized with one of her attacks of dyspnœa, and died in two minutes of asphyxia. An autopsy could not be obtained. The tumor in this case, also, presented none of the signs of a vascular bronchocele.

In discussing the paper, Mr. Hamilton said that it seemed to him that death had occurred from spasm affecting the muscles. He suggested that in such cases a free division of the fascia covering the tumor might be attended with some relief, independent of the operation of tracheotomy, and referred to a case in the practice of the late Mr. Cusick, where the division of the fascia relieved the dyspnœa considerably. The application of a large number of leeches to the gland might also, he thought, afford relief. Mr. Croly stated that he had seen cases where patients, the subjects of goitre, were attacked with cellulitis of the neck, and where free incisions dividing the cervical fascia had relieved the symptoms. Prof. Bennett said that he knew the operation of division of the fascia had been attended with success. Leeching had been suggested in the second case, but in the first there was no time for it. Should another case present itself to him he would be inclined to bleed at the bend of the arm rather than to try leeches. He was not present when the second patient died, but an operation, if attempted, would probably have been attended with success.—*The Medical Press and Circular*, Feb. 11, 1880.

Treatment of Goitre by Chloride of Ammonium.—Dr. Stevens, of Dunham, Canada, states that he has employed chloride of ammonium in the treatment of seven cases of common goitre, or simple hypertrophy of the thyroid gland, with most surprising and satisfactory results. Six of the patients were girls under twenty years of age, and all of them were entirely cured after about three months of treatment. The seventh case was that of a married woman aged forty, and the mother of several children. The tumor in this case was of enormous size, and the patient suffered a good deal from disturbances of respiration and circulation. She took the chloride two or three months, and at the end of that time the bronchocele had reduced one-fourth in size, and all the circulatory and respiratory symptoms were relieved. Treatment was discontinued because she became pregnant. The dose used in all the cases was ten grains three times a day, but Dr. Stearns thinks larger doses might be useful in old cases. No other medicine or hygienic treatment was combined with the muriate of ammonia. In the cases of the six girls, the tumor had made its appearance about puberty, but in none of them was there any evidence of menstrual derangement or uterine disease.—*Canada Medical Record*, February, 1880.

The Treatment of Irreducible Hernia.—At a recent meeting of the Boston Society for Medical Improvement, Dr. J. C. Warren read an interesting paper on this subject. He advocated the use of elastic pressure by means of the rubber bandage, in addition to rest in the *inverted position*. The latter part of the method was new, and had been successfully employed by the author in several cases. The foot of the bed is to be so raised that the neck of the hernial sac shall be at a higher level than any portion of the abdominal cavity, and that not only all intra-abdominal pressure may thus be removed, but that gravity can aid in returning the hernial mass into the abdomen. No special medical treatment was found necessary. When the descent of the hernia is comparatively recent and consists of intestine only, no additional mechanical appliance is needed. When the hernia is of the large and mixed variety, various mechanical appliances must be brought into requisition. Rubber air-cushions and water-bags were recommended where bandaging seemed undesirable or failed to give satisfactory results. In the discussion which followed the reading of this paper, Dr. Hodges remarked that time and confinement to bed could not be over-estimated, no matter what other adjuvants might be brought into requisition. In 1852, attention was attracted in London to some cases of Mr. Bransby Cooper's, in which, by means of a spinal elastic bandage, an air-bag was bound down upon the irreducible tumor, and the whole apparatus having been further reinforced by buckled webbing straps, the air-bag was inflated through a protruding tube, with the gradual result of elongating the adhesions, inverting the sac, and accomplishing a complete reduction of the hernia.—*Boston Med. and Surg. Journal*, March 18, 1880.

Dr. William Thompson has been elected by the Trustees of the Jefferson Medical College, Honorary Professor of Ophthalmology.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, April 17, 1880.

REGULATING THE PRACTICE OF MEDICINE.

THERE is a bill for regulating the practice of medicine in this State now before the Legislature. We fear that the announcement of this fact will hardly be received with the attention it deserves. Although medical men have been satisfied of the necessity for legislation in medical matters, there have been so many failures in securing the necessary reforms, that there is a growing disposition to ignore the whole subject. But this should not be. The profession must rise above such difficulties, and by the exercise of its influence must continue to work on in hope, taking advantage of every opportunity for the suppression of quackery. Such an opportunity offers itself at the present moment by the advocacy of the bill to which we have referred.

It is an encouraging circumstance that the people are beginning to appreciate that something must be done to protect them from unqualified and unauthorized practitioners. The circular which is found on another page, emanating from the Department of Education at Washington, speaks for itself, and is an evidence that the authorities of the general government are also being awakened to the necessity of something being done. Unfortunately, the general government does not possess the power, under the Constitution of the United States, to deal directly with these matters. The State Legislatures, being the supposed guardians of the "health, wealth, and welfare of the people" of their respective States, are the bodies to give the necessary aid. The medical profession is the one most familiar with the facts and necessities of the occasion, and upon it falls the onus of taking the initiative in the necessary reformation.

Under the present laws of this State, licenses to practise are issued by the medical colleges in the State, by the County Societies of the State, and, in addition, the diploma or license from a medical college or chartered society anywhere else outside of the State entitles the holder to practise physic and surgery in this State.

When a few weeks ago we gave the list of colleges granting medical diplomas, to say the least, on very easy terms, we also referred to a number of instances of direct sale of diplomas that came to our notice. And yet there is little doubt that the latter diplomas are valid qualifications for practice in this State at the present time. If this state of things continues, how long will it be before the people of this commonwealth will be at the mercy of every medical adventurer who may see fit to settle in their midst?

In view of this state of affairs it is quite a difficult matter for the public to distinguish an educated physician from one who is not. An attempt has been made to draw the line between these two conditions. The Medical Society of this State at its last meeting, held in February, gave a careful consideration to the question of medical legislation, and settled on the principles which should be incorporated in a bill to be enacted, if possible, during the present session of the Legislature. The matter was referred to a committee, who caused to be introduced a bill on the subject. This, with some modifications and amendments, has been reported from the Judiciary Committee of the Assembly, and is the one now before that body for its action.

In another column we give a copy of this bill, and will take this occasion to draw attention to some of its features. It will be seen that section one does not impair the standing of any who now legally practises medicine, but it will, in the future, very materially curtail the accessions we are receiving from other States and from Europe of men whose qualifications are not equal to those required by our medical colleges.

Section two is one of the most important features of this bill, inasmuch as it provides for the registration of all those now practising in the State. It is true that it may prove a little inconvenient for some practitioners to go to the County Clerk's office and register, while a few may object to the payment of a registering fee of twenty-five cents. These are hardships, it is true, but they should be cheerfully borne for the common good. The fee required in Great Britain for the same service is five pounds, and we believe there is demanded an annual payment in addition. This tax is cheerfully borne by our transatlantic brethren, who are willing to do anything that will insure a carefully kept and authoritative record of the educated and qualified practitioners of the kingdom. Section three merely prescribes the penalties for the violation of the act.

Section four is quite an important one, and invites a thorough and careful consideration. It is safe to say that there are a hundred or more licensing bodies in this State, while there is an indefinite number outside of it. This section restricts the number to

thirteen or fourteen. The medical colleges of the State are at present the warrantors of the qualifications of men who graduate, and this section makes them the warrantors of the qualifications of all who come to us from other parts. The task of ascertaining the fitness to practise of men from outside the State, is not an easy one, and consequently a fee for its performance is allowed. Such a fee as named in the bill is one which appears to be a fair and equitable return for services rendered. It will be perceived that by such a provision, the colleges, as examining bodies, can be held more directly responsible to the profession than would otherwise be the case.

As regards the enforcement of the act, it is necessary to say but a few words. Heretofore, the expenses of enforcement of similar acts have been thrown very unjustly upon the medical profession. It will be seen, however, that in the present bill it is provided that those who give themselves the trouble of enforcing the laws will receive something about equivalent to their actual legal expenses.

We need not go further to show that the present bill is a reasonable one, and that the profession of the State can consistently indorse it, and can use its best influences in securing its passage. It is the enactment of such a law in this and other States that would tend, in a very direct and effectual manner, to arrest the sale of diplomas, to which we have so often referred, and to which the Bureau of Education at Washington now calls public attention.

THE TESTS OF RESPONSIBILITY FOR CRIMINAL ACTIONS, AND THE NECESSITY OF MEDICAL EXPERT TESTIMONY.

The recent trial of John C. Hughes, in the Albany courts, for murder, has excited considerable attention on account of the conflicting character of the testimony and the ability with which the case, on both sides, has been conducted. The charge of Judge Westbrook to the jury has, especially, awakened much complimentary comment, as being a model of perspicacity and legal erudition.

That the charge might have been all this, and yet have presented some defects noticeable and interesting to medical men, is what we at present wish to show.

The claim put in by the defence was that the prisoner had been insane for some time previous to the murder, and was not, therefore, responsible for the crime committed. This theory led necessarily to the employment of medical experts, and the usual questions as to the value of their testimony were brought into consideration.

With regard to the test to be applied to determine the mental capacity and the responsibility of the patient, the court held the view given in a previous decision (the People against Flannigan): that, if a person understands the act he is committing—if he comprehends that and knows that it is wrong, and that the law will punish him for the commission of that act, he is accountable for the same. And this is true, although the person acts under an irresistible impulse—irresistible impulses not being recognized by law.

The position thus taken is perhaps the strongest and most satisfactory of the many which lawyers have assumed in regard to what shall be the test of responsibility. It is certainly better than that of Lord Justice Bramwell, who made the capacity of fear the test of responsibility. It is better, too, than that laid down by Baron Bramwell in the Dove trial. Here it was asserted that if the crime is the result of a series of persistent mental efforts uniformly tending to a certain end, the responsibility is presumed to be complete. But though this test, evidenced by capacity for moral distinctions and appreciation of consequences, has superior merits, it will, we believe, strike medical men at least, as being notably defective in some points.

We may premise that these points are the following: It does not recognize a certain form of disease which is known as volitional insanity, or insanity of the will. Then, it assumes that the fact of a previous condition of insanity is not necessarily to be taken into consideration in estimating the responsibility for a crime; and it consequently makes the value of expert testimony comparatively slight. Furthermore, it does not recognize the fact that the taint of insanity throws a doubt over the responsibility of the person affected, as regards all his actions; and that the existence of such taint ought to lessen responsibility, without by any means doing away with it.

The question of the propriety of recognizing the existence and importance of volitional insanity was not discussed in Judge Westbrook's charge, and we do not propose to enlarge upon it here. That there is such a diseased condition, and that the sufferers from it should be considered less responsible than the healthy, we cannot doubt.

With regard to the second point—that of the tendency of the test, laid down in the charge by Judge Westbrook, to do away with expert testimony—the present trial furnished an excellent illustration. The judge quite ignored the testimony in summing up the case, and a local journal, in its comments, ventured the opinion that medical expert testimony might always be dispensed with, to the advantage of law and justice. It is, indeed, natural to suppose that if the only question to be determined is the condition of mind at the time of the act, no experts will be needed, or at least their testimony will be often unnecessary, and always very subordinate. To persons acquainted with the many subtle phases of insanity, especially in its incipient stages, and with the difficulty at times of making a correct diagnosis,

the possibility of excluding, or of laying slight stress upon the help of those who have devoted a life to studying mental disease, must seem deplorable.

In regard to the third point, this question at once presents itself: Cannot a person be tainted with insanity, and yet "be able to distinguish between right and wrong at the time of and with respect to the act complained of;" and, further, is a person thus tainted with insanity, though apparently able at times to make moral distinctions, to be considered as responsible for his actions as a sane person? The law says he may be; but to medical men this view must appear wrong and liable to cause injustice. A person mentally diseased may be partially accountable for his actions, but never fully so. Such statement is based on the fact that it will always be impossible to say where the mental alienation ends in any given case; at what faculties and to what subjects it is limited, or on exactly what motives it has an influence. This is a view which has been very ably advocated by Dr. N. W. Wright; and, if true, it shows conclusively a defect, or at least an incompleteness, in the test laid down by Judge Westbrook. There is no recognition in this test that a man's responsibility should always be considered less when his mind is diseased. According to it, the man is either sane and a murderer, or insane and innocent. But there is a position between these two extremes. To illustrate further: a man may appear to have done a murder knowingly and deliberately, but it may subsequently be proved that he had been subject to delusions, in the scientific meaning of the word, and had been insane at certain times or on certain topics. In this case his responsibility should be considered less, and he should not be condemned for murder in the first degree, whatever his apparent frame of mind when the act was committed. This proposition will, we believe, be indorsed by most medical men. It follows from it that medical expert testimony is an absolute necessity to securing the ends of justice.

Though not entirely pertinent, a very good illustration of the value of expert testimony has been given recently in the Gosling trial in this city. Here was a man suffering from general paralysis of the insane, a form of insanity distinguishable with almost absolute certainty, by competent physicians, even early in the disease. At the same time there was probably nothing but some exaggerations of speech and conduct apparent to uneducated observers; skilled experts were therefore indispensable to forming a correct conclusion in the matter. Unfortunately the case showed, with equal force, the need of change in the way such testimony should be given. There was sufficient money in the case to get "expert testimony" on both sides. It was shown to the jury that the doctors disagreed, and such disagreement always makes a profound impression on the jury, however poor the knowledge of the opposing expert.

A reform is needed here in the method of securing expert testimony, and such reform has been often enough urged in these columns. It is for the lawyers to secure this, however, and it might be well for them to expend some of the energy now applied to enunciating "great principles," and fitting them to the elusive phases of human conduct, in introducing practical measures for securing a better light upon each particular case.

The recent Hughes trial furnishes an instructive lesson upon this matter, for it shows how little the doctor's testimony weighs as now given, and yet how essential medical knowledge is to securing exact justice in cases where mental incapacity is alleged as an excuse for criminal acts.

HOMŒOPATHY IN THE BOSTON CITY HOSPITAL.

A PETITION has been circulated by the homœopaths, praying the Boston city government to grant them representation on the staff of the Boston City Hospital; or, if not this, to furnish them a separate building where homœopathic treatment can be carried out upon a due proportion of the charity cases. A committee of more or less prominent citizens has been appointed to agitate the matter. The homœopaths are buoyant with hope, and there are vague rumors that the present hospital staff has threatened to resign in case the proposed change is made.

We do not know how serious this movement is. If, however, a pure homœopathic practice could be introduced into the Boston City Hospital, and its results placed in comparison with those obtained by regular physicians, nothing more disastrous could happen to the so-called new school.

Such experiment is not new, however, and it is hardly worth while to try it again. At Vienna and at Ann Arbor homœopathic education has been attempted side by side with instruction in scientific medicine, and it has failed. Homœopathic treatment has been tried in the wards of hospitals at St. Petersburg, Vienna, Paris, and other cities, and it has been given up as ineffective. In the present instance the homœopaths express themselves as being quite willing to have a separate building, and if anything is done in the matter, it will probably be the securing another hospital. To this there can be no especial objection, if the taxpayers desire it. The New York City Homœopathic Hospital has turned out to be a harmless institution. Treating, as it does, chiefly chronic and incurable cases, it probably furnishes interesting opportunities to study the natural course of disease. Similar opportunities need not be denied Boston if she wishes them.

Those laymen, however, who interest themselves in clamoring for the rights and proportionate repre-

sentation of special medical schools, ought to remember, in the first place, that homœopathy in its pristine simplicity is no longer practised by intelligent men. There ought to be care taken, therefore, in appointing men to responsible positions simply because they claim to practise by an exclusive dogma, and on such account feel themselves entitled to a representation.

SCHOOL HYGIENE.

At the recent meeting of the Medico-Legal Society, the Chairman of the Committee on School Hygiene, Dr. O'Sullivan, presented an extended report, in which it was shown that very substantial progress had been made regarding the promotion of the sanitary interests of the public schools. Not only was public opinion in favor of the reformatory measures so earnestly advocated by the society in question and by the profession at large, but the Board of Education itself freely admitted the necessities of the situation. The recently appointed Superintendent has stated that the condition of the schools had improved during the past year, and had accounted for the fact on the ground that there had been a closer scrutiny exercised by the Board of Trustees and by the janitors—all of which had been the direct result of public complaints against the sanitary condition of the schools. So far, then, such facts go to show that the chances of necessary legislation are exceedingly good, and that the opposing elements to such an end are either no longer on the school board or have lost their power. The present school bill before the Legislature is calculated to serve the sanitary interests of the schools, and so far appears to have the support of the Commissioners.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, March 10, 1880.

DR. T. E. SATTERTHWAITE, PRESIDENT, IN THE CHAIR.

DR. PEABODY presented three specimens of dissecting aneurism of the aorta. The first was on behalf of a candidate for admission to the Society. The histories were as follows:

A CASE OF MULTIPLE CEREBRAL HEMORRHAGES WITH DISSECTING ANEURISM OF THE AORTA.

CASE I.—J. K——, æt. 56; married; United States; truckman. About 10.30 on the morning of February 24th, while engaged in his business, the patient complained of not feeling well, and went into an office to sit down. Soon after, he became unconscious, and, when an ambulance was sent for, was found by the surgeon in charge to be suffering from paralysis of the left side of the body and of the right side of the face, accompanied by ptosis and dilatation of the pupil. The patient at that time was comatose and exhibited no convulsive symptoms. He was removed to a hospital where, about one o'clock, he was seized with a number of clonico-tonic spasms involving the left side of the face and the left upper extremity only. No other previous history of the patient could be obtained, except that for ten days before his attack he had been drinking to excess.

Upon coming under personal observation at six P.M., about eight hours after the beginning of the seizure, the patient presented the following condition:

The face was flushed. Coma was profound and accompanied by loud stertorous respiration. The conjunctivæ were insensitive. The right pupil was somewhat contracted and insensitive to light. The left pupil was dilated and responded but feebly to stimulus. On the right side there was ptosis. The left upper and lower extremities were the seat of motor paralysis. There were no reflex movements to pricking on either side of the body, nor to tickling the soles of the feet.

The left side of the face and the left upper extremity were in a constant state of clonico-tonic spasm. The convulsive movements began with clonic twitchings in the muscles of the left side of the face, neck, and in the left upper extremity. These lasted but for a few moments, when the tonic spasm began, the head being drawn powerfully to the left and slightly backward, and the jaws firmly set, grinding the teeth together with great violence. At the same time the upper extremity of the affected side became stiff, the forearm being slightly flexed and the fingers clenched into the fist. The face, during these attacks, was somewhat cyanosed. At no time was the left lower extremity involved. The heart-sounds could not be distinguished, owing to the noisy breathing. The pulse was full, strong, and very irregular, and beating 68 to the minute. The radial arteries were thickened. The temperature, taken in the rectum, was 101.8°, and the respirations numbered 22 to the minute. Both legs were slightly œdematous. The urine was suppressed, none flowing on a catheter being passed into the bladder. The patient remained in the same condition, the convulsions occurring every two to three minutes and lasting about a minute each, until the time of his death, which took place at midnight, he having been under observation six hours. Shortly before death the cyanosis became very marked and the pupils dilated.

Diagnosis.—A diagnosis was made of a meningeal or cortical hemorrhage of the right side, involving the motor centres of the face and arm and gradually extending to the base.

Autopsy.—A post-mortem examination was made thirty-five hours after death.

The Brain.—There was marked flattening of the convolutions of the vertex of both hemispheres. The vessels at the base showed a few patches of atheromatous degeneration. The left lateral ventricle contained rather more fluid than is usual, the fluid itself being normal in character. The cortical and medullary parts of the right hemisphere were studded with countless small hemorrhages, varying in size from a pin's head to that of a small chestnut. They were all recent, soft, and not decolorized. The tissue of the hemisphere was everywhere slightly brownish and softened. The corpus striatum and optic thalamus were softer than the other parts. There was a clot, about the size of a dime, in the anterior part of the fourth ventricle, involving the tegmentum of the right crus cerebri.

Thorax.—The pericardium contained about half an ounce of bloody serum. The adventitia of the aorta appeared blackened for a distance of about two inches from the aortic valves, the result of a hemorrhagic extravasation.

The thoracic aorta was found to be very atheromatous and thickened throughout, the ascending portion of the arch being the seat of an aneurismal dilatation. About half an inch above the aortic valves, on the right side of the arch, there was a narrow rent in the intima and media, extending for half an inch in a direction directly upward. Through this opening blood had escaped, dissecting between the layers of the media, over a space of about two inches along the arch, and along the innominate artery to its bifurcation, filling the cavity so formed with clots. At a distance of two inches from the valves, the adherence of the layers of the media had stopped the progress of the dissection in every direction but behind, where the blood had forced its way through, and winding round to the front, had continued its dissection down the whole anterior aspect of the thoracic and abdominal portions of the aorta. The heart was rather large, and the muscular tissue pale. The valves were competent. The right ventricle was somewhat dilated, and on the anterior surface, near the apex, there was an old thickening of the visceral layer of the pericardium.

The Kidneys were about normal in size. The capsule stripped off with some difficulty, leaving a rather granular-looking surface behind. The cortex was thin, and the markings obscure.

The Liver was fatty. The gall-bladder contained two very irregularly shaped black calculi.

Microscopical Examination.—*The Heart.*—The striæ of the muscular tissue had in many places disappeared, the muscular tissue being replaced by fat globules.

The Kidneys.—There was granular degeneration of the epithelium in the cortex, and many hyaline casts in the convoluted and straight tubes. Some of the glomeruli were atrophied and their capsules thickened by an increase in the quantity of the connective tissue.

RUPTURE OF AORTA DISSECTING ANEURISM.

CASE II.—M. B——, æt. 49; Ireland; widow; domestic.

Admitted to Chambers Street Hospital, December 26th, 8.30 A.M. Died 9.20 A.M. of same day. Patient was subjected to unusual excitement on the night of 25th December and on the following morning. While walking in the street about eight o'clock in the morning, she was seen to stagger and fall. She did not lose consciousness at the time, but was unable to speak. By the assistance of a policeman she was able to walk to the station-house—a distance of a few houses. She was then transported in an ambulance to the hospital. She reached the hospital twenty minutes after she fell. At this time she was unconscious, pupils were normal; there was no paralysis; she could swallow; radial pulse was perceptible, but fluttering; surface was warm; face flushed. Respiration was very rapid. Physical examination revealed nothing definite. She was restless, rolling her head and tossing her arms, apparently in pain. She was given whiskey, digitalis, and morphia subcutaneously in small doses. She sank rapidly, and died fifty minutes after admission.

Autopsy.—Five hours after death. I will omit details, which are not essential.

Inspection.—Body well nourished; rigor mortis well marked; slight œdema of both lower extremities.

Diaphragm at normal height.

Thorax.—There were a few old adhesions on both sides. The pericardium was distended with blood, which was measured and found to be ℥xiv. The loose cellular tissue about the origins of the aorta and pulmonary artery was infiltrated with blood.

The ascending aorta was found to be the seat of a small aneurismal dilatation, in which the intima and media together were ruptured in two places. Through these two ruptures the blood had made its way upward and downward between the layers of the media, over a space of about two and a half inches. One of the two ruptures mentioned above begins, as is well seen in the specimen, at a point between the origin of the left subclavian and left common carotid artery. It passes in a spiral direction entirely around the aorta, terminating about an inch nearer the heart than it began. Three-quarters of an inch above this rupture, and parallel with it, is seen another which is about an inch long. The thoracic aorta throughout has many patches of atheroma which are especially numerous in the region of the ruptures. The heart was normal—the valves being competent. On injecting the aorta from below it was found that the water injected oozed gently from several minute openings in the pericardium covering the aorta about an inch above the heart on its anterior aspect. There was no large opening discovered.

The Kidneys were normal in appearance to the naked eye. Examined by the microscope, numerous hyaline casts were found in the straight tubes.

The Liver showed a marked pigmentation about the central vessels, but was otherwise normal. All the other organs, including the brain, were normal, except that there were several small patches of atheroma in the vessels forming the circle of Willis.

CASE III.—J. G——, æt. 50; Ireland; laborer. The patient confesses to having been a moderate drinker. Had gonorrhœa and chancre twelve years ago, but gives no history of constitutional syphilis. Has had frequent attacks of chills and fever and rheumatism. He was admitted to the New York Hospital October 16, 1879. On the morning of this day, while walking in the street, he was seized with severe pain in the abdomen, choking sensation in the throat, became dizzy and fell unconscious. After regaining consciousness he had several copious evacuations from his bowels. On admission he was conscious, greatly prostrated, suffering severe abdominal pain. His surface was cool, pulse 97 and almost imperceptible at the wrist. Respiration quick and shallow, temperature in rectum 98°. Heart-sounds were feeble, but there was no murmur. He soon complained of pain in the præcordial region. There was slight œdema of the ankles. During the thirty hours following his admission he had total suppression of urine, and complained of pain in the lumbar region in addition to his other pains. During this time he was treated by stimulants, hot-air bath, cupping the lumbar region, poultices to the same part, and digitalis. After the lapse of this time he passed half an ounce of urine, which was loaded with albumen and contained hyaline and granular casts, blood, pus, and renal epithelium. His temperature rose to 101°, but in all other respects he continued profoundly collapsed. Two days after admission he passed several ounces of urine, which yielded much the same result upon examination as the first specimen. On the 18th October a soft, blowing, double murmur was heard all over the præcordium. At midnight he asked for

a glass of water, took it, and suddenly fell back dead, having been under observation two days and a half.

Autopsy twelve hours after death.

Inspection.—Body well nourished; rigor mortis well marked; symmetrical, old, roundish cicatrices on both shins; no œdema.

Brain showed thickened arteries at base. The lateral ventricles contained rather more serum than usual, but brain was otherwise normal.

Diaphragm was at the normal level.

Thorax.—The tissues of the anterior mediastinum were filled with blood. Nothing uncommon about the lungs, except that they were bound down by old adhesions, were congested and œdematous. The *pericardium* was enormously distended with blood, which was partly fluid, partly clotted. It measured 820 cubic centimetres.

Heart and great vessels.—Just above the heart the aorta was dilated slightly, forming a sac about as large as the egg of a goose. In the wall of this sac, about one and a half inches above the valve, was found a rupture into the pericardium just large enough to admit a No. 3 French sound. On opening the aorta from below it was found that this small opening into the pericardium was only in the outer wall of a dissecting aneurism, which extends downward to the heart and upward as high as the origin of the innominate artery. The intima and inner layers of the media were found to be torn completely through over the entire circumference of the aorta, on a level about half an inch above the aortic valve. Through this opening the blood had infiltrated the loose connective tissue in the neighborhood. Muscular tissue of heart was fatty; valves were normal.

The *kidneys* showed the lesions of chronic diffuse nephritis.

Remarks.—In all of these cases the intima is thickened; there are many patches of atheroma in it, and the sac of the dissecting aneurism in each case is not made up of the external coat, as Laennec describes it, but of some of the layers of media, together with the adventitia, as was first described by Peacock in England. The rupture then, in these cases, is really into the tissue of the media itself.

DERMOID CYST OF OVARY.

Dr. C. C. Lee presented a specimen for a candidate, after which he exhibited a dermoid cyst of the ovary, which was removed by operation with antiseptic precautions. The patient was a woman forty-one years old, who was admitted to the Woman's Hospital with a tumor the size of the fœtal head, in the right iliac region. It grew quite rapidly from the size of a lemon to the above dimensions. The patient desired its removal merely because it was a tumor. The clinical history was that of ovarian tumor, and a diagnosis was made accordingly. The patient recovered without a bad symptom. On removal, the tumor was found to be a dermoid cyst. He did not present it for any interest which it possessed in itself, but simply as belonging to a case which illustrated, in a marked manner, the impunity with which operations of the sort could be performed when antiseptics were used. Before carbolic acid had been employed in that manner it would have been thought entirely unwarrantable for any surgeon to remove an abdominal tumor and thus risk the patient's life, when the said tumor did not cause any injury to the general health. He thought the case illustrated, in a very marked degree, the benefits of the antiseptic treatment.

RECURRENT ORBITAL TUMOR.

Dr. C. S. Bull presented a recurrent orbital tumor with the view of adding to the history of a specimen previously presented to the Society. The eye was first enucleated for sarcoma of the choroid, July 7, 1879. Patient was a woman, æt. 26. At that time it was noticed that the growth involved the optic nerve, and at the time of the enucleation a piece of the nerve was pulled out of the optic foramen and excised. This proved to be infiltrated with the same growth.

On August 27, 1879, it was noticed that the orbit was refilling beneath the conjunctiva and bulging the latter forward.

On October 30, 1879, the tumor had grown to an alarming degree. The whole orbit was filled by the neoplasm, which protrudes through the widely-distended lids for a distance of two inches beyond the orbital margin. The skin of the forehead, temple, and cheek were very much swollen, probably owing to the great pressure exercised by the tumor. The interpalpebral aperture was filled almost to bursting. There was constant, severe, gnawing pain in the orbit and head. The surface of the neoplasm bled on the slightest provocation and discharged fetid pus. The external canthus was split, the conjunctiva divided along the junction of palpebral with retrotarsal conjunctiva, and then by means of strabismus hooks, scissors, and the finger, the adhesions of the tumor to the orbital walls were broken up. These adhesions were none of them firm except near the apex of the orbit. After a thorough removal from the orbit the same gray appearance of infiltrated tissue was seen presenting in the optic foramen and sphenoidal fissure. The upper orbital margin at both canthi was found diseased, the periosteum being thickened and infiltrated. This was scraped clean as far as the disease could be traced, the orbit thoroughly washed out with carbolic acid, and a twenty grain solution of zinc chloride applied. The orbit was then filled with carbolized sponge and covered by carbolized dressings and a tight bandage. All went well, and the orbit filled by granulating from the bottom, until December 3, 1879, when a suspicious nodular swelling in the skin of the upper lid appeared, at the external angle. This was somewhat elastic, was attached to the bone, and grew forward and inward toward the median line.

December 27th.—The growth in the lid was removed with the entire outer half of the lid. The periosteum was found extensively diseased, and hence the external canthus was split for the distance of one and a half inch toward the temple, the periosteum carefully removed from orbital margin, roof of orbit, outer wall and floor, for a distance of nearly half an inch, and then by gouge and scraper the superficial layers of bone-tissue removed, until apparently healthy bone was reached. The wound was carefully cleansed with carbolic acid, and dressed with carbolized lint and borated cotton and pads. The wound healed by first intention, and the case did well from the start. The orbit has entirely filled up, and the opening is covered by skin.

March 8, 1880.—Patient presents herself with a large nodule of inner end of upper lid, which involves skin of side of nose and lower lid, and a second distinct nodule in the outer third of lower lid.

At no time have there been any head symptoms, nor any infiltration of any of the neighboring glands.

CONGENITAL OPENING BETWEEN THE TWO VENTRICLES OF THE HEART.

Dr. Ridlon presented a specimen showing a congenital opening between the two ventricles of the heart. On the left side there seemed to be a valvular opening into the right ventricle. It was situated at the summit of the ventricular septum. The left ventricle was hypertrophied.

Dr. Wyeth asked concerning the relative frequency of this abnormality.

Dr. Putnam Jacobi said that it came second to stenosis of the pulmonary aorta, upon which it depended.

Dr. Wyeth thought that the most frequent form of communication between the two sides of the heart in the adult was that which resulted from failure of closure of the foramen ovale.

FIBRINOUS PERICARDITIS AND PLEURITIS—INSUFFICIENCY OF MITRAL AND AORTIC VALVES—CIRRHOSIS OF LIVER (HOUSE'S PNEUMONIA).

Dr. Ridlon presented a second specimen, which was one of fibrinous pericarditis, and had the following history:

Caroline K——, æt. 55; Germany; widow; nurse; admitted to St. Luke's Hospital February 27, 1880, Service of Dr. Wheelock.

On admission, patient was found to be nearly moribund. Respiration difficult and painful, 52 to the minute; pulse feeble, 104; face and hands cyanotic. Two days previous to admission she had been exposed to cold, had a chill, and felt great prostration, which was followed by fever and some cough; there was little expectoration. She gave the history of rheumatic attacks which occurred annually since 1850. Has, to her knowledge, had heart disease for the last twelve years. Physical examination showed pneumonia at left apex. No heart lesion could be made out, as the patient groaned with every breath. Examination of urine gave: specific gravity, 1026; acid; albumen, 20 per cent.; no casts. Death occurred at 11.50 P.M.

Autopsy fifty-eight hours after death.

Pericardium contained eight ounces of turbid serum. Both parietal and visceral layers of the pericardium were covered with a recent fibrinous exudation, forming a false membrane, which could readily be peeled off. The heart was slightly hypertrophied. There was calcification and insufficiency of both aortic and mitral valves. The left pleural cavity contained twenty ounces of turbid serum and was lined up to the level of the fourth rib with the same new false membrane as was found on the pericardium. There were no old adhesions between the visceral and parietal pleura. Pneumonic consolidation existed in the upper and posterior portions of the upper lobe of left lung. On the right side the pleura was normal, and the lung only showed some hypostatic congestion. The *liver* was of the nutmeg variety, and weighed 3¼ lbs. *Spleen* congested and feeble. *Kidneys* moderately congested; otherwise normal (to the eye).

Dr. Carpenter asked if the kidneys had been examined microscopically.

Dr. Ridlon answered in the negative, and Dr. Satterthwaite remarked that there were no evidences of kidney disease at post-mortem, and that the presence of albumen was probably a mere functional disturbance. Persistent lowness of specific gravity was a more important diagnostic symptom of organic kidney disease than albuminuria.

Dr. Putnam Jacobi believed that in the production of albuminuria it was necessary that the uriniferous tubes should be denuded of their epithelium.

Dr. Satterthwaite could not understand, if this were always the case, why patients who had albuminuria could so frequently become healthy again.

Dr. Putnam Jacobi replied that the denudation might be confined to the larger tubes, in which case the disease was curable.

Dr. Hinton referred to the fact that certain articles of food produced albuminuria in perfectly healthy individuals.

Dr. Peaslee remarked that milk will produce albuminuria in some healthy persons. In regard to the question of desquamation of epithelium as a necessary preliminary to albuminuria, he referred to the following significant fact. A patient was brought in the Chambers Street Hospital suffering from injury of the head from which he shortly afterward died. His urine during life was found loaded with albumen, but a careful examination of the kidneys afterward showed them to be absolutely healthy.

Dr. Satterthwaite alluded to the case of well-known professional wrestlers of this city presumed to be in perfect health, who would always have albumen in their urine after vigorous physical exercise, and also to the case of a gentleman who had the same thing occur as the result of extra mental efforts. In both cases the albuminuria would disappear when rest was taken.

Dr. Putnam Jacobi alluded in this connection to experiments which had been made upon fifty healthy German soldiers. In a certain number albuminuria was found after fatiguing exercise.

Dr. Sell remarked that very anæmic persons have functional albuminuria, the latter disappearing when health is restored.

EPITHELIOMA OF LEG—AMPUTATION.

Dr. Elizabeth M. Cushier presented a specimen of epithelioma of the leg, with the following history:

Mrs. B——, native of Canada, aged 32 years; family history good. Patient is married and has had two children, both healthy. Ten months since had an abortion at six weeks; no assignable cause. Is now pregnant, three months advanced. General health has always been good. Present trouble dates from about seven years since, when she began to have pain in right leg. The pain was at this time referred to upper and anterior part of leg; it was unattended by any redness or swelling, and was always worse at night. Two or three years later a spot of discoloration was observed at about the middle of the leg, at inner side of tibia, and this began to be at times painful. There was never any severe pain, however, until two and a half years since. At about this time patient struck her leg in getting out of a carriage. This did not give her immediate trouble, but soon after there began to be intense pain at one point over tibia, at site of present lesion. During the entire winter the patient had no rest, and for several weeks morphine was given to control the pain. In the May following the patient noticed, for the first time, a swelling over the tibia at the point above mentioned. It was not an even swelling, but was made up of "little lumps." From the time of the appearance of the swelling the pain was not so intense, although still at times severe. The swelling and redness continued to increase, and constant treatment in the form of applications was resorted to without relief. During the following year there was but little change, excepting the increase in size, until

last May, when the surface opened. The ulceration spread at first rather slowly; the surface of the ulcerated portion remained quite flat, and the discharge was but slight and watery. In July last patient noticed that "proud flesh" began to form, and projected above the level of the skin. About one month before coming under observation the spot began to increase more rapidly in size, and at the same time began to heal in the centre. When patient was first seen on February 13th she looked in excellent health, and gave no evidence of constitutional disturbance. Upon examining the leg there was no swelling, nor any enlargement of the veins. Directly over the middle of the tibia an open surface was presented, measuring two inches in diameter. It was circular in form, the edges were slightly excoriated, and the entire centre was filled with large papillomatous growths, which, although crowded together, were quite separable from each other. They were pale in color, firm and painless to the touch, and did not bleed readily upon handling. There was a very slight discharge, and this was from the periphery of the mass. The whole was quite immovable upon the underlying bone. At the lower border, and separated from the main lesion by a narrow isthmus of integument was a small ulcerated spot about the size of a pea. This spot did not present any of the papillæ above mentioned. The integument of the limb was of a purplish-red hue for some little distance from the growth. The shaft of the tibia was sensitive as high as the garter, and at about two and a half inches from the head of the bone there was a small sensitive nodule.

While from the history and appearance of the growth, I believed it could be limited to either one of specific origin or to an epithelial new formation, I was very doubtful as to which of these pathological conditions it belonged. I then asked Dr. R. T. Weir to see the patient with me. Upon examining the patient, Dr. Weir also expressed a doubt as to the character of the lesion, and while inclined to regard it as an epithelioma, was still unwilling to pronounce a definite opinion without a microscopic examination. I accordingly removed some of the papillæ above described, and, after hardening them, made the sections which are presented this evening. These sections show irregularly cylindrical masses of large epithelial cells dipping down to the base of the portion removed; from these cylinders were side processes containing the well-known horny bodies. The stroma surrounding these masses was filled with granulation-cells. The section was shown to Dr. Weir and also to Dr. Adler, and was unhesitatingly pronounced by them to belong only to an epithelioma. Drs. D. Stimson and Peabody, who also saw the specimen, expressed the same opinion. It was suggested, while waiting, to place the patient under treatment for specific disease, but, with the possibility of a near operation, it was decided to await the revelation of the microscope before subjecting her to such depressing medication. All the more as I had been informed that the patient had for a long time taken large doses of the potass. iodide.

During the few weeks that the patient was awaiting a decision, the growth rapidly increased at its periphery, and began as rapidly to cicatrize in its centre. The newly ulcerated portion was immediately filled with the above-mentioned excrescences, as was now also the small ulcerated spot which at the same time increased in size.

The undoubted malignity of the growth, its rapid increase within a few weeks, and the hope of preventing its recurrence by an early and complete removal, led to an amputation being advised, and this was readily acceded to on account of the suffering which had been endured, and the comparative uselessness of the limb. The operation was accordingly made, with the kind assistance of Dr. Weir, on Friday last. The antiseptic method was completely carried out, and the progress of the wound has been most satisfactory.

The main point of interest in the case rests upon the question of diagnosis. This, in the opinion of several well-known and experienced clinicians, could not be decided upon without a microscopic examination. All who saw the growth agreed that it presented many of the characters of a specific lesion. One of the points mentioned in this connection attracted my attention, and led me to consult authorities with reference to it. This was, that in epithelial growths there was not the tendency to cicatrization in the centre at the same time that an increase took place at the periphery. I find, however, that both Tiesch and Neumann mention a variety of epithelioma which is characterized by this tendency. As a result of the casting off of the epithelial elements, after which the connective tissue, instead of remaining highly vascularized and continuing to exist, as in some cases, as granulation tissue, becomes less vascular and forms cicatrices.

Dr. Satterthwaite stated that in the flat epithelioma of the Germans, of which this seemed to be a variety, it was the rule that cicatrization took place after cauterization. In connection with the general subject of cicatrization in carcinoma he referred to a case of epithelioma of the tongue under charge of Dr. L. A. Stimson, in which for a time the disease not only seemed to be arrested, but to show a tendency to heal under large doses of the iodide of potassium. Subsequently it extended, continued to exhibit the evidences of epithelioma, and was removed by Dr. Stimson.

Dr. Wyeth had seen a case precisely similar to Dr. Cushier's, while on a recent visit to Baltimore. Dr. Smith, the surgeon in charge, had determined on amputation.

Dr. Ripley was of the opinion that the amputation in Dr. Cushier's case was somewhat premature. In connection with a possible escape from such a radical measure of treatment, he referred to Dr. Robinson's case of epithelioma of the larynx, which had recovered entirely. In that particular instance the growth had been examined by a number of expert microscopists, who agreed that it was epithelioma, and afterward the growth had entirely disappeared and the parts had remained in a perfectly healthy condition for many months. Dr. Robinson's case had been fully reported to the Society on previous occasions.

Dr. Cushier remarked that the undoubted malignity of the growth, the utter uselessness of further treatment—the patient having been thoroughly saturated with iodide of potassium, and suffering great pain, made amputation necessary.

Dr. Putnam-Jacobi observed that the presence of epithelial cylinders in the growth would be an extraordinary anomaly in syphilitic ulceration.

Dr. Satterthwaite remarked that they were hardly interchangeable conditions, as syphilis was a connective-tissue growth by which epithelioma was epithelial in its nature. On the question of the possibility of carcinoma being cured by operation, Dr. Satterthwaite referred to a case of scirrhous cancer of the breast, of which he has records, which had not returned for seven years; Dr. Ripley, to an epithelioma of cervix uteri removed by Dr. Jacobi, and which

had not reappeared four years after the operation, and Dr Carpenter, to a case of cancer of the breast amputated four years ago without return.

THE PHILADELPHIA ACADEMY OF NATURAL SCIENCES.

Regular Meeting.

A NEW FLUID FOR THE PREPARATION OF ANIMAL AND VEGETABLE TISSUES.

At a late meeting Professor Barlseck called attention to a subject of much practical importance to naturalists, physicians, and scientific men generally. The German papers had a short time ago brought to notice the fact that Mr. Wickersheimer, of the University of Berlin, had invented a fluid for the preparation of animal and vegetable tissues, which surpassed anything before known in its power of preserving the color, form, and elasticity of specimens treated with it. It was reported that the fluid was either injected into the veins of the body to be preserved, or the entire object was immersed in it. After having been taken out of the fluid and dried, the elasticity of the tissue and flexibility of the joints were secured.

A number of skeletons were shown, in which all the complicated movements could be executed. Some of the skeletons exhibited beautifully the combined movements of the chest, larynx, and other parts engaged in the mechanism of breathing. Several skeletons of snakes, which had been treated with the fluid more than a year previously, permitted of undulatory and spiral movements. Lungs thus prepared may, even after years, be inflated by means of bellows. Such old lungs were seen to swell to ten times their size in the collapsed state; the lobes became distinct, the brown color gradually changed into red, and the whole organ appeared as if taken from a fresh body. Sections of delicate tissues, morbid formations which have been removed by an operation, will appear after months as if in a fresh state, and may thus be preserved for future study. All sorts of vegetable organisms may also be preserved in this fluid. A colony of exquisite fresh-water algæ, which had been in the fluid for a year, appeared to be growing in the water.

The Prussian government had purchased this valuable discovery, and the Minister of Instruction had published it in his official organ for the benefit of the scientific world. The formula for the preparation of the fluid is as follows: in 3,000 grammes of boiling water dissolve alum, 100 grammes; common salt, 25 grammes; saltpetre, 12 grammes; potash (kali carbonicum), 60 grammes; arsenious acid, 10 grammes. After cooling and filtering, add to every ten litres of the solution four litres of glycerine and one litre of methylic alcohol.

The method of application differs according to the nature of the objects to be preserved. Anatomical preparations that are to be preserved dry are immersed in the fluid from six to twelve days, according to their size, then taken out and dried in the open air. Hollow organs, such as the lungs, etc., must be filled with the preserving fluid, then laid in a vessel containing the same liquid, and afterward distended with air and dried. Smaller animals, such as crabs, beetles, lizards, frogs, etc., if the natural colors are to be preserved unchanged, are not to be dried, but put immediately into the preparation. The same fluid may be used for the purpose of preserving human bodies during transportation, or even for more permanent embalming.

TAPE WORM IN THE LUNGS.

In the course of Dr Henry C Chapman's remarks on certain anatomical points observed by him while dissecting animals which had recently died in the Philadelphia Zoological Garden, he described the lungs and liver of a monkey, which were completely disintegrated and filled with cysts, produced by an immature form of tape-worm. The states of development of these parasites in various animals were described at length.

Correspondence.

THE SALE OF DIPLOMAS.

The following correspondence explains itself:

DEPARTMENT OF THE INTERIOR,
BUREAU OF EDUCATION,
WASHINGTON, March 31, 1880.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Your co-operation in fulfilling the objects of the enclosed circular-letter of March 26 (respecting the "sale of diplomas," issued by fraudulent corporations in this country to subjects of foreign powers), is earnestly desired.

I shall be happy to receive any suggestions that you will be good enough to make, as well as any publications on the topic. I am, sir, very respectfully,

Your obedient servant, JOHN EATON,
U. S. Commissioner of Education.

Mr. Evarts to Mr. Schurz.

DEPARTMENT OF STATE,
WASHINGTON, March 12, 1880.

SIR:—I have the honor to transmit herewith for your information a copy of a dispatch (No. 87) of the 24 ultimo, from Mr. White, the Minister of the United States at Berlin, in relation to spurious diplomas issued by a so-called American University at Philadelphia. I beg to express the hope that it will be found practicable to devise measures, through the Bureau of Education or otherwise, for the effectual suppression of the practice of issuing spurious diplomas at Philadelphia, which is proving so injurious to the reputation of this country with respect to higher education. I have the honor to be, sir,

Your obedient servant,
WM. M. EVARTS.

The Honorable CARL SCHURZ,
Secretary of the Interior.

Mr. White to Mr. Evarts.

LEGATION OF THE UNITED STATES,
BERLIN, February 2, 1880.

SIR:—I regret to state that there seems to be a revival here of the sale of diplomas purporting to be issued by an institution of learning in the United States.

Some weeks since a Mr. Pappenheim brought me a diploma, engrossed on parchment in very handsome style, and issued nominally by "the American University at Philadelphia," conferring the degree of doctor of medicine upon one Christopher Schuetz, living, as I understand it, at Leipzig. It would appear that the diploma was offered to Schuetz upon condition of his paying a sum of money for it. It bears the signatures of a number of persons claiming

to be professors in the aforesaid university, at the head of them being the signature of "John Buchanan, M.D." Schnetz desired the Legation to give him a declaration of its genuineness and value, which I refused to do. One peculiar feature of the diploma was that, although evidently entirely new and recently issued, it was dated 1872.

About ten days since another and more serious case was brought to my notice. The judicial authorities at Prenzlau forwarded a copy (which I enclose) of a diploma issued by the same alleged institution to Paul Christoph Erdmann Volland, and signed by a faculty at the head of which appears the same name of "John Buchanan, M.D." The authorities at Prenzlau asked the Legation regarding the genuineness of the diploma and the standing of the institution, it being with them a question whether Volland could be allowed to practice his profession under such a diploma.

After looking through the correspondence on record in this Legation (a memorandum of which is inclosed), and seeking in vain for the name of the institution in the list of colleges and universities published by the Bureau of Education in the Department of the Interior, at Washington, my answer was unfavorable to Volland's claim.

From the correspondence above referred to, I find that attempts have been made by the Legislature of Pennsylvania for the suppression of this nuisance; but that, after all, it is a question whether these attempts have been successful, and whether the institution has not still a legal existence. This being the case, I would respectfully suggest that the matter be brought to the notice of the Commissioner of Education in the Department of the Interior, at Washington, and that he forward me any documents or information in his possession regarding the subject.

You will observe among the papers accompanying the diploma of Volland something much more serious than the diploma itself, and that is the authentication of it by Philip A. Cregar or Gregar, notary public of Philadelphia; and I bring this matter especially to the notice of the Department, hoping that something may be done to prevent officials in Pennsylvania lending themselves to what is undoubtedly a fraud, whether under the forms of law or not.

That such cases as these have brought disgrace upon the American system of advanced education, and upon the American name in general, is certain. This has been recently revealed to me incidentally in a curious way: in a very successful play now running at the Royal Theatre in this city, a play written, strangely enough, by a judge of one of the highest tribunals in the Empire, one of the characters, in casting a reflection upon another who is dignified with the title of doctor, declares a belief that the latter had simply bought his degree in America; and in a recent novel, by a popular author here, the scoundrel of the book, having escaped justice in Germany, goes to America, and is at last advices very comfortably settled and practising medicine with a sham diploma which he has bought for money.

All this, of course, is of no especial significance in this case, save as it shows that the fair fame of our country has been, and can be, injured in the minds of a large number of people, even by such contemptible transactions as those herein referred to.

I have the honor to be, sir,

Your obedient servant,

AND. D. WHITE.

The Hon. WILLIAM M. EVARTS,
Secretary of State, etc.

REMARKS ON

THE BROMIDE OF ETHYL, OR HYDROBROMIC ETHER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In criticising this admirably-written paper (read before the New York Academy of Medicine, March 18, 1880), by so distinguished a surgeon and able writer as my friend Dr. Sims, I feel I am undertaking a very delicate and difficult task, and yet I consider it to be a duty which I cannot lay aside, as part of the responsibility of the reintroduction of the hydrobromic ether as an anæsthetic is due to me.

In several careful readings of the report (published in the MEDICAL RECORD, New York, April 3, 1880), my impressions were as follows:

First, that after the patient had been relieved, "the uterus replaced, the cervical canal enlarged, with menstruation normal in quantity and painless" (p. 362), no more fault could be found with the ovary or the uterus which received the menstrual fluid; the epileptic seizures were, therefore, not due to the diseased ovary, but were more likely caused by anæmia of the brain, which fact numerous experiments on animals have proven to be the case. There is every reason also, on clinical grounds, to believe that in the epileptic paroxysm the brain is successively anæmic and congested. Again, if these epileptic attacks had been entirely due to the diseased ovary, pressure on it or them would have produced these convulsions, or, on the other hand, would have checked them. There was, so far as we have noticed, no test of this kind instituted.

Second, we have always considered "Battey's operation" one of the most barbarous and unjustifiable in surgery, and it is well known that several deaths have followed the abdominal incision for removal of the ovaries.

Third, an operation of such magnitude and of so much importance to the life of the patient, should not have been performed upon a confirmed epileptic.

Fourth, before performing this hazardous operation the urine should have been most carefully examined by various tests and by the microscope. It is now a well-recognized condition that in disease of the kidneys anæsthetics almost invariably produce coma and death. In the post-mortem examination of the kidneys of the patient, in the examination by the microscope, "there was a slight increase of the interstitial connective tissue, and many of the convoluted tubules showed swollen and coarsely granular epithelia and considerable narrowed central calibre, a characteristic feature of acute catarrhal nephritis."

Fifth, no laxative or purgative medicine is at all justifiable or even allowable on the day of the operation, or soon after the operation of extirpation of the ovary; and we know of one case in which everything was going on well after an operation for ovariotomy, when an officious neighbor called to see the case, and the patient stated that she had considerable pain in her stomach and bowels, and the friend advised a dose of castor oil, which the nurse gave without consulting the doctor. It operated, and the patient forthwith passed into a state of collapse and died. In three cases of ovariotomy in which I assisted the late Dr. Washington Atlee, he invariably shut the bowels up by means of McMunn's elixir of opium, and never disturbed them for days, and had the patients so strictly watched that no outside interference was possible. Now, Dr. Sims's patient "took three drachms and fourteen grains of Rochelle salts at 8.30

a.m. on the morning of the operation, the food or stimulants given not tasted. It operated freely twice before 11 o'clock a.m., and no more till 7 p.m., about two hours after the operation." She then had six thin, brownish, watery discharges from the bowels between 7 and 11 p.m.—not large, but attended with tenesmus, and the last with a little mucus. At 12.15, 2.40, and at 6 and 7 next morning there were other thin, watery, brown discharges with tenesmus and a little mucus, and the patient wanted the bed pan under the pelvis constantly." "Thus we see that between 7 p.m. and 7 the next morning there were no less than ten watery, not profuse, but exhausting evacuations, over which opiates and astringents did not exercise the least influence."

Dr. Nast, one of the physicians who made the post-mortem, says: "A few hours before death there were several (two or three) large, involuntary movements from the bowels, such as she had previously had—dirty, thin water, with the disagreeable ethyl odor. In the post-mortem "the lower portion of the ileum and colon were black and congested, and altogether presented an appearance far from a normal healthy one."

In all the operations performed by Dr. Levis, Pancoast, Samuel W. Gross, and myself there has not been one single instance in which there has been the slightest disturbance of the bowels, not even in the case of mine reported by Dr. Sims, or in other protracted operations, such as amputations, resections, etc.

Sixth, it will also be noticed that in the report of the post-mortem no mention is made of the injury of the bromine, which was not free, on the mucous membrane of the throat and lungs referred to by Dr. Squibb. There is absolutely nothing stated concerning the appearance of the brain, when so much importance is given to the "pain in the head," and yet up to 7.45 of the morning of her death there was no coma, she being perfectly conscious when spoken to at 6.40. Her convulsions were truly epileptiform in character from the drain upon her system by the loss of blood, and the exhaustive diarrhœa causing the most positive anæmia of the brain, with the superadded inflammation of the colon and ileum, as was proven by the post mortem.

I place on record two post-mortems of animals killed by almost entire exclusion of air and by crowding the hydrobromic ether upon them, and showing the peculiar appearances of the parts.

The late Dr. Thomas Nunnelly* placed "a cat in a six hundred cubic inch jar in which there was one drachm of hydrobromic ether. He absolutely did not move a muscle, but gradually sunk down head foremost to the bottom of the jar, and in one minute he was perfectly insensible. The respiration became laborious, then slower, and in fifteen minutes it altogether ceased. In twenty-five minutes he was removed from the jar, which still smelled very strong of the ether."

"*Post-mortem examination* immediately.—Muscles quite flaccid. On dividing the phrenic nerves the diaphragm moved slightly. Chest: lungs crimson in color and much collapsed; pulmonary veins very full; bronchial membranes pale and dry; heart, both auricle and ventricle, on the right side, as full as possible; the venæ cavæ also excessively distended; the left auricle also very much distended, but the left ventricle was firmly contracted and empty; the proper vessels of the heart were not much filled; the blood was alike dark on both sides. Head: sinuses filled, the pia mater congested, as was the brain, but not in a corresponding degree; its substance was serous, and there was little fluid in the ventricles."

The following experiments were made before the class of the Pennsylvania Dental College by me with hydrobromic ether to show that if no atmospheric air were allowed to enter the lungs with the ether inhaled, both man and animals must die. I then produced profound anæsthesia in a pigeon and a dog. I informed the class that we would so exclude the air from the rabbit that we would kill it, as an evidence that caution must be employed with all agents that would produce such an amount of insensibility. It will be noticed that the post-mortem agrees with that of Mr. Nunnelly. The eye was open, bright, and pupils dilated, no evidence of any redness or congestion about the cornea, and yet the animal had inhaled over an ounce of the ether. There were no convulsions, no great rapidity of pulse or action of the heart, the animal sinking into a lifeless mass. No means were taken to resuscitate it.

Post-mortem. The right side of the heart was found engorged with dark venous blood; the left side very much contracted and empty. The lungs very slightly congested at their base—not enough to have had any effect in causing death. The kidneys were much congested with venous blood. The brain was entirely free from blood, not even the puncta vasculosa being seen, but at the Torcular Herophili was found a large drop of dark blood.

Much importance is given to the retained odor of the hydrobromic ether; but this is a common occurrence, as in any operations of long duration, when ordinary ether has been employed, the odor is noticed for several days, not only by the patient, but by his friends.

The subject of the injurious influence of the decomposed hydrobromic ether has been dwelt upon, and the injurious or poisonous effect of the bromine as stated, by one of the physicians who took part in the discussion. Now, this bromide of ethyl is termed a loosely molecular article, is decomposed very easily, much more so than bromides of ordinary bases which act as salts, and are eliminated as such. Now we know, from numerous practical experiments, both on animals and man, that hydrobromic ether is eliminated from the skin, kidneys, and lungs not at all decomposed, and has no special irritating effects either on the stomach or intestines of man or animals. When animals are killed by hydrobromic ether, there is no irritation about the eyes, nose, or mouth. In certain cases this ether exerts a beneficial influence on irritation of the intestines; for instance, in the colic which sometimes affects children, and in the pain of nervous dyspepsia and headache. Again, instead of causing convulsions it checks them; it is also useful in delirium and acute mania. The whole amount of hydrobromic ether employed was two ounces, in drachm doses, covering the time of one hour and a half. Part of the ether was, no doubt, left on the cloth or napkin, and part of it was lost in the struggles of the patient. Now, the whole amount of bromine was comparatively small in quantity in the hydrobromic acid, into which the bromine is converted by the reaction of potassium bromide and diluted sulphuric acid, with alcohol, into hydrobromic ether.* The amount which the patient re-

* Transactions of the Provincial Association, vol. ix., London, 1849.

* "By the improved method of preparing this agent, the reaction is as follows: potassium bromide and diluted sulphuric acid are heated in a flask. When hydrobromic acid begins to be disengaged, alcohol

ceived, we are sure, did not contain much more of bromine than is contained in the forty to sixty grains of bromide of potassium she was accustomed to take for her epileptic attacks three or four times a day.

Now, what is the true physiological effect of the bromides when taken in large and repeated doses? Acne of various forms, diminished sensibility, followed by complete anæsthesia of the soft palate, uvula, and upper part of the pharynx, when the patient is fully under the bromine influence.

In summing up all the facts in the case, I feel assured that less than two ounces of hydrobromic ether were not the cause of death.

Very truly yours,

LAWRENCE TURNBULL, M.D.

PHILADELPHIA, PA.

NITRITE OF AMYL IN CHLOROFORM NARCOSIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In reply to the query of Dr. J. J. Boynton, I beg to relate a case illustrating the valuable effect of nitrite of amyl in chloroform narcosis. A young gentleman, on whom I proposed to perform abscission of the prepuce, was placed on the table, the tumbler containing chloroform held over the nose and mouth, and just as I seized the prepuce his face became blanched, respiration ceased, and I found myself in the presence of the most trying ordeal in my experience. No pulse could be detected, the pallor of death deepened, the lower jaw fell, and in the agony of the moment I sprang astride of his body and began artificial respiration, directing my assistant to crush the nitrite of amyl pearls (manufactured by Reichardt) in the handkerchief, which I had fortunately prepared in readiness for the accident. No time was thus lost, but the third time the chest was freed from my pressure a whiff of amyl nitrite seemed to enter the lungs, and the patient's face lost its pallor. A few more inspirations caused suffusion of the skin. As the ruddy hue returned to those pallid lips I felt as if a fearful load had been lifted from me, for I had promised a successful result to a young man who was the only hope and stay of a helpless family, and his sudden death would have been a terrible blow to me personally, while the prejudice against chloroform in this community would have received a strong impetus. If the mouth is shut, air can be made to enter through the nose by artificial respiration, conveying the volatile nitrite of amyl vapor.

While upon this subject, permit me to mention a valuable inhaler, for the knowledge of which I am indebted to Dr. E. S. Gaillard. Press a folded handkerchief, just as it comes from the laundry, into a light tumbler, pour the chloroform upon the handkerchief, and invert the tumbler over nose and mouth. The inequality of the naso-labial space permits the free entrance of air, and the vapor is thus properly diluted. In cases of labor, I am in the habit of removing the tumbler when pain is passing off, and pressing it in an inverted position upon the pillow until it is again necessary. A great saving of chloroform is thus gained, while the delay involved in frequent pouring of fresh chloroform is avoided. Only in surgical operations do I hold the nitrite of amyl globules, wrapped in a handkerchief or cloth, in readiness for crushing.

Very respectfully,

S. BARUCH.

CAMDEN, S. C., April 5, 1880.

is allowed to flow in slowly. The distillate is hydrobromic ether, which requires washing with water and alkaline carbonate, and rectification."—The Advantages and Accidents of Artificial Anæsthesia, by Lawrence Turnbull, M.D., 2d edition, p. 294. Philadelphia: Lindsay & Blakiston, 1879.

ON COMPENSATION FOR THE REGISTRATION OF BIRTHS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—It has been wittily remarked that nothing so thoroughly exasperates the average American politician as the sight of an honest man receiving honest payment for an honest day's work. This, probably, involves a slight exaggeration; but, certainly, there is much in recent "sanitary legislation" to justify the assertion, so far as the relations of legislators to the medical profession are concerned. We must report diseases, and births and deaths, at no little expense of time and convenience, and even money, without one cent of compensation, and at the very great risk, oftentimes, in cases of disease, of destroying the relations which should exist between physician and patient. Worse than all this, we have to undergo the humiliation of seeing certain *quasi* members of our profession, with a cringing servility that is painfully remindful of the days when doctors were slaves, actually begging our legislators to fine us and degrade us in various ways, to the best of their ability, if we refuse compliance with such injustice.

Two things, however, are very certain: first, that no honorable physician, with his eyes open to the nature of the act, will submit to the degradation of acting the part of a voluntary and unpaid spy and informer for the government; and, second, that we will not rest content with any set of laws or officials that attempt to force us to work, without pay, for that employer which is best able to pay for services, to wit: the state. Of the difficulties raised by these two facts, the first can easily be removed by the adoption of the plan recommended by the British Medical Association, for the registration of infectious diseases. The other difficulties are not as easy to manage. It is, however, an encouraging thing to find that a man with the influence of Dr. J. S. Billings, is willing (see his introduction to Buck's Treatise on Hygiene and Public Health) to admit the justice of the claims for compensation to physicians and others who make returns of births and deaths. He does not, however, undertake to propose any mode of compensation, other than to volunteer the statement that it should probably be indirect in its character.

Now all this is wrong, and far from creditable either to the public or to the medical profession. It is no doubt true that with the present temper of the average legislator, inspired by his observation of the timidity with which the average doctor submits to all kinds of petty injustice, it will be found difficult to secure direct and sufficient payment for the work which we are called upon to do, and which should be done if it can be paid for. But it does not seem impossible to effect what is necessary in an indirect way. We are not mercenary, nor disposed to drive an unnecessarily hard bargain with our rich patron (task-master, I might have said), the state. All we want is a recognition of our rights as honest, working men. Let us begin with one thing at a time—

the registration of births. Waiving all discussion of the expediency of removing this duty from the shoulders of the parties most interested, namely, the parents of the children, let us see if there is not some way to compensate the doctor who makes the registration. The act does not require any degree of specially skilled labor—it is mainly clerical. Consequently, the compensation need not be very large, but it should be something tangible. Now I am every year obliged to expend a considerable sum of money for bovine virus. The use of this article is becoming more general as experience of its value increases. If our State Boards of Health do their duty, there will in each State soon be an official vaccine establishment for the production of this virus. Let it be understood, in a legal way, that this virus will be supplied, without cost, on application, to every physician and midwife who makes returns of births, *and to no other persons*, and the causes of discontent which now exist will be in great measure relieved. The reporter of numerous births will need more virus than the reporter of few; so that a certain quality of compensation will thus be secured, while the great principle of honest payment for honest work will be sufficiently vindicated.

HENRY M. LYMAN, M.D.,
Prof. Pr. [illegible] and Surgical Diseases,
Rush Medical College, Chicago.

MEDICINAL SPRING WATERS.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—A series of papers upon Medicinal Spring Waters have recently appeared in the columns of the RECORD from the pen of Dr. John C. Peters. They appear as an *expose* of the pretensions of mineral waters in general. It is to be regretted that a physician occupying the prominence of Dr. Peters should have made so gratuitous an attack on medicinal agents which have so long had the confidence of both laity and profession, and which time and familiarity have only more firmly established in their esteem.

As I differ from the doctor in the views expressed, I beg leave to offer a criticism on the papers as far as they have appeared: 1st, in regard to their reference to Saratoga waters; and 2d, as to their scientific worth.

The thirty odd mineral springs of Saratoga are something more than condensed into the space of seventeen lines, of which nearly seven lines are devoted to but one spring. The remainder is occupied with what claims to be an analysis of "Saratoga Water," and a four-line chapter on its uses. I had at first supposed that the analysis presented was an average of the ingredients in all the principal springs, but a closer examination shows it to be the current analysis of the spring which has already monopolized the most of the doctor's space.

As it is a water considered "among the poorest," to use the phrase of an old resident practitioner, and but seldom prescribed by physicians most familiar with the mineral fountains of Saratoga, the injustice of presenting such an analysis is patent. A comparison of its constituents with those of some of the other springs will make this still more apparent.

The amount of chloride of sodium which is attributed to "Saratoga Water" (quantity not stated, presumably a gallon), is 390 grs. The Champion contains over 700 grs., and the Red Spring but 83.5 grs. per gallon, and yet they are reduced to the same level. Other constituents are in like proportion. The amount of bicarbonate of magnesium is stated at 61 grs. against an actual amount in the five principal cathartic springs of 191 grs., 176.4 grs., 149 grs., 122 grs., and 107.9 grs. respectively per gallon.

In addition to the inadvertent misrepresentation in the paper, it must be borne in mind that the springs are extremely various in their properties and applications, and no one spring can be taken as an example of all the rest. This is a fact not so well known among the profession as it should be. Thus, in some of the springs, the cathartic principle is almost lacking, as in the Red Spring, Vichy, or Seltzer. Again, the cathartic is strong, but the alkaline very weak, as in the Hathorn, or, the alkaline predominates over all others, as in the Vichy. In some, the iron is scarcely traceable; in others, as the Columbian or Putnam, the impregnation is so strong that they have to be taken with great care lest violent headache is produced. The sulphur waters introduce still another element of great medicinal value, and certain of the springs are remarkable for diuretic and alterative qualities. It has been said that Saratoga waters all contain the same ingredients. To a certain extent this is true, but therapeutic effects at the various springs are as different as the ingredients are prodigiously diverse in quantity. Moreover, certain of the constituents of some of the springs are totally lacking in others. It is as unfair to make this assertion as to say that all woods or all men are alike.

There are three possible sources of error in the ground taken in the papers: 1st, in assuming that a therapeutic action must admit of a chemical explanation. It very often does not, and the whole groundwork of the articles is based upon that assumption; 2d, in assuming that the analyses represent all medicinal agents contained in the waters, i. e., that there are no unknown elements or unfamiliar combinations present; 3d, that small doses are inoperative. When I see the iron in certain of these spring waters, insignificant though the dose may be, producing severe physiological effects, not once but constantly, I regard an insinuation that such results are largely imaginary, as a piece of pedantic impertinence. And the same thing holds good of other ingredients.

In conclusion, let me say that there are many excellent men in the medical profession who disbelieve in medicinal springs, and say their work is accomplished by change of scene and habits. I think it will be found that after excluding all the valuable effects allotable to change, there is still a large remainder which can alone be attributed to the waters. Undoubtedly change works much. What if it does? There is an old saying which requires even a certain unmentionable individual shall receive his due. There is good accomplished by the springs, and I say, "let the miracle be done, even tho' Mahomet do it."

Sincerely yours,
W. O. STILLMAN, M.D.

SARATOGA SPRINGS, March 29, 1880.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from April 4 to April 10, 1880.

By S. O. 74, A. G. O., April 3, 1880, the following changes are made;

Assistant Surgeon G. P. JAQUETT is relieved from duty in Department of the South, and assigned to temporary duty at David's Island, N. Y. H., relieving Surgeon A. K. SMITH. Surgeon SMITH, when relieved,

will report in person to C. O. Department of Arizona for duty as Medical Director of that Department, relieving Surgeon J. C. McKee. Surgeon McKee, when relieved, will proceed to New York City and report arrival to the Surgeon-General.

The following named officers are relieved from duty in the departments set opposite their respective names, and will report in person to the President of the Army Medical Examining Board, in New York City, for examination for promotion, and, upon completion of examination, report by letter to the Surgeon-General: Asst. Surgeon Daniel Weisel, Department of the Columbia; Asst. Surgeon P. F. Harvey, Department of Dakota; Asst.-Surgeon C. K. Winne, Department of the Platte.

Asst. Surgeon V. Havard is relieved from duty in Department of the South, and will report to President of Army Medical Examining Board, New York City, for examination for promotion, and upon completion of examination, in person to Commanding General Department of Texas, for assignment to duty.

The following named officers are relieved from duty in the Departments set opposite their respective names, and will proceed to New York City, reporting arrival to the Surgeon-General: Surgeon C. E. Goddard, Department of Texas; Asst. Surgeon F. Meacham, Department of Texas; Asst. Surgeon F. C. Ainsworth, Department of Arizona; Asst. Surgeon C. E. Price, Department of California; Asst. Surgeon M. W. Wood, Department of the Platte; Asst. Surgeon W. C. Shannon, Department of Texas.

Asst. Surgeon L. S. Tesson is relieved from duty in Department of Dakota, ordered to St. Louis, Mo., and report arrival to Surgeon-General.

Asst. Surgeon W. Reed is relieved from duty in Department of Arizona, will proceed to Richmond, Va., and report arrival to Surgeon-General.

Brewer, J. W., Captain and Asst. Surgeon.—The sick leave granted him from A. G. O., September 22, 1879, extended three months on surgeon's certificate of disability. S. O. 67, A. G. O., March 26, 1880.

"An Act to Regulate the Licensing of Physicians and Surgeons," introduced by Mr. Bullock, in Assembly (No. 578)—read twice and referred to the Committee on the Judiciary—reported from said Committee for the consideration of the House—and committed to Committee of the Whole.

The People of the State of New York, represented in Senate and Assembly, do enact as follows:

Section 1. A person shall not practise physic or surgery within the State unless he is twenty-one years of age, and either has been heretofore authorized so to do, pursuant to the laws in force at the time of his authorization, or is hereafter authorized to do so as prescribed by chapter seven hundred and forty-six, of the laws of eighteen hundred and seventy-two, or by subsequent sections of this Act.

§ 2. Every person now lawfully engaged in the practice of physic and surgery within the State shall, on or before the first day of October, eighteen hundred and eighty, and every person hereafter duly authorized to practise physic and surgery shall, before commencing to practise, register in the clerk's office of the county where he is practising, or intends to commence the practice of physic and surgery, in a book to be kept by said clerk, his name, residence and place of birth, together with his authority for so practising physic and surgery as prescribed in this Act. The person so registering shall subscribe and verify by oath or affirmation before a person duly qualified to administer oaths under the laws of the State, an affidavit containing such facts, and whether such authority is by diploma or license, and the date of the same, and by whom granted, which, if wilfully false, shall subject the affiant to conviction and punishment for perjury. The county clerk to receive a fee of twenty-five cents for such registration, to be paid by the person so registering.

§ 3. A person who violates either of the two preceding sections of this Act, or who shall practise physic or surgery under cover of a diploma illegally obtained, is guilty of a misdemeanor punishable by a fine of not less than fifty dollars, nor more than two hundred dollars for the first offence, and for each subsequent offence by a fine of not less than one hundred dollars, nor more than five hundred dollars, or by imprisonment for not less than thirty days, nor more than ninety days, or both. The fine when collected shall be paid, the one-half to the person or corporation making the complaint, the other half into the county treasury.

§ 4. A person coming to the State from without the State may be licensed to practise physic and surgery, or either, within the State in the following manner: If he has a diploma conferring upon him the degree of doctor of medicine, issued by an incorporated university, medical college, or medical school without the State, he shall exhibit the same to the faculty of some incorporated medical college or medical school of this State, with satisfactory evidence of his good moral character, and such other evidence, if any, of his qualifications as a physician and surgeon, as said faculty may require. If his diploma and qualifications are approved by them, then they shall indorse said diploma, which shall make it for the purpose of his license to practise medicine and surgery within this State the same as if issued by them. The applicant shall pay to the dean of said faculty the sum of twenty dollars for such examination and indorsement. This indorsed diploma shall authorize him to practise physic and surgery within the State upon his complying with the provisions of section two of this Act.

§ 5. The degree of doctor of medicine lawfully conferred by any incorporated medical college or university in this State, shall be a license to practise physic and surgery within the State after the person to whom it is granted shall have complied with section two of this Act.

§ 6. Nothing in this Act shall apply to commissioned medical officers of the United States Army or Navy, or of the United States Marine Hospital Service.

STOUT MEDICAL SERVICE.—A bill for the establishment of a night medical service is being prepared, and will shortly be presented to the Legislature. It will embody all the principal features of the Paris system, as explained by Dr. Stichtel, and will be adapted to the special requirements of New York. In view of the care taken to make this bill as perfect as possible in all its provisions, and to render it as free as possible from objections, it is to be regretted that a medical gentleman of this city has seen fit to construct a night medical service entirely on his own responsibility, to frame an absurd bill for the same, and to publish, in one of the daily papers, the names of a few medical gentlemen who are said to be willing to attend night calls. Without wishing to cast any reflections on the disinterested and honorable motives of the gentleman in question, we would ask the legislators to wait until the main body of the profession can be heard before taking any action.

DR. NORMAN BRIDGE has been appointed one of the visiting physicians to the Cook County Hospital, in place of Dr. Joseph P. Ross, resigned.

THE CASE OF ABRAHAM GOSLING, which has recently been in the courts of this city, has excited much attention, and has some interesting features. Mr. Gosling is a merchant who had accumulated considerable property. Within the past two years his conduct has been eccentric at times and marked with great exaggerations in speech. A short time ago he married. The relatives, being by this time convinced that he was insane, had him arrested, and the case was tried before Judge Lawrence. Dr. A. E. McDonald testified that he had examined Mr. Gosling. He found excessive dilatation of the pupils, thickness, and incoherency of speech, tremor of the limbs, and delusions of grandeur. He boasted of his abilities as a tenor singer, far surpassing Campanini. He boasted also of his business abilities and the great wealth he was to acquire; of his physical powers and purpose to outwalk any pedestrian in the world. He could walk a week at a time, he said, by tying bandages around his limbs, chest, and head, so as to keep in the first long breath for the entire week.

Dr. Hammond, W. L. Hardy, and others, testified to having found the same symptoms; that he was eccentric in his speech and manner, and extremely indecent, obscene, and profane; that he talked of being immensely rich; that he had done and contemplated doing millions of dollars' worth of business during the year; that he was the most powerful man and the fastest walker among all human beings; that he could excel any human being in his vocal powers, and that his superbly handsome appearance attracted universal attention.

This testimony was all in favor of the view that Gosling was suffering from a very typical form of general paresis of the insane.

Nevertheless, two medical experts were obtained who testified that they found nothing in his condition to indicate that he was more than eccentric, boastful, or intoxicated. The jury, influenced by such disagreement, rendered a verdict of sane, and the man was discharged.

The case being discussed at a subsequent meeting of the Medico-Legal Society, the parents and friends of Gosling, not being satisfied with the verdict declaring him sane, have procured an order for a new trial.

SANITARY LEGISLATION.—The Spanish Government has appointed a commission in Havana to investigate the sanitary condition of the island of Cuba, and plan suitable measures for improving the present condition of its ports. Special quarantine regulations at Cuban ports have been decreed by the Captain General.

A bill to create a State Board of Health in Ohio has been introduced into the Legislature of Ohio. It resembles the bill now before the Massachusetts Legislature as regards the regulation of medical practice.

A bill similar to that of Massachusetts has been defeated in the Wisconsin Legislature.

A bill to reduce the salary of the health-officer of the port of New York to $10,000 has been introduced into the New York State Assembly.

THE BLOOMINGDALE ASYLUM is to be enlarged by the erection of a new wing. The work is to be done at the expense of Mrs. John C. Green, who erects it as a memorial of her late husband. It is intended for female patients whose insanity is of a mild type, and who will not need any special restraint. The building will be elegant in all its appointments, and be made to resemble a comfortable home as much as possible. Its cost will be about $130,000. In addition to this, Mrs. Green has bestowed a fund of $200,000 for the benefit of insane women who have been accustomed to the comforts of life, but who have no means to pay for their support in a good asylum.

THE RIGHTS OF AUTHORS.—Dr. Leo T. Meyer considers that an injustice has been done him by the reference in the RECORD of April 5th to the suit brought against him by the Messrs. Putnam. We quote from a letter written by his attorneys. We do not claim that "substantially the same matter" is contained in it that the Messrs. Putnam propose to publish. "Even Prof. Darling said that many of his (M.'s) talks and ideas were original. Besides this, Dr. M. did not undertake to publish a book, it had already been published, but he was about publishing a second edition of his work. The statement that an appeal has been taken is also untrue." We make the correction with pleasure.

DEATH OF DR. C. H. H. SAYRE.—Dr. Sayre, the accident to whom we chronicled last week, died on the 11th inst. from the effects of the severe injuries he had received. During his brief illness he was devotedly attended by Drs. Robert Taylor, James R. Wood, T. M. Markoe, W. M. Polk, J. D. Bryant, Geo. A. Peters, R. F. Weir, E. S. Peck, and M. A. Pallen. He was twenty-nine years old, and since his graduation at Bellevue Hospital Medical College, had been in active practice with his father. Dr. Sayre had already acquired much surgical skill. He was of an impulsive and generous disposition, and leaves many friends to regret his untimely death. His funeral took place on Wednesday, April 14th, from his father's house, the remains being interred in the family vault at Harlem.

THE BILL TO CREATE A LUNACY COMMISSION was brought before the Assembly by Speaker Sharpe on the 13th inst. Mr. Sharpe took the floor and argued in favor of the bill. Mr. Cookinham, of Oneida, and Mr. Travis, of Westchester, spoke against it. On a test vote there was found to be a majority of three against the bill, the vote standing 42 to 39. Wishing to save it, Mr. Sharpe moved its recommittal to committee for amendment. In this he succeeded by a vote of 51 to 42. It is hoped that by making some alterations, a majority in favor of the bill can yet be secured this session.

Original Lectures.

FACIAL PARALYSIS AND LABYRINTHINE VERTIGO.

A Clinical Lecture Delivered at the Cincinnati Hospital.

By C. G. COMEGYS, M.D.

CINCINNATI, OHIO.

Gentlemen:—In the beginning of my course I beg to say that clinical medicine is a science of observation, and to interpret the phenomena of disease we employ the same method which has been so fruitful in discovery in every department of nature. I wish to impress this upon you in the beginning of your clinical studies, for the purpose of encouraging you in methods of fixing data in every case of sickness which you shall encounter in order to give precision to your final judgment. If you are brought to perceive that it is no fortuitous work, but that there is a line of observation to follow which will lead you to intellectual conceptions of diseased action, and if this is the same process as that employed by men in all the sciences, who are laboring to aggrandize human knowledge, it will excite enthusiasm in your studies, and lift you above the dulness and indifference which hard and unsatisfactory tasks so often impose. I freely assert that nothing arouses more our mental activity than the patient investigation and close thought employed in attempting to unravel obscure cases of disease. It will be a pleasure to you to learn that diagnosis can be obtained by the study of symptoms with which you become familiar by bedside observation, founded upon your didactic instruction.

With these preliminary remarks I present for your observation to-day four patients with facial paralysis, but differing from each other in important particulars: first, a case of common peripheral paralysis with labyrinthine vertigo; second, a peripheral one, associated with trismus of the same side; the third, a simple hemiplegic specimen; the fourth, a hemiplegic form, with aphasia.

For their methodical study I shall make use of the methods employed in the sciences of observation. I am talking to students of different attainments, and it is my duty, I think, to teach in the most elementary way. In clinical observations all of our knowledge is employed in the study of a series of facts in order to define the principle or law of their association; that is, to establish one fact whose whole significance is determined by the other facts which it numerically includes; therefore we must, first, attempt to define the organ diseased; second, to localize the point of lesion; third, the nature of the affection; and fourth, the treatment.

To accomplish our object we make three procedures: first, the nomenclature and description of the case; second, a classification of the conditions; third, an inference respecting their functions or laws of operation.

Wm. R——, mulatto, æt. 23; laborer; single; always well, until four months ago, when he had a venereal sore, which very readily healed, and was not followed by any secondary symptoms. Three months since he was exposed to a cold rain, and the next day was seized with a severe pain in the right ear, which spread over the right side of his head, followed by dizziness and reeling towards the left; but he had no sense of weakness on that side. Five days after, found his face drawn to the left, and that he had lost his hearing in the ear, though a buzzing remained. He could not close his right eye; it smarted, and was watery. He states that his food slipped into the hollow of his cheek, so that he could not chew on the right side. When he entered the hospital he was noted as a man of medium height, fairly nourished, though he said he had lost some flesh; appetite good; tongue clean; bowels regular; heart, lungs, kidneys sound; no fever, nor acceleration of pulse. Upon further investigation it was found that all voluntary power over the muscles of the mouth, nose, eyelid (except the upper one), brow, forehead, and cheek of the right side was lost, and that the features could give no expression whatever to any mental state, except such emotion as is represented by a blush or pallor. The nose was drawn to the left; the right nostril contracted and immovable; the eye open, staring; the conjunctiva red; the lower lid everted, and the tears flowing over on the cheek. On attempting to shut the eye only the upper lid moved, while the ball rolled upward, inward, concealing the cornea, which gave the patient the notion that the whole eye was closed. The pupil is natural. Breathing is obstructed when the left nostril is plugged, owing to the tendency of the right one to collapse. He cannot purse his mouth to whistle, and on blowing, as at a candle, the right cheek puffs out, and the air escapes at the right corner. His articulation is imperfect for the labial letters such as b, p, v, f, etc. The palatine muscles act well in articulation and deglutition; fluids escape at the right corner also. His hearing is completely extinct; the taste slightly impaired; and smell a little so, too, through the right nostril.

The secretions of the mouth are not disturbed. The muscles of the tongue are intact, as are also those of the right side of the body, and the muscles of mastication. When you examine a patient in this condition, do not mistake the movement of the jaw by the pterygoid muscles for such movement as the facial muscles produce.

The symmetry of the face you know is maintained with all its wondrous mimetic powers by the synergism of numerous pairs of muscles placed on opposite sides, and as these muscles have no spontaneity of movement, I must, to complete my description, make a statement of the facial nerve by whose action they are brought into play.

The apparent origin of the portio dura of the seventh pair is from the medulla oblongata just behind the pons (I show it here in this admirable model of Ayoux), where part of the fibres are in connection with a special nucleus; but there are others which cross the floor of the fourth ventricle, ascend beneath the pons and follow the cerebral peduncle through the corpus striatum in the internal capsule, forming a part of the corona radiata and finding their ultimate origin in the cortical centres along the fissure of Rolando. Besides this decussation of the fibres of the main track, there are commissural fibres that connect the cortical and basilar centres among themselves, thus establishing a complete bilateral organization of the portio dura or facial nerve. A diagram of this is exhibited on the blackboard. No dissection, it is true, has ever been made demonstrating all this, but it is abundantly proven by experimental and pathological anatomy.

The seventh nerve, as it leaves the medulla in its centrifugal route, is a compound nerve, for it is accompanied by the auditory and intermediary nerve

Wrisberg, and the separation only takes place at the end of the meatus auditorius internus, where the auditory enters into the labyrinth, while the facial and intermediary follow the canal of Fallopius and traverse this bony canal together nearly to its termination at the styloid foramen. Within the aqueduct of Fallopius the facial gives off its greater and lesser petrosal branches, and parts from the nerve of Wrisberg which is henceforth denominated the chorda tympani, but it is really the gustatory nerve and, therefore, afferent in character. I think it would be more correct to say that this is a centripetal nerve—an organ of special sense and joins the facial in the aqueduct and thus connects the anterior two-thirds of the mucous membrane of the tongue with the sensorium. Beyond the junction of the chorda, the facial gives off one or two small branches to the muscles of the tympanum, leaves the cranium at the styloid foramen, runs through the parotid gland, and extending forward divides into two great branches to supply the facial muscles above and below. The upper petrosal branch goes to Meckel's ganglion, whence its fibres are further distributed to the levator palati and azygos uvulæ muscles, and, it is said, some of its fibres go to the submaxillary gland to influence their secretions; but, I think it quite improbable that these purely motor branches of the facial play any such part; it is more likely that fibres of the sympathetic running with it, affect the functions of the glands. The lower petrosal branch goes to the otic ganglion and reaches finally the tensor palati and animates it. I question the influence of a branch of this nerve exciting the secretion of the parotid gland, as is asserted for reasons just given.

The second step in our inquiry must now be taken, for you see that we have as yet made no diagnosis. We have presented a description and the nomenclature, that is, the terms, of the question; we have found that our patient is paralyzed on the right side of his face, but what organ is diseased that produces this, when is it affected, and what is the nature of the affection, remains to be shown before we can be said to have made a diagnosis.

It is essential that all the symptoms should be noted, for any important one overlooked or not ascertained through ignorance of methods of examination, may vitiate any subsequent procedure. What to observe at the bedside requires a high order of medical education. There are many symptoms that any one can see, but there are important ones which an expert only can discover and interpret.

The second step in our research is a classification of paralytic affections of the face. Are the muscles themselves diseased, or is it the nerve which supplies them? If the nerve, is it a pure facial or a peripheral paralysis, or is it a hemiplegic or central paralysis? These are the only propositions we can entertain. The phenomena in this case admit of no further classification.

To solve our problem we must invoke the methods of the differential and integral calculus.

By the differential calculus we explain the methods of finding the differential of determinate functions. Symptom in a pathological inquiry is a synonym of function in physiology.

It is accepted that an alteration in function indicates a change in the structure of an organ.

Vital contractility is the differential of muscular tissue, and this may be excited by chemical, mechanical, physical, or nervous irritation. I prick the sound side with a pin, and it excites promptly muscular contraction of the face and of the body generally. This is a reflex action. I prick the paralyzed side; there is a general start but no muscle of the face moves. This proves that these paralyzed muscles are not under the excito-motor law. I can use electricity only for a further examination of the muscles. I now apply the faradic current to the sound side and promptly all the muscles contract. On the paralyzed side the current produces no contractions—only pain—a pain that excites general reflex movements, but no reflex manifestations through the facial nerve. I now apply a weak galvanic current, and slowly break the flow, and the paralyzed muscles contract; but if I break and make the current rapidly, the muscles do not contract. From this exhibition, you are taught that the muscles themselves are not diseased so as to cause this facial paralysis, and that the contractility they manifest is by direct action on the muscular fibres themselves.

Next, we must examine the facial nerve itself. Already I have shown on the palsied side, that it does not convey reflex action, and therefore it is functional. I now apply both of the electrical currents in succession to the main trunk of the facial nerve on the sound side, and you observe muscular contractions. Every facial muscle moves, but when I make the same experiment on the palsied side, there is no contraction of a single facial muscle. But now, as I increase the strength of the current, so as to reach other sound extra-muscular nerves, you see the jerking of the head and neck; but the face itself is unmoved. Yet, when I apply the galvanic current to the muscles themselves, slowly interrupting it, the muscles do respond. Thus I differentiate again that the organ diseased is the facial nerve.

You are ready to ask, why is it that the muscular contractions follow the slowly interrupted galvanic, and not the faradic current. I am hardly physicist enough to explain this; I merely state the precious clinical fact, that when a muscle is inexcitable to a faradic or a quickly interrupted galvanic flow, while at the same time it is excited by a weak, slowly broken, constant current, we have positive proof that the disease lies in the motor nerve supplying a muscle, and not in the muscle itself. The only explanation I shall attempt is, that muscular tissue deprived of motor nerves is a much slower conductor of electricity than when the nerve is intact. A weak, constant current saturates it, so to speak, which is not the case by a rapid to and fro faradic current.

I have now demonstrated that this paralytic condition is an affection of the facial nerve. I must next show whether it is due to a central or a peripheral lesion. If it were a central disease, the facial paralysis could not be so complete, owing to the bilateral organization of the portio-dura, pointed out in our description; for though the centres of the right nerve in the medulla or in the cortex were involved, yet the decussating and commissural fibres from the opposite and sound side would maintain more or less function in the muscle at its peripheral end. We should have a paresis rather than a paralysis of the facial muscles. Besides other muscles of the right side of his body, the extremities and the tongue in particular, would be involved, and a condition of aphasia might possibly exist. But you see, at my request, his actions of limbs show no hemiplegic symptoms; and the only defect in articulation is in the labial letters. The flabby lips cannot sound b, f, m, v, w, y, clearly. If the lesion of the nerve involve the whole tract anywhere external to the centre, a complete facial paralysis must ensue. This

man cannot shut his right eye, nor move any muscle of his face on the right side.

A peripheral lesion of the facial nerve between the medulla and the origin of the upper petrosal branch would cause a paralysis or paresis of all of the muscles of the face, and of the palate, also andition, equilibration temporarily, gustation would be involved, because these nerves of special sense are all in one sheath with the facial, even down to the origin of the Fallopian canal. If the lesion were between the upper and lower petrosal, the same destruction of physiological function would exist, except in the tensor palati, and azygos uvula muscles. If below the lower petrosal, and above the chorda tympani, no muscles (I leave out of consideration those of the internal ear) other than those of the face would be concerned: but as the chorda tympani is the nerve of taste, that sense would be impaired. Beyond the origin of the chorda tympani, injury of the facial disturbs the facial muscles only.

I now test his sense of taste, in order to study the function of the gustatory nerve, and I shall employ various substances, sweet, sour, bitter. I prevent his seeing them as I apply them. He recognizes them, but, he says, indistinctly.

Our patient is completely deaf in his right ear, and my colleague, Prof. Aub, the aurist and oculist, now on service, assures me that it is from inflammation of the internal ear. Remember that all of his troubles began from exposure in a cold rain. His pain in the ear was great, and he was affected with dizziness and reeling towards the left. Now the facial nerve passes within the pathological area of an inflamed ear, and the chorda tympani runs through the tympanum. The adjoining semicircular canals of the labyrinth have as a function the preservation of the erect station.

The consensus (Ferrier) of the tactile, visual, and labyrinthine impressions maintain the function of equilibration. The vision is of the greatest value in standing or walking—that is, it gives firmness and precision to our movements—yet we can walk with the eyes closed. On the other hand, locomotion may be performed imperfectly when the sensory tracts connecting the extremities with the brain are cut off, the vision remaining intact; but there is no compensation in sight, or touch, to maintain the erect station, if the semicircular canals of the ear on both sides are destroyed—at least, such is the fact when the experiment is performed upon animals. But if only one side be destroyed or injured, the loss of equilibration is *not permanent;* the system gradually recovers its ordinary powers. This, says Ferrier, is an important fact in reference to the pathology of Ménière's disease. Another fact is brought out by Flourens and Goltz, viz.: that the portion of the auditory nerve that conveys aërial vibrations is not *the same* as that which transmits labyrinthine impressions. Destruction of the cochlea (Ferrier) causes deafness, but not disturbance of equilibration, while the destruction of the semicircular canals increases the acuteness of hearing, but destroys equilibration. In Ménière's observation, confirmed by others, besides the vertigo, the tendency in locomotion is to reel from the injured to the sound side.

I have now explained the method of finding the differential of determined functions in the diseased organs of this patient. It now remains to employ an integral calculus to establish the diagnosis so far as relates to the organ and the portion affected. First, I have shown that muscles of the right side only are affected in function; that no voluntary nor instinctive power of expression by them is possible; that the eversion of the lower lid and epiphora are due to the paralysis of Horner's muscle; that these muscles are not diseased in themselves, because they contract under galvanic electrical excitement. Second, that it is the facial nerve alone that is infunctional, because no reflex action whatever is manifest through it, nor will it convey any electrical current so as to excite muscular contractility. Third, that it is not diseased in the centre, nor in its tract higher up than the accession of the chorda tympana, because the muscles of the palate which are animated by the petrosal branch are intact, and there is no hemiplegic symptom in the patient. Fourth, that as the parotid gland is not involved, and because a serious inflammatory action exists in the internal ear, the lesion of the nerve is behind the tympanum in the aqueduct of Fallopius. Fifth, that inflammatory products compress the tract so as to destroy its functions, and it may be well to disintegrate it.

What is the nature of the disease arresting the function of the facial nerve? This question also involves classification; but, having located the affection in the section behind the tympanum, it will be unnecessary to consider all of the pathological conditions to which the nerve and its environments is subject. I will mention such only as are common in such cases: 1, a traumatic lesion; 2, a cachexia; 3, inflammation; 4, disease of the ear.

An injury of the canal of Fallopius by a wound or fracture cannot be inferred from the history; nor is there any evidence of constitutional syphilis which could develop characteristic neoplasms. The venereal sore mentioned in the history was undoubtedly a chancroid. But we have evidence of an acute inflammation following exposure, which attacked the ear, causing great suffering, accompanied by vertigo and temporary perturbation in equilibration, ending in complete deafness and facial paralysis—the condition the patient now presents.

For treatment, we shall depend mainly on the iodide of potassium, beginning with ten grains three times a day, to be increased gradually to forty grains, to be taken in a glass of water. I think no one of experience will question the high value of this agent to remove recent inflammatory products. Also the paralyzed muscles will be exercised every day with the constant current to prevent their atrophy. I regard recovery as very problematical, owing to destructive effects of the inflammation being so apparent in the ear. I am now treating successfully two patients in my private practice, who were seized with complete facial paralysis on account of exposure. The cases have been very obstinate, covering a period of three months. My remedies have been the constant current and iodide of potash up to forty grains three times a day. I have applied tincture of iodine externally beneath the ear, but I think it has been of little value. Be sure to claim a long time to cure a complete case.

The remaining cases present will form the subjects of the next lecture.

The University of Edinburgh has just been made the subject of a munificent bequest by the late Dr. Andrew Vans Dunlop. He has left it the sum of $250 000. Most of the money is to be expended in founding sixteen scholarships, furnishing each an annual income of $500, tenable for three years. Six of these scholarships are for students of medicine.

Original Communications.

A CASE OF

REPRODUCTION OF THE SHAFT OF THE HUMERUS, AFTER EXCISION FOR ACUTE NECROSIS.

BY GEORGE F. SHRADY, M.D.,

[illegible] AT THE PRESBYTERIAN AND THE ST. FRANCIS HOSPITALS, NEW YORK.

[illegible] Member of the Academy of Medicine of New York; Secretary [illegible]

Operations for the removal of dead bone are so common, and the reproduction of osseous tissue as an associated condition is so frequent, that by way of introduction an interest in the following case, it is proper to state that the disease was very severe and extensive, that its treatment was a forced departure from the rule, and the results obtained were exceptionally gratifying.

George G——, aged fifteen years, a newsboy by occupation, was admitted March 3d into St. Francis' Hospital, N. Y., suffering from acute general periostitis of the left humerus. The assigned causes of the inflammation were an injury and subsequent prolonged exposure to inclement weather. The disease had existed for two weeks. His arm, forearm, and hand, were greatly swollen, the skin of the same was smooth and erythematous, and readily pitted on pressure. Fluctuation was plainly marked throughout almost the entire arm, which seemed to be transformed into a large abscess. The general condition of the patient was very bad. His pulse was quick and feeble, his temperature 103¼ F.; his appetite was gone, and his pain was constant. A free incision to the bone was promptly made below the middle of the arm posteriorly, and a large quantity of fetid pus was evacuated. Stimulants were freely given, morphine administered, and a large poultice was applied. The patient was much relieved by this treatment, but in the course of three days the temperature rose again from 101 F. to 105 F., and a new point of fluctuation was discovered just below the insertion of the greater pectoral muscle. Another free and deep incision was made accordingly. Through this wound, as well as through the one made previously, the probe detected bare and dead bone. The entire upper extremity still remained oedematous. An increase of swelling around the elbow gave rise to serious apprehensions concerning the safety of that joint. Fortunately the pus burrowed its way between the supinator longus and brachialis anticus, and appeared under the deep fascia on the upper and external aspect of the forearm. Here another incision was made.

It was only by the most careful nursing, by frequent incisions to remove new accumulations of pus, and by the most generous stimulation, that the patient was kept from sinking.

Two weeks after his admission a spontaneous separation of the upper epiphysis occurred, placing the humerus in the condition of a compound fracture through the surgical neck of the bone. The arm was so stiff and oedematous, and even the slightest pressure upon its inner aspect was so intolerable, that no supporting pad could be placed on the axilla. Accordingly, the arm was secured as well as possible to the side, and maintained there by suitable supports.

This complication of the disease, together with the general condition of the patient, gave such an alarming aspect to the case, that some radical measure for his relief were unmistakably indicated. The natural course would have suggested the waiting until an involucrum formed and the dead bone had separated. But time was precious, and the chances of saving the life and limb were fast becoming desperate. It was evident that the greater part, if not the whole of the humerus, was dead. The removal of such an extent of bone without an involucrum to take its place, and with the soft parts in such an unfavorable condition, did not hold out much hope for a serviceable arm. Amputation, severe as was the measure, was seriously considered as the best chance for the patient. The connection of the utility of this measure came near being a settled fact, when one day word was sent to me by the house surgeon that a hemorrhage had occurred through an incision on the upper and inner aspect of the arm, and that some of the axillary vessels appeared to have been wounded by the separated edge of the shaft. I hastily obeyed the summons, prepared, if necessary, to amputate at the shoulder. Fortunately, the hemorrhage was easily checked, and the parts were restored to proper position without much difficulty.

A turning-point in the patient's general condition was anxiously awaited, in the conviction that his best chance lay in the cessation of the profuse discharge, and in the formation of an involucrum that would allow the dead bone to be removed, as in the ordinary operation for necrosis. But instead of improving he fell back, and operative procedures were narrowed down to a slim chance of saving his life.

On making my visit a few days after the occurrence of the hemorrhage, Dr. Edebohls, the house-surgeon, expressed his belief that the lower epiphysis of the humerus had also separated. Although I was unable to verify this opinion, on account of the swollen and painful condition of the elbow, the possibility of such an occurrence helped me to the conclusion to remove the dead bone entire, save every possible piece of periosteum, and trust in nature for the formation of a new shaft.

The operation was performed March 26, 1879, in the presence of and with the assistance of Prof. J. W. Howe, Dr. C. K. Briddon, and the members of the house-staff of the hospital. Ether was cautiously administered, and brandy was injected hypodermically. An incision was made on the outer aspect of the arm, from the point of the shoulder downward. On introducing the finger into the wound the shaft was found separated from the upper epiphysis, denuded of periosteum and dead. This upper extremity of the shaft was then buttoned through the opening, the idea being to thus enucleate the dead shaft entire, without endangering the musculo-spiral nerve by a longer incision directly downward. Failing in this, with the same end in view of saving the nerve, I determined either to curve the lower portion of the incision forward in front of the anterior border of the supinator longus muscle or to make a second perpendicular incision below the trunk of the musculo-spiral, and on the external and posterior aspect of the bone.

It soon became evident, from the sinking condition of the patient, that the separation of the periosteum must be made as rapidly as possible, and that more room was required. Accordingly, the incision was continued nearly to the level of the condyles. The periosteum, which was thickened, was easily detached, and here and there flakes of new bony mate-

rial were left upon its inner surface. Some of these osseous shells were unavoidably broken and detached. The surface of the bone was smooth, non-vascular, and presented the usual appearances of death from acute suppurative periostitis.

When the condyles were reached no separation of the lower epiphysis was found, although there was a distinct false point of motion in that situation. I could not discover that the elbow-joint was opened or diseased. In fact, I doubted the possibility of the disease extending beyond either epiphysis. A contrary opinion was held by one of the surgeons present, and he was, on that account, strenuous in advising immediate amputation at the shoulder. I declined to do this. Wishing, for obvious reasons, to keep clear of the lower epiphyseal line, I sawed off the bone about half an inch above it. When this was done, and virtually the entire shaft was removed, the arm presented a very unpromising condition. There was no support whatever between the elbow and shoulder for the muscles of the arm. The forearm hung at the end of the flabby and infiltrated muscles flail-like and useless. So little promise did there seem for the future of the arm, that I almost regretted that I had not amputated in the first place. As an additional matter for anxiety, my patient came near dying several times while on the table. Indeed, it was only by dint of the most careful nursing by the attending Sisters of St. Francis that he was kept alive during the night.

The operation being completed, the periosteal sac was washed out with a solution of carbolic acid (one part to forty parts), a drainage-tube extending from shoulder to elbow inserted, and the wound sewed up. When the patient was removed to the ward the arm and forearm were enveloped in antiseptic gauze, laid upon a single inclined plane, and extension made upon the hand by means of a weight and pulley. This kept the arm to its full length; at the same time there was the freest possible drainage through the extremity of the tube at the depending shoulder. Within forty-eight hours after the operation the patient was out of immediate danger. For several days there was a profuse discharge, but the patient's general condition improved notwithstanding. In the course of the fourth week the arm began to stiffen, and it became evident that new bone was being formed. The limb was then placed in the rectangular position. The osseous deposit increased, so that at the end of five weeks more the humerus was firm enough throughout its whole extent to allow the patient to set up and support the arm by the elbow while the wounds were being dressed. It is, perhaps, unnecessary to say that the central portion of the incision healed by first intention. The openings above and below did not close for several weeks.

The extensor muscles of the hand, which were partially paralyzed during the inflammatory process by the involvement of the musculo-spiral nerve, were still more damaged by the unavoidable section of that nerve during the operation. The power of sensation in the parts supplied by this nerve was very much diminished. There was no reaction to the faradic current, and galvanism was applied with the view of preserving the integrity of the muscles, in the reasonable hope that a subsequent union of the divided nerve might occur.

During my absence from the city in the summer, my patient remained in the hospital, and Professor J. D. Bryant, who kindly took charge of him, removed from the outer side of the elbow what proved to be the portion of the diaphysis left attached to the epiphysis. Subsequent to this the elbow became much swollen, violent inflammation of the surrounding fibrous structures occurred, and the angle of flexion became more obtuse. It was not considered prudent at that time to use forcible flexion, and notwithstanding passive motion was faithfully tried the elbow became in a condition of false anchylosis.

When I returned to the city in the autumn the new bone was perfectly solid throughout. The union of the shaft with the head of the bone was complete, as was also the union with the lower epiphysis. The shoulder-joint was freely movable in all directions, and the surrounding muscles were in reasonably good condition. There was slight motion in the elbow-joint. The extensors of the forearm were still paralyzed, but not to such a degree as before. The flexors were quite strong and active.

By the use of Stillman's splint, which allows of fixed flexion at different angles, I succeeded in bringing the arm nearly at a right angle with the forearm. The condition of the extensors has so much improved by elastic support and the faradic current, that there is good reason to believe that the lost nerve power will be eventually restored. If, however, the improvement does not continue, the trunk of the nerve will be exposed by dissection, and any portion of it that may still be ununited will be brought together by suture. In the meantime the affected muscles are kept responsive to the electrical current.

The new humerus is half an inch shorter than the same bone on the opposite side, and is of an irregularly cylindrical shape, the centre of the shaft being somewhat enlarged. The wounds have entirely healed, and the soft parts are perfectly sound.

In referring to the points of clinical interest in this case, it is proper to remark that while excision of the shafts of bones for acute necrosis has been performed several times, the operation is still on trial as to its merits. Such operations, as far as I am able to learn from quite extended examination of the literature of the subject, and from a diligent search so kindly made for me by my friend Dr. E. C. Wendt, of this city, have been confined, for the most part, to the bones of the lower extremity, and notably to one of two parallel bones, as in the case of excision of the tibia. Holmes reports several of

cases. When any bones of the upper extremity have been excised for acute necrosis or any other disease, they have been usually either the radius or ulna, and in such case the companion bone has, as in excision of the tibia, formed an efficient splint during the process of reproduction. Thus being the case, a new bone has been reproduced under most favorable circumstances. With the excision of single bones in either extremity the results have been coherent. Especially is this true when any considerable portion of the shaft has been removed at one time. In regard to the excision of the humerus, I know of but one instance of reproduction of the bone in which more than five inches of the shaft were excised, none, save the one herein reported, in which a similar operation was performed for acute necrosis at such an early period in the disease, and in which such a complete and extensive reproduction of bone occurred. My friend Dr Alfred C. Post informs me that he had on one occasion removed two inches of the upper part of the shaft of the humerus for acute necrosis within three weeks from the commencement of the attack, and that firm union with the upper epiphysis followed.

In the second volume of the *Medical and Surgical History of the War* a large number of cases of primary resection of the humerus for gunshot injuries are recorded, but reproduction of bone took place in a very few. In most of these the excision amounted to little more than the removal of small fragments of detached bone, and the reproduction was, for the most part, a union of the fracture. Where larger portions of bone were removed the rule was a false joint, great shortening of the arm, and the necessity for the wearing of a splint.

A most striking case of reproduction of a considerable portion of the shaft of the humerus was related to this Society by Dr. William Gilfillan (*Trans. Med. Soc., State N. Y.*, 1866). The patient was a soldier, with gunshot fracture of the arm. The excised portion measured four and one-half inches. Dr. Stevens, in the same volume, reports a similar operation with similar result, in which three and one-half inches of dead bone was removed.

Dr. Grandfirm (*Detroit Lancet*, Oct., 1879) removed five inches of humerus for gunshot fracture. There is some doubt as to the perfect reproduction of bone, as the operator leaves us to infer that it was necessary to support the arm in order that the patient might flex his forearm.

Ricordi, of Milan (*Bulletino della Scienze Mediche de Bologna*, May, 1879), reports the case of a boy, aged twelve years, in which reproduction of four inches of the shaft occurred after a resection for compound fracture.

Dr. J. W. Howe (N. Y. Path. Soc., Nov. 27, 1878) removed four-fifths of the humerus (four inches) by subperiosteal section for chronic osteitis. The patient was a child three years of age. Reproduction complete.

Heyfelder, in his work on resections (*Traité des Resections*, Paris, 1863), has collected fifty-seven cases of reproduction of portions of the humerus after excision. Fifty-one of these were for compound fracture. The fragments removed averaged two and one-half inches in length, with the exception of a case by Chassaignac in which the fragment was one-half the diaphysis, equivalent to four and one-half inches. Six of the fifty-seven cases were for chronic osteitis. The largest piece of bone removed in these latter did not exceed three inches. The patients were children. Four recovered with useful arms, one had false joint, and the remaining one died shortly after the operation.

Largier (*Gaz. Med. de Paris*, 1854) resected four and three-quarter inches of humerus for chronic osteitis in a boy aged fifteen years. Reproduction perfect.

The same surgeon (*Gaz. Med. de Paris*, 1859) also excised the humerus from the surgical neck of the bone to four inches breadth above the epicondyle, for chronic osteitis in a patient aged twenty years. Complete reproduction of bone followed. Immediately after the operation there was extensive contraction of the humeral muscles, requiring the use of extension.

In both the above instances the musculo-spiral was evidently severed during the operation.

Borelli relates a case (*Gaz. Med. de Paris*, 1859) in which reproduction of the upper portion of bone, to the extent of four and one-quarter inches, occurred after resection for chronic osteitis in a patient aged fourteen years.

Giraldi (*Bull. de la Societé Chirurg.*, Paris, 1863), in a discussion before the Surgical Society of Paris, referred to a case in which four and three-quarter inches of humerus was excised from a child aged ten years. Reproduction was perfect, and a useful arm resulted.

Bonnesoeur (*Thèse*, Paris, 1866) refers to a case of excision of two and three-quarter inches of the humerus by the same surgeon in a child four and one-half years of age. Necrosis resulted, and the healing of the wound extended over a period of four years. Eventually there was a good arm, which was a little longer than that of the opposite side.

Bourguet (*Compt. Rend.*, 1860) excised three inches from the humerus of an old subject. Result good.

Ollier (*Traité Exp. et Clin. de la Régénération des Os*, Paris, vol. ii.) alludes to a case in which over five inches of the humerus was exsected, but reproduction was incomplete, the arm being at the same time shortened two and one-half inches.

Chassaignac (*Trait. des Op. Chirurg.*, Paris, 1861) reports a case of reproduction in which the inferior two-thirds of the humerus (four and one-half inches) was removed for gunshot injury. Anchylosis of the elbow resulted, also paralysis of the radial extensors from section of musculo-spiral nerve.

The case to which allusion has been made in the commencement of these remarks, and in which the extent of reproduction of the humerus was similar to that in my patient, is reported by Dr. J. A. Donovan (*Lancet*, Jan. 18, 1874). His patient was a boy aged 15. The history seems to prove that necrosis of the upper portion of the shaft existed previously to the attack of acute periostitis, for which the operation of excision was performed. The specimen removed, as figured in the *Lancet*, appears to be composed of two parts—a central sequestrum above, partially enclosed in a cylindrical involucrum below. Notwithstanding the removal of this involucrum, the thrifty periosteum replaced it by new bone at the same time that it reconstructed the remaining portion of the shaft. The head of the bone was likewise removed, it having been fractured at the epiphyseal junction during the operation. The lower section was made just above the condyles. The reproduction was complete throughout the whole extent of the shaft, and all the motions of the limb were well performed, except abduction of the shoulder. It does not appear that the head of the bone was reproduced. The musculo-spiral nerve was avoided by a curved incision forward. The arm was placed in a padded angular splint.

In the recital of cases of reproduction of portions of the humerus, it is not intended to include those

for which the ordinary operation for necrotomy has been performed. A number of such examples are on record, and several in which a complete reproduction of the humerus has taken place. One is reported by Langenbeck, and I have heard of two by Prof. Esmarch. In all of them an involucrum had previously formed, and the operation consisted in the extraction of the sequestrum.

The clinical importance of the case which forms the basis of the communication can hardly be overestimated. The operation was performed under circumstances most unfavorable to the reproduction of bone. The patient was run down to the last degree, so that the question of saving his life by amputation at the shoulder-joint was seriously entertained. The soft parts of the arm were infiltrated with pus, and ploughed by numerous deep incisions. The progress of the disease was so rapid that no time had been allowed for exfoliation of the sequestrum and formation of an involucrum. The extent of the humerus removed, eight and three-quarter inches, was an important consideration in the face of the well-known liabilities to defective osseous reproduction in that bone, as shown in numerous cases of non-union even after simple fracture. The want of any internal support for the soft tissues of the arm after the bone was removed was a feature which militated against a complete and uniformly firm reproduction of osseous tissue. Fortunately, the brachial muscles were so infiltrated as to be powerless of retraction, and were kept intact easily by the extending apparatus.

Under the adverse circumstances to which allusion has already been made, it is not only somewhat remarkable that any osseous tissue should have been produced at all, but that there should have been a reproduction of the entire shaft of the humerus, giving the bone a firmness and strength throughout equal to that of the other arm.

247 Lexington Avenue, N. Y.

ON THE CAUSE OF RIGOR MORTIS.

By THOMAS W. POOLE, M.D.,

Lindsay, Ont., Canada.

The attempts to explain the occurrence of rigor mortis as the result of a lowering of the temperature of the body, and as caused by the coagulation of the blood in the vessels, have definitely failed, and have given place to a more recent hypothesis, by which it is attributed to the coagulation of the albuminous myosin, or plasma of the muscle. It will appear from what follows, that this explanation is equally defective, and must in turn be abandoned.

During repose, the reaction of the muscle plasma is alkaline. As the result of vigorous contraction of the muscle during life, and also during rigor mortis, the reaction becomes distinctly acid. Prof. Kuss ascribes the formation of acidity during exercise to the carbonic acid generated during the more active combustion then taking place in the muscle. To the presence of this acidity, and as an effect of it, the coagulation of the myosin is attributed. ("Lect. on Phys." (Duval, Amory), pp. 77, 83.)

We are thus presented with a series of results, as follows: Active muscular exercise generating acidity; the acid coagulating the myosin or muscle plasma, and this coagulation resulting in rigidity of the muscle.

If this be true, it ought to be highly dangerous to indulge in active muscular exertion; and it is surprising that the "spontaneous rigidity, after a continued activity which produces great excess of acid," of which Prof. Kuss writes, is not of more frequent occurrence, if it occur at all.

But in death from ordinary causes, how is the acid generated? There is and can be no active contraction of the muscles, of which the acidity is the consequence. And can the *effect*, or product of muscular contraction during life, be the *cause*, or inciting agent, of muscular contraction or rigidity, after death? Muscular contraction produces acidity, but there is no proof whatever that acidity produces muscular contraction. Indeed, the facts seem to show that the acidity *follows* the contractions of rigor mortis, just as it follows the muscular contractions during life. It is impossible to believe that during normal life the myosin of the muscle is coagulated at all; and after death, the conditions assigned for its coagulation, namely, muscular contractions as the source of acidity, are entirely wanting until rigor mortis sets in. Thus the alleged cause of rigor mortis is not in operation until rigor mortis has occurred, and it follows that the alleged cause is not the true cause, and the hypothesis fails.

In justice to Prof. Kuss (who is simply stating contemporary opinion), it must be added that he does not profess that the myosin hypothesis is sustained by the evidence. He refers to it simply as "now generally supposed" to be a valid explanation. But, strange to say, this is not the only instance in which medical theories or hypotheses are admitted to general acceptance on very imperfect data.

Some minor discrepancies in what is alleged regarding myosin, may be briefly glanced at. Thus, Dr. Brunton finds that muscle plasma "coagulates too quickly in the muscles of warm-blooded animals to allow of its preparation from them." Now rigor mortis does not usually set in for several hours after death—often much longer—and its onset may even be artificially delayed. The statement therefore is only explicable on the supposition that coagulation of the myosin and rigor mortis do not occur together; that is, do not take place as cause and effect. It would seem to be implied that the myosin coagulates at too early a stage to admit of its being the cause of rigor mortis. That the myosin may coagulate without producing rigor mortis, is definitely shown by Dr. Brunton, in an experiment in which half a muscle is placed for a few minutes in boiling water, with the result that "before rigor mortis had time to set in, the albumen of the muscle was coagulated." ("Hand-book for the Phys. Lab.," pp. 363, 449.) Until these adverse facts and discrepancies are refuted or explained, the myosin hypothesis must be held as invalid, and the true cause of rigor mortis sought elsewhere.

The very occurrence of such a state as rigor mortis is a fact seriously embarrassing to the theory of the relations of nerve and muscle long in vogue. That muscle should require the aid of a stimulus from nerve force, in order that it may contract, and that during life such a stimulus is forthcoming, is a conclusion not unnaturally arrived at in the early days of physiology, when appearances were often regarded as realities. But that several hours after life is extinct, after a comparatively long period of cessation, nerve force should thus suddenly display an extraordinary activity, and continue thenceforth to stimulate the muscle in an unwonted degree, for many hours, and even days, maintaining its excessive contraction until decomposition sets in, is a phenomenon which draws largely upon our credulity. It is, therefore, not to be wondered at, that the advocates

of these theory should seek to deny that in rigor mortis the state of the muscle is one of electrotonus at all. On this point, the elder of our modern physiologists, at least, are a unit. Dr. Todd and Bowman say: "The rigor mortis, or stiffening of the body after death, is due to the contraction of the muscles" ("Phys. Anat.," p. 179.) Dr. W. B. Carpenter writes: "All the muscles are affected alike, but the flexors are usually more contracted than the extensors, so that the fingers are flexed on the palm, the forearm on the arm, and the lower jaw is generally drawn firmly against the upper." When very strong, it renders the muscles prominent, as in voluntary contraction. ("Human Phys.," p. 342.) Dr. Aeste (then editor of the London *Lancet*) wrote: "It is notorious that the most steady and persistent contraction which muscle can possibly exhibit, is that which sets in after death, which does not occur until the last remnants of vitality have disappeared, and which, once having commenced, never relaxes till putrefaction releases the tissue from the ordinary laws of molecular attraction." ("Stim. and Narcot.," p. 70.) Even Prof. Kuss, notwithstanding his approval of the myosin hypothesis, declares "muscular contractility is a purely physical property of elasticity; the rigidity of a corpse is a phenomenon of the same order as molecular contraction in the living body." (Ib., p. 88.) If the deliberate opinions thus recorded are now to be repudiated as untrue, something more than a mere announcement of the fact is naturally to be expected. If these opinions are to be maintained, the question arises, how is the post-mortem contraction of muscle in rigor mortis to be explained consistently with the doctrine that requires a stimulus from nerve-tissue as a condition of muscular contraction?

What are the differences in the condition of the muscle during rigor mortis, and in muscular contraction during life? It is sometimes assumed that there is a very material difference; and Dr. Carpenter, in a recent (seventh English) edition of his great work, states that in these states the condition of the muscle "is in many respects different;" but, as between persistent muscular contraction during life, and the persistent contraction of rigor mortis, he appears able to recite only two very immaterial points of difference, namely, a difference of elasticity, and "a change in the state of electrical tension," the extent of such "difference" or "change" not being stated. It is therefore fair to conclude that the modification of the actual condition of the muscle in these two states of contraction is but very slight; and moreover, that the differences in question may be accounted for by differences in temperature during life, and in death, or to other causes wholly extraneous from the act of contraction itself.

Dr. C. B. Radcliffe, F.R.S., writing on this subject, asserts "that ordinary muscular contraction and rigor mortis are only different aspects of the same process." ("Lec. on Epilepsy," p. 124.)

It was necessary to bring this point plainly before the reader, in connection with the subject of rigor mortis, as a preliminary to some considerations on the relations of nerves and muscles, which (with the editor's permission) may be found in a future issue.

MONONUCLEATED CAMPHOR is soluble in the fixed oils, and oil of sweet almonds makes an especially good menstruum. Seven grammes of oil containing one gramme of the camphor can be emulsified with gum arabic and then suspended in syrup.

PUERPERAL FEVER.

AS TO THE PROOF OF HOSPITAL SURGEONS COMMUNICATING THE POISON OF SO-CALLED HOSPITAL DISEASE TO PATIENTS IN LYING-IN WARDS, AND THUS CAUSING PUERPERAL FEVER.

By C. L. MITCHELL, M.D.,

PHILADELPHIA, PA.

By puerperal fever is meant "a continued fever communicable by contagion, occurring in connection with childbirth, and often associated with extensive local lesions, especially of the uterine system."

During the prevalence of childbed fever in the Vienna Lying-in Hospital, from 1840 to 1846, Dr Semmelweiss found that the mortality in the clinical wards was one in ten, while the mortality in non-clinical wards, where students were not admitted, was one in seventy-four. By requiring the students to wash their hands in chlorine-water before examining patients, the mortality in the clinical wards was reduced to one in seventy-four, the same as in the non-clinical wards. Finding also that the fever was connected with the visits of the surgeons in the hospital in particular, all connection with the surgical wards was cut off, and the mortality was reduced to less than one per cent.

This shows the danger of contagion by means of those who were engaged in surgical wards; and shows also, though incidentally, the remarkable efficiency of antiseptics in preventing contagion *by destroying the poison*. Simply washing with soap and water, with which the students had previously satisfied themselves, was insufficient.

There has probably never been an assembly of more able and practical men in the department of midwifery than that called together by the London Obstetrical Society, in 1855, for the purpose of discussing the subject of childbed fever. At these meetings there were present, by invitation, representatives from the schools and hospitals of the cities and large towns of Great Britain and also of this country.

The importance of the topic enlisted the deepest interest of all engaged in obstetric practice, and it is not, perhaps, claiming too much to say that whatever learning, sagacity, observation, and experience could furnish to promote a knowledge of childbed fever was brought out on this occasion.

The value of the discussion may be partially inferred from the fact that the first speaker, Dr. Leishman, of Glasgow, thought that when one approached the subject of puerperal fever he felt that he was approaching a subject with which he was, in a measure, incompetent to deal; while, after the close of the meetings, it might be said, in the words of the Puerperal Committee of the Berlin Obstetrical Society, that "The cause of puerperal fever and the manner in which it was brought about were more accurately known than the cause and mode of propagation of almost any other disease."

That puerperal fever is a septic fever was the almost unanimous opinion of those present. Dr. Grailly Hewitt, of the British Lying-in Hospital, says it is essentially a form of blood-poisoning; again, it consists in nothing more nor less than an injection into the general circulating fluid of a poisonous material of animal origin—a form of *pyæmia*, for the production of which the minutest portion of the morbific agent may suffice. Dr. Wynn Williams, of the Royal Southern Hospital, Liverpool, says every case of so-called puerperal fever is due to sep-

ticæmia — to septic contamination of the blood; again, the disease is purely septicæmic; and again, it is always due to the presence of putrid animal matter.

Many others of the highest authority might be quoted to the same purpose.

The president of the Society, in "reviewing what had been said and written on the subject," says, "The outcome of the discussion in this Society, and the evidence from other sources, is, that puerperal fever is due to the inception of a morbid poison which vitiates the blood."

The Obstetrical Society of Berlin appointed a committee on puerperal fever, who report that "Puerperal fever is nothing else than the infecting of fresh wounds, such as are found in every newly-delivered woman, with septic materials. Thus every newly-delivered woman is liable to suffer from infective wound diseases, which in persons under other circumstances are called pyæmia, septicæmia, wound-fever, blood-poisoning, purulent infection, etc., as soon as suitable septic materials are brought into contact with the genital organs."

From the foregoing it is fair to conclude that every case of puerperal fever, and especially such as is caused by connection with surgical wards, is a septic fever, due to septic poison.

The septic material afforded by surgical wards, contamination with which will cause puerperal fever, has its sole source in decomposing animal matter. The poison is found in hospital *gangrene;* in traumatic *erysipelas,* which is itself a septic disease; in *ill-conditioned wounds and ulcers,* the pus from which is in a state of decomposition; and in the resulting septicæmia.

The poison thus generated may be conveyed by the hands of the practitioner, midwife, or nurse, or by clothes, instruments, sponges, bed-pans, and sheets, and other fabrics. Of all the ways in which the poison may be conveyed none is proved more certainly than that it may be by the hand of the practitioner in making vaginal examinations.

It is almost exclusively by this last-named means that the poison is conveyed from surgical wards to lying-in women. It remains to be shown whether this danger can be obviated or not.

However highly the use of antiseptics in surgical diseases may be valued, their great importance is far from being generally appreciated. The Berlin committee but express the opinion of those who have carefully considered the matter, when they say that "*the greatest advance, probably, which surgery has ever made, consists in the antiseptic method of treating wounds.*" Dr. Duncan, of the Royal Maternity Hospital, Edinburgh, says: "The most important researches (as to the poison producing pyæmia)—those of Lister and his followers—consist in the attainment of results in practice, equally *wonderful* and *valuable,* results that justify the belief that pyæmia is a septic disease, and that puerperal pyæmia may be almost, if not altogether, prevented by the application to delivery of a practice based on antiseptic principles." He further writes: "As practice is at present conducted by careful practitioners, I believe it is nearly as safe as can be. During nearly thirty years of obstetric experience, in private, in hospitals, and in consultation, I have not, as a precaution, given up work for a single day. The grand precautionary measures for obstetric practitioners are: 1st. Avoidance of duties as nurses. 2d. Avoidance of using the hands in post-mortem examinations. 3d. Antiseptic cleanliness of the hands and clothes."

Dr. Playfair says: "I am quite at one with Dr. Duncan, that if proper precautions are taken, any risk from this source might be eliminated, whether we use iodine or any other disinfectant that we like. I have no doubt that danger from this source might be obviated. It is my belief that the risk is not from the facts themselves, so much as from refusing to take the proper precautions which those facts suggest. . . . I do not believe, especially in these days when the use of antiseptics is so well understood, that it is essential for a practitioner to relinquish obstetrical work every time that he is in attendance on a case from which contagion may be carried. *It was otherwise when antiseptics were not employed;* but I can scarcely conceive any case in which the risk of infection cannot be prevented by proper care."

The contagion of childbed fever is much more active than that of septic poison in surgical wards, yet during the continuance of an epidemic of puerperal fever in Charity Hospital, Dr. Lusk passed several hours daily in the wards, but not a single case in his private practice developed an unfavorable symptom. He used "Labarraque's solution to disinfect his hands, washing them to the elbows, perhaps twenty times a day."

Dr. Gillette says: "Puerperal fever is as suppressible, when once it has started, as small-pox, and we never have failed to check it in Charity."

Mr. Callender says: "I have learned to banish, for all practical purposes, septicæmic affections from surgical wards. No such thing exists as pyæmia in the hospital wards under my immediate care. . . . Septicæmia is a disease which, in surgical practice, may be absolutely prevented."

So far, then, as surgical sources of poison are concerned, puerperal fever is a septic fever; and as all septic diseases in surgical wards may be absolutely prevented, and, where septic diseases exist, antiseptic cleanliness on the part of the attendant will prevent its propagation, it is fair to conclude that hospital surgeons, since the introduction of antiseptics into general use, may, with ordinary "antiseptic cleanliness," attend patients in a lying-in asylum without danger of communicating disease.

Occasions sometimes arise when no measures can eradicate the poison or prevent contagion.* Such was that described by Dr. Vache when puerperal fever prevailed epidemically at the New York Almshouse in 1840. "The disease made its appearance on the 12th of June, and was quickly followed by two more cases, apparently so malignant that it was immediately determined to vacate the room, with a view to its purification. The inmates were accordingly removed, and the apartment was whitewashed, ventilated, and scrubbed; the bedsteads were cleansed, new beds and bedding introduced, and, at the expiration of about a week, it was considered sufficiently disinfected to return to it in safety. But the disease immediately reappeared, equally as violent and irremediable as before, and it was concluded most judicious to abandon the building. Another was therefore prepared at some distance from the alms-house, and appropriated as a nursery, after being put in the most perfect order; the bedsteads were cleansed and painted; new beds and bedding were furnished; the physician and nurse were changed; the pregnant women were directed to cleanse their persons by bathing; new clothes and shoes were given to them immediately previous to transferring them to their new habitation, and all intercourse arrested with the inmates of the surrounding premises. Notwithstanding these precautions, the first woman confined,

and subsequently four others in succession, out of five labors, were attacked with the disease, and in every case it was fatal. The lying-in apartments at Bellevue were then abandoned, and other provided at Blackwell's Island. The same precautions were observed, and, for a time, the change of air, free ventilation, and a more generous diet, seemed to have accomplished the object; several were delivered, convalesced, recovered, and were discharged without an untoward symptom; but the disease soon broke out with redoubled fury, attacking almost every woman confined, and setting at defiance every effort for their recovery. The disease in each locality was almost uniformly fatal."

Dr Charles A. Lee, in referring to this epidemic, says: "It could be distinctly traced to a vitiated state of the atmosphere, both general and local. For twelve or fifteen months preceding, there had been an unusual tendency to epidemic disease, generally of a typhoid character. An incurable diarrhœa, followed by mortification of either extremity of the alimentary canal, often with the loss of eyes, defied the efforts of medicine. Mortification often succeeded blood letting. Ophthalmia, when treated in the usual antiphlogistic manner, was followed by rapid ulceration of the cornea. Scarlatina was very malignant and fatal. In short, there was a universal typhoid tendency in all diseases."

In an atmosphere so constituted as that here described by Dr. Lee, a puerperal woman has little chance for escape. A lying-in asylum is no longer a refuge, but is, as expressed by Dr. Bristowe, "a dangerous institution, which ought not to be allowed to exist, except under very peculiar circumstances." The only safety is in the liberal and skilful use of antiseptics, familiarity with which pertains especially to the hospital practice of surgery.

A CASE OF
SUDDEN DEATH FROM AIR EMBOLISM.

By THOMAS A. DUNDAS, M.D.,

ELMIRA, N. Y.

On the 27th day of January last I was notified of a sudden and mysterious death; that physicians had been called, but the patient was dead before the first of them arrived.

I visited the house, and found the person above mentioned to be a woman of ordinary stature, of compact build; aged 27 years; married six years; two children, the youngest three years old.

This woman, previous to her sudden demise, had been in her usual good health; worked hard the few previous days, and on the fatal day was out on business matters. She returned home with her husband from his place of work at 6 P. M. He remained at the house for an hour and then left, that being the last time he saw his wife alive. Her sister, sixteen years of age, testified to being with her till about 8 o'clock that evening—no one else in the house, but the two small children. At 10 o'clock she called the sister down, groaning; was on the floor; was questioned, but only gasped one word.

A Davidson's syringe was found between her limbs, the long female tube was attached, the tubular part was smeared with fresh blood; there was blood on her hands, also on a towel at her feet; the syringe had been inserted into her person.

There was no basin or water around.

Autopsy held by Drs. J. E. Weaver and C. W. M. Brown, January 27, 1880, elicited the following: Lungs were everywhere adherent to the pleura, otherwise healthy. Found the heart, to external appearance, evidently containing gas of some kind; accidentally opening the right external jugular vein, there escaped bubbles of air with frothy blood. All vessels connected with the heart were immediately ligated; heart was then removed. Placed it under water, carefully manipulating it so as to cause any air on external surface to rise from it. The right auricle and ventricle were then opened under the water; large bubbles of air escaped with blood, the blood presented a frothy, churned appearance; the left heart was empty of blood. At the least calculation, one cubic inch of air escaped at this time. Uterus and ovaries were then removed. Length of uterus five inches, largest circumference seven inches. On the posterior surface, two and a half inches above external os, saw something protruding from a puncture; on feeling through external os, felt the other extremity. The uterus was full of air; it was then laid open in the median line, and the points of entrance and exit of the protruding substance carefully examined. The substance proved to be a portion of an ordinary knitting-needle, two and a half inches long. This, for at least three-quarters of its length, was directly imbedded in the uterine walls, and extricated with considerable force. Below the point of puncture, on the external surface of posterior wall, was an ecchymosis, which was produced from another artificial sinus, made from through the os, probably at the same sitting from the same cause. Found a similar spot on the anterior surface near the fundus. On the inner surface, found a clot of venous blood opposite the external ecchymosis. Also a fœtus of about three months development. On the inner surface, directly opposite the external ecchymosis, the placenta was detached, from force of some kind. On the inner surface of placenta, opposite this, was a venous clot about the size of a finger-nail. In the left ovary was a tumor two inches in diameter; it was a dermoid cyst filled with hair and sebaceous material. Drs. Weaver and Brown gave it as their opinion that death was caused from air embolism gaining entrance through the uterine sinuses.

A somewhat similar case was reported by Medical Examiner Dr. J. C. Gleason, of Rockland, Mass., in *Boston Medical and Surgical Journal*, Aug. 7, 1879. In his case a woman, pregnant about six months, was given an intrauterine douche by one Dr. Gilson; while undergoing the operation she suddenly expired. A careful autopsy was had in his case, but no *postem* evidence of air embolism found, though it was supposed to be the cause of the death, by air being forced in with the water through an imperfection in the douche used.

This case of Dr. Gleason's was shown me some little time after the inquest in the case I report; up to then I had never heard of a case anywise similar.

Death from air embolism is dependent upon the amount, or rapidity with which air enters the veins. In experiments upon animals, a small quantity, quickly injected, causes immediate death; while a much larger quantity, slowly injected, does not end fatally. Death from air embolism is not instantaneous in many cases; from a few minutes to several hours generally intervene. As physicians we are aware of the desperate and frantic efforts often made by women to bring on abortion. In the present state of society, a large ratio of American women deem an increase above one or two children a burden; some of them will stop at naught to prevent an additional

member. In this case, so far as could be learned, the needle was used by the woman's own hands, to bring about the desired boon. Much force must have been used in the desperate adventure, which resulted in breaking the needle after being so firmly imbedded in the uterine walls. Probably when the terrible mishap was discovered, the syringe was grasped as a last resort. With a rapid pulse and an emotional respiration the empty syringe was used.

But what the idea was is hard to know. Was it to further the induction of the crime, by injecting strong currents of air into the womb? or could she hope to extricate the broken needle by the suction force of the syringe? No doubt it was used with a desperate hand, and the entrance of the air into the torn and open sinuses caused the terrible result.

If the large vessels had been closely examined, considerable air could have been discovered in the circulation itself, as a large quantity was denoted both by the number of bubbles and the very sudden death.

The constitutional effects were graphically described by the sister: "extreme faintness; oppression about the chest; screaming out and continuing to moan; with rolling eyes and gasping respiration."

The air and blood, mixed together in the right cavities of the heart into a frothy mass, cannot be driven through the pulmonary vessels; thus the brain does not receive sufficient blood-supply, resulting in fatal syncope, usually attended by convulsions. The frothy mixture in the ventricles is unable to close the valves of the heart, and that organ finally comes to a stand-still. The normal blood regurgitation from the large arteries, as soon as the impulse of the heart's contraction is removed, is competent to close the valves at the orifices of these vessels. Now, substituting air for blood, the valves are not closed, hence the propelling power behind the circulation is destroyed, no matter how vigorously the heart continues to work.

An original theory for treatment for the relief of patients suffering from this accident, was advanced to me by Dr. Weaver. Place the patient on the right side, with the shoulders considerably lower than the hips, say at an angle of 45°, then tap smartly on the chest, back, and left side. The object being, first, to cause all air still in the heart to retreat to the apex, thus not embarrassing the valves, nor entering the circulation, save so fast as it may be absorbed by the current of blood constantly passing underneath. Second, to cause, if possible, a regurgitation of the air which may have already entered the pulmonic circulation. If a much larger angle of inclination is made, the right heart will not be near enough to the vertical to keep the air at its apex; and if a smaller angle, regurgitation of what air may be in the pulmonary arteries will not be accomplished.

A Royal Physician.—Charles Theodor, of Bavaria, the royal Prince, has just been regularly admitted to practise as a physician. He is a specialist of some renown in eye diseases. He has practised for several years with considerable success, and has been at the disposal of his many patients at all hours of the night and day. He is a generous as well as a wealthy man, and to his poorer patients gives not only medical advice but substantial help. The Prince is the brother of the Empress of Austria, the Queen of Naples, and the Duchess of Alençon, and upon his elder brother's death will be the head of the Bavarian ducal line.

Reports of Hospitals.

BELLEVUE HOSPITAL.

Notes of Practice and Peculiarities of Treatment.

Artificial Feeding — The Œsophageal Tube and Funnel.

In a recent lecture delivered by Dr. John P. Gray at the Bellevue Hospital Medical College, attention was directed specially to feeding patients by means of the œsophageal tube and funnel. The point of interest was the adaptability of the plan to sustaining nutrition in cases other than those in which the patient is insane. The plan is to introduce an ordinary flexible œsophageal tube into the stomach, adjust a funnel to its outer extremity, which carries a metallic ferrule to keep it from brooming, and then pour in such quantities of fluid food as may be desirable. The tube is easily introduced by carrying it along the side of the mouth and around the tonsil, and so down, and when introduced in that manner gives less inconvenience to the patient than when carried through the centre of the pharyngeal space. The tube and funnel were recommended in cases of faucial paralysis, for example, following diphtheria; in cases of acute tonsillitis attended with difficult and painful deglutition; in cases of even severe inflammatory sore-throat; in short, in *any* case in which the patient finds marked inconvenience from any cause in swallowing. The lecturer remarked that there was not only no excuse, but, on the other hand, a culpable neglect for allowing patients to starve to death when the means could be so easily used for supplying them with food.

Those who hold the jaws closed and thus resist the introduction of the tube, can be easily overcome by insinuating the end of a strong spoon-handle, or a piece of firm wood covered with cloth, between the teeth and then turning it up edgewise, when the tube, being only about five-eighths of an inch in diameter, can be readily introduced.

Interstitial Hepatitis—Splenitis.

The following case presented points of interest relating to diagnosis and treatment: A middle-aged colored man had been sick nearly four and a half months. He had lived in New York for twelve years, except for short periods when he was at Long Branch, Saratoga, and Niagara. He had had syphilis, and had drunk alcoholics steadily. His habit had been to take one or more drinks before breakfast. During the past two months he had been obliged to take two Seidlitz powders to keep his bowels open, but prior to that time was regular in that respect, and never passed any blood from the bowels.

Four months and a half ago he was, as he supposed, perfectly well when he was taken with pain in the left side and vomiting a short time after each meal; the material thrown up being stringy phlegm, sometimes food, but he had never vomited blood. After a time he began to notice a swelling about the stomach, and about ten days ago he noticed for the first time that his feet were swollen. On making a physical examination a tumor was found, not uniform, extending from the median line to the left, and from the upper part of the abdomen downward to within two inches of the crest of the ilium. It had a well-defined sharp edge. The area of hepatic dulness

was increased vertically about one inch. There was evidence of fluid in the abdominal cavity. The veins upon the surface of the abdomen were enlarged. Just below the free border of the ribs, on the left side, where the tumor became prominent when he laid upon that side, there was a feel as of indistinct fluctuation, and at that point there was flatness upon percussion. He had never had chills; no history of malaria could be obtained; he was losing flesh; he had been in the hospital ten days; his pulse and temperature were normal; he was tapped, and ten quarts of fluid removed from the abdominal cavity, and after tapping a friction sound could be heard over the tumor, just below the free border of the ribs. It seemed that his symptoms began with enlargement of the spleen. It was thought not to be due to obstruction to the return circulation in the liver consequent upon cirrhosis, although the patient gave a history which showed a predisposition to interstitial hepatitis. It was believed that the pain was due to perisplenitis, and the friction-sound, after withdrawing the fluid, seemed to make it conclusive that there was inflammation of the capsule of the spleen. If there was a sac there containing fluid, the question of hydatids would arise, but the fact that there was no evidence of hydatids in any other organ would exclude the probability of hydatids being present in the spleen, for they usually make their appearance first in the liver.

It was thought that it possibly might be an infarction of the spleen which had undergone rapid degeneration and, in that manner, formed a cavity containing pus and broken-down splenic tissue. It seemed quite evident that there were two conditions present not dependent upon each other:

First. Interstitial hepatitis, with probably sufficient fatty degeneration to prevent the liver from becoming much diminished in size.

Second. An inflammation affecting the spleen, which had its origin either in degeneration of an infarction, or some other cause, and had led to an accumulation of fluid that probably was pus. An exploratory puncture was to be made, and if pus was found, the aspirator was to be used for its removal.

CHRONIC URETHRITIS.

A plan of treatment given was the following: First obtain the complete confidence of the patient. He was twenty-one years of age, had used all kinds of injections, had had his meatus cut, but notwithstanding had had a discharge from his urethra for two years. Use such medical treatment as the constitutional symptoms seem to demand. For surgical treatment in this class of cases the following suggestions were made: if the meatus is narrow and has not been cut, divide it, but be careful and not make a hypospadias, and do not cut it sufficient to set up inflammation, balanitis, etc.; cut just sufficient to give to the meatus the normal calibre represented by an instrument which cannot be expanded. There is no absolute rule as to how much cutting should be done. Hypospadias produced by porotomy cannot be cured. After cutting, dilate daily until the wound be closed, and afterwards continue to dilate, perhaps over-distend the urethra gradually, not suddenly, where the tender spot may be; for one or more tender points are usually present. The tendency is for the disease to extend backward toward the bladder and continue for years.

No indiscretion must be allowed with either Bacchus or Venus. Cure the urethral discharge as soon as possible. Early and efficient treatment is all-important. All the ordinary injections are useless. Irrigation properly used, will do a great deal of good if proper dilatation with sounds is made. To irrigate, introduce a medium sized catheter as far as the bulb of the urethra, if you wish to irrigate the anterior portion of the urethra, and then with either a fountain or Davidson's syringe throw in fluid, beginning with cold water, and wash out the urethra thoroughly. More than that, as in the case before us, it was deemed proper to irrigate the prostatic region; and to do that, carry the eye of the catheter to the membranous portion, and from that moment the wash will go the entire length of the urethra. If it be deemed advisable subsequently to use astringents, bichloride of soda may be used, and afterward perhaps nitrate of silver in *weak* solutions, which was said to yield more satisfactory results than strong ones. One-tenth of a grain to the ounce of water was regarded as sufficiently strong to begin with, and *one* grain to the ounce as strong as should be used at any time. Allow the patient to hold half a pint of urine before the injection is used, or if the bladder is empty, the same quantity of water may be thrown in. Nitrate of silver has a special advantage, because it blunts the sensibility of the mucous membrane.

Progress of Medical Science.

METHODS AND RESULTS OF OVARIOTOMY.—Dr. Goodell, of Philadelphia, reports eight cases of ovariotomy performed during the past year, with the result of six permanent recoveries, one temporary recovery, and one death. The fatal result in this last case was expected, on account of previous inflammation of the cyst. The temporary recovery was in a case of malignant papillary cyst of the ovary, which had burst and infected the whole peritoneal surface; the patient recovered from the operation, but died soon afterward, as was expected. Dr. Goodell attributes his low percentage of mortality partly to his growing experience, and partly to the use of the antiseptic methods. He used a five per cent. solution of carbolic acid for the atomizer, and also for the sponges and hands, but thinks it too strong for the latter uses, as it made the hands tingle, and seemed in two cases to prevent union by first intention. It does for the spray, because it is then diluted fully one-half by the steam. The advantage of including two ribbons of peritoneum in the abdominal stitches, was well shown in one case, where the wound would have gaped entirely open, if the peritoneal surfaces had not united. The quick union of these surfaces also prevents the pus from the wound above from getting into the abdominal cavity. His fatal case showed the need of using antiseptic precautions, even in the simple operation of tapping, to guard against the decomposition of the residual cyst fluid, or inflammation of the cyst wall from the introduction of poison germs. Dr. Goodell believes that the intra-peritoneal method of dealing with the stalk is the best, when antiseptic precautions are used. The only sound objection to it is the liability of the raw end of the stump to seal itself to a loop of the bowel and cause obstruction. In one case, to prevent this he doubled over inward the cut edges of the stalk, and stitched them together with fine gut, thus covering the large raw surface with a lid of peritoneum. The ligature used for the stalk was always of fine carbolated silk, and the stalk was always transfixed and

tied on either side. Gut was not used, because it is liable to become untied, and to be absorbed too early. In short and broad stalks, the thin and membranous, or broad ligament side, *i. e.*, the side opposite the one in which are the oviduct and ovarian ligament, is liable to slip out of the loop of the ligature and cause fatal hemorrhage. This happened in one of the cases, but was fortunately discovered in time. It may be prevented by using the cobbler's stitch, or by passing a gut thread through the outer edge of the stalk just above the ligature, and tying it in a knot. All the details of Lister's antiseptic method were carried out in these cases, with the exception of the dressing, which is bulky and stiff. Instead of it, salicylicized cotton was used; a thick and wide roll of the cotton was laid over the wound and gently pressed in between the wires. Long strips of adhesive plaster kept the cotton in place, and over all, a fine white flannel binder was pinned. This dressing was simple, and its elasticity brought the abdominal walls in firm contact with the bowels, and thus checked any persistent oozings. It was kept on as long as no odor could be detected, viz.: from a week to ten days. Dr. Goodell has discarded entirely the use of drainage-tubes, as he believes them not only useless but hurtful, from the irritation they produce. Ovariotomy should, in his opinion, never be performed except by the antiseptic method, and drainage is then needless, because the antiseptic clots do not break down, but become organized, and because, after the use of the spray, denuded surfaces of peritoneum heal up kindly without the formation of pus. —*The Clinical News*, March 6, 1880.

Reduction of an Inversion of the Uterus of Fifteen Months' Standing.—Prof. Lewis, of New Orleans, recently reported the successful reduction by Emmet's method of a chronic inversion of the uterus of five months' standing. He now reports a case of successful reduction where complete inversion had existed for fifteen months. The treatment consisted mainly in steady pressure by means of the rubber bag distended with water. The bag was removed every second day to cleanse the vagina, and on two occasions manipulation under chloroform was tried without much effect. On the thirteenth day, when the bag was removed, the uterus was found more than half reduced, the body and fundus being within the cervix, and on the sixteenth day the reduction was found to be complete. The cavity of the womb was then examined and found to be normal. In introducing the bag, Prof. Lewis points out that the uterus should be well pushed up first, as otherwise the pressure is but slight upon the fundus, and the bag at the moment of distention may rise between the vaginal walls and the uterus, compressing it laterally.—*The New Orleans Med. and Surg. Journal*, March, 1880.

Casts of the Uriniferous Tubules.—Dr. Tyson read an instructive paper on this subject before the Philadelphia County Medical Society at its meeting January 14, 1880. The author makes the following general statements: 1. Hyaline casts are found in all forms of Bright's disease, as well as in temporary congestions of the kidney, active or passive. 2. Epithelial casts are found in acute, subacute, and chronic parenchymatous nephritis. In the latter two forms the cells are generally degenerated and fragmentary. 3. Blood casts are found in acute parenchymatous nephritis, and when hemorrhages have occurred in the kidneys. 4. Pale granular casts are found in interstitial nephritis (congested kidney) and chronic parenchymatous nephritis. 5. Dark granular casts are found in parenchymatous nephritis, acute and chronic, and rarely in interstitial nephritis. 6. Waxy casts are found only in chronic Bright's disease, and attend either of the three principal forms. 7. Oil casts are found in subacute and chronic forms of Bright's disease, and may attend any of the three principal forms, but are most numerous in chronic parenchymatous nephritis (fatty kidney). 8. Free fatty cells and free oil drops are found in chronic parenchymatous nephritis. 9. The form of fatty cell known as the compound granular cell is found in acute and chronic parenchymatous nephritis.—*Phila. Med. Times*, March 13, 1880.

Phlebitis of the Lower Extremities—A Secondary Complication of Injuries of the Head.—Dr. H. G. Croly, of Dublin, has observed two cases of this unusual affection. In the first one, a Mr. K., æt. 35, met with a severe injury of the head by having been thrown with much violence from a carriage. He was unconscious for a short time after the accident; there was arterial hemorrhage from the left ear, vomiting of blood, and sanguineous effusion in the left mastoid region, and, subsequently, facial palsy, but no injury whatsoever of the lower extremities. Consciousness was soon restored, but the arterial hemorrhage continued from the left ear for several hours. The patient suffered from the usual symptoms consequent on injuries of the head. The treatment adopted was the application of ice constantly to the head, James's powder, absolute rest, quiet, and a most carefully directed dietary. The head symptoms gradually subsided, and in a month the patient felt so well that he was approaching convalescence, and was anxious to be allowed out of bed. However, just a month and three days after the accident, he complained of acute pain in the left groin and thigh; the inguinal glands became enlarged, and very hard and painful to the touch. The pulse rose from 64, its normal number, to 100, and the temperature also rose to 100°. The foot also became swollen and painful, and the entire limb œdematous; the patient complaining much of the heavy weight, as well as the pain of the limb, which presented all the appearances usually attending phlebitis. From the 21st to the 30th of November, the pulse and temperature remained stationary at 100; both then fell gradually, the pulse to 64, the temperature becoming normal. On the 7th of December the patient complained of pain in the opposite leg. The swelling which followed did not extend higher than the knee; severe rigors and perspirations occurred at the same time. The femoral and posterior tibial veins were hard and painful, and the pulse of the posterior tibial artery could scarcely be felt behind the internal ankle. The treatment adopted was leeches to the groin, anodyne draughts, hot sedative fomentations, linseed poultices, and elevation of the leg. The whole limb was wrapped in wadding, followed by stimulating and anodyne embrocations, besides friction and careful bandaging with flannel rollers, nutritious diet, and quinine. The patient gradually and slowly recovered (but both legs, especially the left, remained swollen and œdematous for several weeks), and is now in good health and able to walk as well as ever. Case II. was in all essential respects exactly similar to Case I. The same line of treatment was also adopted, and the patient is now recovering.—*The Med. Press and Circular*, Feb. 25, 1880.

Fibroid Phthisis.—Dr. Shattuck, in a paper read before the Essex North District Medical Society, Jan-

vary 13, 1880, cites the following case: J. R., 40 years of age, was discharged early in September, 1879. His grandfather died of asthma, and two brothers out of nine have died of quick consumption. He served four years in the navy during the war, contracting typhoid and intermittent fevers. After his discharge, in 1865, was strong and hearty, and worked in a printing office. In October, 1870, caught cold while housemoving, from exposure, and from this cold he dates his present troubles. Though he had persistent cough did not consult a physician for upwards of a year, at the end of which time he had night-sweats, and was so much run down that he sought advice. Spat blood for the first time in 1872, since when has had attacks of hæmoptysis, recurring at intervals every spring except that of 1879. Is positive that he must have spat blood at least eighteen or twenty times—the last time in October, 1879. Between 1873 and 1877 worked off and on; was laid up once for ten months, once for five, and alternately lost and gained in weight. Since the spring of 1877 has been able to do no work; his weight was at that time at its lowest point. Since then has gradually gained in flesh. Has had the opinion of many physicians, and has been twice an inmate of the Boston City Hospital. All agreed in the opinion that he was in consumption. Gives a history at one time during his sickness of expectoration as from a large cavity. He now complains of dyspnœa, greatly aggravated by exertion, and cough, with profuse muco-purulent expectoration. There is decided flattening and deficient expansion of both upper fronts, and the integument is drawn inward during inspiration. There is also marked dulness on percussion on the upper part of both lungs, front and back, with very harsh respiration. During February, 1880, he became insane, and died in an asylum to which he had been taken. The autopsy showed characteristic fibroid phthisis, marked peribronchitis, and a number of bronchial dilatations, but no foci of lobular pneumonia or cheesy nodules.

An Invisible or Third Corpuscular Element in the Blood.—In a paper read before the Birmingham Philosophical Society, Dr. Norris describes a research on a "third corpuscular element" which he believes to exist normally in the blood. He propounds an entirely new view regarding the histology and growth of the blood-corpuscles. He concludes that in normal mammalian blood there are certain colorless, invisible, biconcave disks, similar in every respect to the red corpuscles, with the exception of the absence of color; that these corpuscles exist in the blood in large numbers, and that they are, in fact, an earlier stage of the red corpuscles in which they have not yet obtained hemoglobin. He further considers that they are lymph-corpuscles which have assumed a biconcave form immediately on being introduced into the current of the blood. Between the two kinds of biconcave disks (the ordinary red and Dr. Norris's invisible corpuscles), others, having every intermediate gradation of color, are demonstrable. The author states that he has been able to observe the conversion of the discoid lymph-cell into a biconcave corpuscle. He is entirely opposed to the current view that the white corpuscle of the blood is a nucleated cell; he considers it to be a mere "accidental aggregate of adhesive lymph-corpuscles," the false appearance of nucleation being caused by post-mortem changes.

Mrs. Ernest Hart, in a critical note on Dr. Norris's research, very justly observes that the author's methods are open to the objection of tending to produce artificial appearances. Three methods by which the "colorless corpuscle" is rendered visible were: 1. By changing the refractive index of the serum by the addition of a saturated solution of common salt. 2. By withdrawing the serum from the corpuscles by the method called "packing." 3. By withdrawing the corpuscles from the serum by the method described as that of "isolation."

As to the first, Mrs. Hart calls to mind the fact that the solution of sodium chloride causes many blood-corpuscles to lose their hemoglobin, and thus assume the appearance of Dr. Norris's "invisible corpuscle." Regarding the method of packing, she points out that the corpuscles are here subjected to an extreme degree of pressure, which causes certain of the corpuscles to discharge their hemoglobin and to become transparent. The method called by Dr. Norris "isolation," again does violence to the delicate structure of the red blood-corpuscles, so that many of them have the appearance of being ruptured, and of having lost their contents. Hence the reality of Dr. Norris's third corpuscle as a normal constituent of living blood is extremely doubtful.—*Reprint from the Lond. Med. Record*, Jan. 15, 1880.

Rupture of the Heart. Instant Death.—Dr. Gershon H. Hill, first assistant physician in the Iowa Hospital for the Insane at Independence, writes: "Mrs. Sarah F. B——, æt. 51, born in Kentucky. She was 5 feet 3 inches in height; of late years has been hearty, fat, and at death weighed about 200 pounds. Insane twenty-eight years; under hospital treatment nineteen years. She was pretty thoroughly demented, incoherent, and, unless kept by herself, irritable, noisy, and more or less violent. On account of a quick temper and a solitary disposition she was allowed to remain in her bedroom during the day. On the morning of March 3, 1880, she ate heartily, put her room in order, washed a few garments for herself, got into bed, and at 9 A.M. sat there mending socks as usual. At 12 M. she was dead. Without exertion or excitement, without protracted pain or a struggle, she died instantly. Her right hand was in her lap with her work, her left hung at her side, her head was bowed, resting upon her knees. An autopsy, four hours after death, gave no evidence of cerebral hemorrhage. The lungs were in good condition, without pleuritic adhesions. The pericardium was distended with blood and somewhat adherent to the heart. The organ was hypertrophied; there was not an unusual deposit of adipose tissue nor dilatation of the ventricles; it contained but little blood; when emptied, weighed twelve ounces.

The valves were in good working order; there was not the appearance of fatty degeneration. The proportionate thickness of the ventricles was normal, but the left was ruptured in front near the septum, midway between the auriculo-ventricular groove and the apex. The aperture was one-third inch in length, more like an incised than a lacerated wound. There were a few small clots infiltrated beneath the serous coat near the rupture, probably deposited immediately before the bursting of this membrane. Within, there was a circumscribed spot of myocarditis on the anterior wall corresponding with the rupture. The ventricle was not thin at this point, but there was a fissure through the disorganized muscular tissue. The abdominal viscera were not examined.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, April 24, 1880.

THE BILL TO ESTABLISH A LUNACY COMMISSION.

THERE has been much disappointment felt that the bill to create a Lunacy Commission did not pass at the first attempt. There is still, however, a prospect of its getting through, as the majority against it was very small, and as the opposition of several members was on account of certain minor defects which can be easily remedied.

The only objection to the bill which can be fairly presented, is that the plan to unite a Lunacy and Charity Board will prove cumbersome and ineffective. This objection, however, has been fully considered by the committee who drew up the bill, and a candid examination of the matter will, we believe, show that the argument is not valid.

There has been a good deal said about the conjoint Board of Health, Lunacy, and Charity in Massachusetts, and many complaints have been made of its inefficiency. It is not condemned by the Governor, however, and its evils, if any, are probably due more to lack of officers and money, than to the system itself. But, at any rate, the proposed Lunacy and Charity Board of this State is by no means a copy of the conjoint Board of Massachusetts, and it would be unfair to argue from one to the other. The plan now before the State Legislature has all the elements of feasibility, economy, and effectiveness, and it ought not to be opposed because it faintly resembles an economical experiment in Massachusetts.

But the bill is not in danger on these accounts. Underlying these objections, which really amount to very little, there is the active opposition of the Medical Superintendent of the State Asylum. Why this should be the case it is hard to explain, save upon the supposition that a law which would benefit any of the asylums in the State might have a contrary effect upon the institution at Utica. It has been shown in these columns, and the figures have been confirmed by a special report of the Comptroller in 1879, that the Utica Asylum has been conducted with considerable financial looseness. We do not care to go into the matter now, or repeat old figures, but we are putting it as mildly as possible when we say that the Asylum has been, and presumably now is, quite extravagantly managed. This is the inference from official reports. The active opposition of its superintendent, therefore, to all attempts at securing anything like exact supervision, can hardly be considered a very strong argument against the real utility of the bill.

RAISING THE STANDARD OF MEDICAL EDUCATION AT HARVARD.

THE Harvard Medical School has recently given substantial evidence that the present agitation for a higher medical education is not to be without fruits. In its announcement for 1880-81, it provides for a four years' course of study, and prescribes a more rigorous preliminary examination. This fourth year of study is at present optional, a degree being still attainable in three years; but an inducement to take the longer course is given in the increased facilities for practical work that are offered. In addition to this, a degree of doctor of medicine *cum laude* will be bestowed on students who go through the four years' course, and obtain an average of seventy-five per cent. upon all the annual examinations.

The preliminary examination requires English composition, the translation of easy Latin prose, a competent knowledge of physics, and a knowledge of either French or German, algebra, geometry, or botany.

This step upon the part of the Harvard Medical College is a most commendable one, and we hope its success will justify the trial of a similar or even more radical plan elsewhere. We do not feel so deeply, perhaps, as those living nearer Boston, that the adoption of an elective fourth-year course at Harvard "marks a great era" in the history of medical education, but it does indicate real progress, and credit should be given to the authorities for taking the lead as they have done.

MEDICAL LEGISLATION IN IOWA.

AT the recent session of the Iowa State Legislature, two bills were passed that will be very beneficial to the State and helpful to the profession. These were: a law establishing a State board of health, and a law regulating the practice of pharmacy and the sale of medicines and poisons. The provisions of these laws resemble largely those already established in some of the other States. The board of health is to consist of nine members, seven being physicians. Their duties will be to look after the sanitary condition of the State, make appropriate scientific investigations, and secure the registra-

tion of vital statistics. Such registration is made compulsory upon physicians, the penalty for not reporting a birth or a death being a fine of ten dollars. We have before referred to the fact that there is a good deal of arbitrariness in thus forcing physicians to do gratuitously work which often calls for special knowledge. It may not be well to complain, however, until the people have learned to appreciate the necessity of sanitary boards and the value of vital statistics.

An effort was made to confer upon the health board, thus established, power to regulate the practice of medicine. A bill to this effect was introduced, its provisions being very similar to those of the Illinois law. It passed the Senate, but failed in the House; and as the Iowa State Legislature has biennial sessions, nothing in this direction of regulating the practice of medicine can be expected for some time.

The law to regulate the practice of pharmacy, etc., provides for the appointment, by the governor, of a board of commissioners of pharmacy. This board sees to the registration of every pharmacist in the State, and forbids the dispensing of medicines, except by such a registered pharmacist, or by a physician. Any person proposing to become a pharmacist hereafter, must pass an examination before the commissioners or obtain a diploma from a pharmaceutical college. The law, in addition to this, makes stringent provisions as to the sale of poisons. It also compels all itinerant vendors of medicine to pay an annual license-fee of one hundred dollars.

The general tenor of the law shows that the Iowa legislators intend to be very careful who measures out their drugs and poisons. It seems unfortunate that they did not show equal anxiety as to who should prescribe for them and their constituents. For a charlatan is, on the whole, more dangerous than a poor druggist.

ABUSES OF MEDICAL CHARITY AT CHICAGO.

THE report of the committee appointed to investigate the abuses of medical charity in Chicago has been presented to the Chicago Medical Society. The document is an able and just one in many respects. It states very plainly the evils that need to be remedied; and it confirms the previous statements that about one-third of the city population is treated gratuitously, one-half of these being undeserving. But the tone of the report on the whole is too full of personal feeling to be perfectly satisfactory; and in addition to this, there is an evident scattering of forces, so that the essential point first sought is much subordinated. It was thought when the discussion began that the crying evil of medical charity was in the dispensary system. But the committee having condemned this and the ring of doctors who control it, pass on and resolve that the college professors have too much of a monopoly, that druggists repeat prescriptions and prescribe on their own account too often; also that the clerical profession, "though doubtless a respectable one," ought not to be allowed to subsist upon the medical profession.

Now all this is very well, perhaps, and very true; but we submit that it would be better to have condemned things less extensively and to have presented more practical suggestions for reform. Some of the evils enlarged upon are comparatively trivial. It will be new to many to learn that the clerical profession of Chicago subsists upon the doctors of that great city. If it is so, the hardship is probably not on one side alone, and in any case the allegation is not to the point. The practice of treating clergymen gratuitously can be amended with comparative ease, and is not a very severe burden. The great and shameful abuses are those connected with the public charities, and all the energies of persons desiring reform should be concentrated here. It is better to attack one thing at a time; and it should be remembered that they get the most, eventually, who ask but a little at first. The supporters of the Chicago report will doubtless appreciate this more fully hereafter.

As the report stands now it is not a valuable one. There are in it suggestions that the young men have more to do with the management of the dispensaries; that college teachers should not monopolize all clinical material; that dispensaries should be, in general, better managed, and that a system of investigation of applicants for relief should be adopted. The only practical suggestion among these four is the last one, and there need not have been any wide research or profound thought to have produced this.

Perhaps we have expected too much of the committee and the society; but their work, though in the right direction, was certainly disappointing. The need of reform was shown, but everything further seemed to be lost sight of in the desire of those outside the ring to get even with those inside. Some practical good, however, may come indirectly even from this, since those who have the power may be stirred up to show that they can use it better than has been done in the past. And this is more than a hope or a conjecture, for we learn that some of the dispensary authorities are making efforts now to lessen the evils of which there are so many complaints. That something can be done, even under the old system, is shown by the recent report of the New York Dispensary. By the small-fee system, and close investigation of applicants for relief, this institution has cut down the number of patients from 43,623 in 1877, to 26,944 in 1879.

This indicates some progress; but it was not accomplished by sweeping resolutions of censure, or by suggestions as to the comparative merits of young and old practitioners.

THE ANNUAL REPORT OF THE STATE BOARD OF HEALTH OF NEW JERSEY.

The third annual report of the State Board of Health of New Jersey is a document of somewhat more than ordinary interest. This is partly due to the care which has been put upon the papers it contains; and it is further due to the fact that New Jersey being a State the majority of whose population resides in towns and country villages, the feasibility and benefits of a State health board in such a population are well illustrated. It was objected at first that vital statistics could not be collected in rural districts, and that for this reason one of the prime objects of a general board would fail. And at first some difficulties were encountered. In the present report, however, we are informed that vital statistics have been very thoroughly collected, and the basis for important sanitary work in the future has been laid. These statistics show that the average death-rate for the whole State was 20.02 per 1,000. Of the deaths caused by what are termed "principal causes," which excludes accidents and unusual factors of mortality, 17.95 per 1,000 occurred in the cities, and 13.21 per 1,000 in the towns and country. Estimating the per cent. upon the basis of all the causes of death, it will be found that the mortality rate in the country is 17 per 1,000; in the cities, 23 per 1,000. This is about the proportion that has usually been found to exist between country and city. It shows that neither locality is as healthy as it should be.

A paper by Albert R. Leeds, upon "Adulterations of Food," shows much research, and is a practical and useful article. The general tenor of the investigations made by Mr. Leeds is to the effect that adulterations are not so extensive or injurious as some writers would lead us to believe. In a large number of samples of bread no adulteration except alum was found, and this was in small quantity. Baking powders contained a good deal of terra alba, and cream of tartar a still larger per cent. Sugar, milk, tea, and coffee, rarely contained harmful ingredients. On the whole, the facts given by Mr. Leeds will be likely to put people on their guard, but will not fill them with alarm.

A circular to householders, city authorities, and local boards of health, gives some very practical directions in regard to the sanitary defects to be looked out for, and the way in which they should be remedied.

The report shows throughout its contents the able hand of the secretary, Dr. Hunt, and is eminently creditable to the Board and the State.

Dropping into Poetry.—The *Dublin Journal of Medical Science* has among its medical reviews an elaborate notice of Schiller's "Lay of the Bell," and other ballads. The translation is made by Andrew Wood, M.D., LL.D., etc., who has made several other excellent translations of German poetry.

Reviews and Notices of Books.

The Therapeutics of Gynecology and Obstetrics, comprising the Medical, Dietetic, and Hygienic Treatment of Diseases of Women, as set forth by distinguished Contemporary Specialists. Edited by William B. Atkinson, A.M., M.D., Author of "Hints on Obstetric Procedure," etc., etc. Philadelphia: D. G. Brinton. 1880. 8vo, pp. 365.

There is no doubt that there is a demand in the profession for thoroughly practical works. Such a demand has in part been met by Napheys's Series of Therapeutical Treatises on Medical and Surgical Diseases, and the present work, which is a continuation of the same series, is likely to meet with similar success. Dr. Atkinson, as editor, has used rare judgment in culling from the large field at his disposal, and has laid the medical practitioner under peculiar obligations for the immense amount of valuable material presented in this volume. The best points of the leading specialists in gynecology and obstetrics in this and other countries have been given under their appropriate headings, and the commoner diseases which the practitioner is called upon to treat are discussed from a purely therapeutical standpoint, and, in that respect, leaves nothing else to be desired. The work, as a whole, is full of practical suggestions, and contains a large number of prescriptions from eminent authorities. It is of the greatest possible value to every physician who practises obstetrics or gynecology. By its perusal, the reader will be surprised to find how much can be accomplished without resort to the fancy operations which are becoming so fashionable with some of our specialists.

Physiological Laboratory, Harvard Medical School. Collected Papers, 1873–1879.

This collection of papers is marked as intended for private circulation. The contents, which has already been published at various times in different journals, includes eighteen papers. All of these are original, and some of them embody valuable contributions to physiology. Among the more interesting are that of Mr. C. H. Williams, On the Action of Bile in Promoting the Absorption of Fats; those of Dr. H. P. Bowditch, On the Force of Ciliary Motion, and on The Effect of the Respiratory Movements on the Pulmonary Circulation; and that of Mr. C. S. Minot, On Growth as a Function of Cells. Dr. T. M. Rotch has an article of practical value on Absence of Resonance in the Fifth Right Intercostal Space Diagnostic of Pericardial Effusion.

Key to Ghostism: Science and Art Unlock its Mysteries. By Rev. Thomas Mitchell. New York: S. R. Wells & Co. 1880.

The author of this work has accumulated a considerable amount of information in regard to the history of spiritualism and the scientific aspects of its phenomena. He endeavors to explain all these phenomena by certain natural forces, and includes among them a kind of pyæmic force. The motive is good, but Mr. Mitchell's scientific training is evidently not profound, and we very much doubt the value of the theories of psychic or "mental electric force" which he substitutes for ghosts in table-movings, levitation, etc. It must always be shown, first, that spiritual phenomena, so called, cannot be explained by jug-

glery, illusions of the senses, trance or unconscious muscular movements. Only when these have proved inadequate can new forces be brought in.

A System of Medicine. Edited by J. Russell Reynolds, M.D., F.R.S., with numerous additions and illustrations by Henry Hartshorne, A.M., M.D. In three volumes. Philadelphia: Henry C. Lea. 1879.

The English edition of Reynolds' System of Medicine is published in five volumes. Its bulk and cost have placed it beyond the reach of most American practitioners. In the present edition the American publishers have reduced the number of volumes to three. By printing it in smaller type and by leaving out some elaborate tables they have been able to present the work in a cheap and accessible form. The American editor has made a number of additions which are in the form partly of separate articles and partly of notes, the latter being mostly therapeutical, and tending to show some of the current methods of treatment among American physicians.

The plan of the English editor has been to assign the different subjects to prominent specialists, and he has secured as his contributors such men as Wm. Aitken, Anstie, Bastian, Bristowe, Chambers, Fox, Gairdner, Garrod, Gull, Hutchinson, Jackson, Ringer, Roberts, Maudsley, and others, about fifty of the leading English practitioners in all. Such a list of names insures the value and success of the work.

The method of treating the various subjects does not differ from that usually followed in medical cyclopædias. The thoroughness with which this plan is carried out, however, differs considerably with different authors. As a whole, it will be found that there is a less systematical treatment of the subjects than is to be found in Ziemssen's Cyclopædia.

Neither bibliography, history, nor physiological pathology are dealt with so exhaustively, as a rule. This may be intentional, however, for the system has not the bulk nor hardly the pretensions of the complete cyclopædia. The authors are, on the other hand, men who have had a wider experience and greater reputation than have most of those who wrote for Ziemssen. The volumes have also somewhat more of a solid and practical character. There are no new and radical views advocated, but the aim in general is to show the methods of practice and the pathological views at present held by the majority of English practitioners. Taken with the additions of Dr. Hartshorn, then, the reader will get a very good idea of the state of medicine as it now is among the English-speaking part of our profession.

It is, of course, impossible to give any adequate idea here of the special merits of the work. A reference, however, to what is said upon several of the more prominent, and still unsettled, therapeutical and pathological questions, may be of some interest.

As regards diphtheria, Dr. William Squire holds the usual view that it is an acute, specific, general disease, epidemic and contagious, and attended with a rapid exudation of fibrin, or non-organizable lymph. He does not identify it with croup, nor does he deem it worth while to discuss the question of bacteria. His treatment is to give five or ten grains of the perchloride of iron every three or four hours, and to use local applications of nitrate of silver or some substitute. In scarlet fever, Dr. S. J. Gee, besides the usual expectant methods, recommends strongly cold affusions in malignant cases.

The treatment for whooping-cough strongly recommended by Dr. Edward Smith is to keep the child slightly under the influence of morphine for three or four days.

A very exhaustive discussion of pyæmia is given by Dr. Bristowe. As regards its pathology he states his belief that, owing to some form of unhealthy process supervening in the region of primary disease, unhealthy pus or its elements (either serous or corpuscular), finds its way into the circulating fluid and poisons it, that this poison partly shows itself in producing in the blood a tendency to coagulate in the smaller vessels, partly shows itself by inducing more subtle but even more serious effects upon the system at large. Although some of the local effects may be due to embolism caused by travelling pus-corpuscles, thrombosis alone is the more general explanation of that obstruction of the minute vessels which leads to the secondary deposits. Dr. Bristowe believes puerperal fever to be in many cases a genuine pyæmia.

Dr. A. B. Garrod reviews the numerous theories in regard to gout, and plants himself solidly, so to speak, upon the urate of soda. This he asserts to be present always both in chronic and acute gout. Its presence in the tissues least supplied with blood causes a deposit there, which sets up the gouty inflammation.

The articles upon diseases of the nervous system are very practical and useful. They do not embrace elaborate physiological or psychological discussions. Dr. Hartshorn has added articles upon hystero-epilepsy and athetosis; he also adds a brief notice of metallotherapy. It is to be regretted that the subject of neurasthenia was not taken up by him also.

It is curious to read the pathological views of Dr. J. H. Bennett on the subject of tubercle. This he asserts, with an unwavering faith, to be due to the coagulation of molecular blastema that exudes from the blood-vessels, the blood having first got into a low state favorable to such a process. Dr. Bennett has never been able to see any such adenoid structure as is commonly ascribed to tubercles. The so-called cheesy pneumonia, he tells us, is the result of a tubercular exudation, and the solid masses of yellowish tissue which are found in phthisical lungs are all due to tubercular exudation and degeneration. But Dr. Bennett's pathological peculiarities, though they may appear absurd, are at least harmless: for no man has done more to improve the treatment of phthisis, and his remarks upon this point in the present volume are of the very best.

One does not find very much that is new in the treatment of pneumonia as discussed by Dr. Wilson Fox. He recommends bleeding at first in certain sthenic cases, and he urges the value of alcohol almost always. There is not much danger from over-stimulation, and if any error be made, it is better on that side.

The longest articles on diseases of the heart are by Dr. Sibson. His contributions are discouragingly bulky, although some of the tables are cut out by the American editor. A perusal of his work, however, will discover the mass of facts, and a conscientious and philosophical treatment of them which led Dr. Reynolds to insert the whole without abridgment.

Space forbids us extending this notice farther. We can only add that the typographical appearance of the volumes, although far inferior to the English edition, is very good. The paper is cheap, but the printing is well done, and the illustrations might be worse.

PROCEEDINGS OF THE NEW HAMPSHIRE MEDICAL SOCIETY at its Eighty-ninth Annual Session, held at Concord, June, 1879.

THE New Hampshire Medical Society is one of the oldest of the State societies, and the present report shows it to be a well-organized and energetic association.

A considerable part of the time of its meeting was occupied in discussing practical questions connected with the profession. Resolutions were passed protesting against the contract system of caring for the sick poor, a system that still exists in some counties. Resolutions were also passed urging the importance of giving to the pauper insane in poor-houses the same benefits of care and treatment extended to others of that unfortunate class. The Society endorsed the Code of Ethics adopted by the American Medical Association. The address of the President, Dr. Alonzo F. Carr, is a brief and practical one. Other addresses were given by Dr. George B. Twitchell, on Medical Ethics; by Dr. Chas. C. Odlin on The Country Doctor; and by Dr. D. S. Adams, on Differential Diagnosis of Mammary Tumors. The latter shows much care and study, and contains a valuable comparative table of symptoms. A Report on Surgery, by Dr. J. H. Wheeler, shows some of the things which New Hampshire surgeons have accomplished in the past twenty-five years. A timely paper upon the evils of the present system of Medical Testimony, by Dr. L. G. Hill, and papers upon Gynecology, with a history of Dover Physicians, and of an Epidemic of Diphtheria in Groveton, complete the volume. The typographical appearance of the Transactions is unusually good.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, March 24, 1880.

DR. PEABODY, VICE-PRESIDENT, IN THE CHAIR.

DR. LEE presented two specimens on behalf of candidates for admission to the Society.

EMBOLISM OF AORTA IN THE HORSE.

DR. LIAUTARD exhibited two specimens of embolism of the aorta in horses, which were interesting not only in connection with the extent and duration of the disease, but with the absence of symptoms until within a few weeks of death.

The first specimen was removed from a bay horse, aged seven years, which became lame forward, several months since, and, after being treated for awhile, was sent to the country. Returning in apparently perfect health, he was put to work. With the exception of a slight œdema of the sheath (prepuce), there was nothing abnormal in his condition, and he did as well as usual for fourteen days. At the end of that time he became stiff in his posterior extremities, and gave evidence of great suffering. In the evening of that day the animal was comfortable in his stall, and to all appearances in good condition. The following day the left hind leg became enormously swollen, the horse became bathed in perspiration, suffered great pain, and was seized with diarrhœa.

The next morning the leg was again of its natural size, all pains had subsided, and the animal was able to lie down or get up with difficulty. In the evening, however, about three quarts of blood were passed per rectum. Mr. Lockhart, who was attending the case, called Dr. Robertson in consultation, but no positive diagnosis was made. The opinion was expressed, however, that there were some lesions of the intestinal blood-vessels.

For a week afterward the horse remained in the same condition as last described, and toward the last he was unable to rise in his stall without assistance. At the end of that time he was transferred to the American Veterinary College for a diagnosis and subsequent post-mortem examination. An opinion was then expressed that there was an embolism of the posterior aorta or some of its branches, but no opportunity was afforded for verifying it, as the animal died before a thorough examination could be made.

At the autopsy, an aneurism of the greater mesenteric was found, of the size of an apple and entirely filled with an organized clot. The latter extended backward into the posterior aorta, obliterating its trunk, and also that of the left circumflex, iliac, external and internal iliac arteries of both sides, producing obliteration in all. On the left side the plug could be traced downward as far as the termination of the tibial arteries. The left obturator and left ileo-femoral arteries were likewise obliterated. The right external iliac was empty, but its coats were diseased. The embolism of the aorta in the situation of the circumflex iliac was evidently an old affair, as it presented a tough and bleached appearance. Extending from this, the clot was of softer and of a reddish color.

The second specimen was removed from a horse which, while being driven, became suddenly lame. This condition disappeared and returned, according as the animal was allowed to rest or was put to work. At the end of three weeks Dr. Robertson saw the case, and expressed the opinion that there existed some lesions of the arterial trunks of the right hind limb. At his suggestion, the animal was brought to the American Veterinary College. On the arrival of the patient, his skin was found to be covered with a profuse perspiration, and he was evidently suffering great pain. He walked with the greatest difficulty, and, when standing, his right hind leg would be forcibly flexed and abducted. This leg was much cooler than the one on the opposite side. After being placed in a stall, the animal seemed to be free from pain.

On rectal examination, Dr. Liautard discovered that there were no pulsations in the right internal iliac artery, and but feeble pulsations in the right external iliac artery.

A diagnosis of embolism was made accordingly. It was advised that the animal be destroyed, but the owner objected, and the treatment was transferred to a veterinary surgeon, who treated the patient for so-called "cold in the loins." After a few days the horse was returned to its owner as convalescent, but, being trotted for exercise, became again suddenly very sick, and expired in a few hours in great agony.

On post-mortem examination, the abdominal aorta was found free as far down as the origin of the internal iliac, where a clot had formed extending into the latter vessel, and also to a certain extent into the external iliac, completely obliterating the posterior tibial. Some parts of the clot seemed to have been of old formation. The arteries of the left side were also diseased, but not to the same extent.

CASE OF CONGENITAL DEFORMITY WITH FŒTAL AMPUTATION (?)—ARREST OF DEVELOPMENT, AND ADVENTITIOUS BANDS, CONSTRICTIONS, ETC.

DR. GIBNEY presented a living specimen, the case

of a child, aged three weeks, brought to the Out-door Department of the Hospital for the Ruptured and Crippled, March 22, 1880, for congenital equino-varus of left foot.

There was found, on examination, the following points of interest about the *right hand*: A slight constriction around the middle of the first phalanx of the thumb; a similar constriction, though much more marked, around the same phalanx of the forefinger—as if a thread had been bound tightly about it having a bulbous end; the last phalanx of the middle finger seemed to be about one-half normal length, while the nail is small and rudimentary; the third finger seemed to have no second phalanx, and was altogether one-fourth of an inch shorter than the little finger, and it is doubtful whether there is any motion at all at the phalangeal joint; the little finger was devoid of a nail, and round and bulbous at the end.

The left hand is normal, with the exception of a depression of the nail on the third finger. At the junction of the middle and lower thirds of the right leg is a deep groove, posteriorly about one-quarter of an inch deep, half encircling the limb, while anteriorly there are two grooves on a lower plane, yet not so deep, and extending about half-way round the limb.

The *right* foot presents the stumps of a great toe and second toe, both of which appear to have been amputated (?) in utero, through the first phalanx. The stumps left are irregular. The foot is otherwise normal.

The *left* foot is the seat of talipes equino-varus of a mild type. The varus can be easily overcome with a little force. The great toe is shorter than it should be, the arrest of growth being in the last phalanx, and there is no nail. Between this toe and the third toe is stretched a narrow band of integument, looking like cicatricial tissue, and said band is about the size of an ordinary pin, united to the skin over dorsum of the first phalanges by a broad base, and binding down the second toe, though not adherent thereto.

The fourth toe presents a deep annular depression similar to those already described on the fingers. This one, however, is deeper than any yet mentioned, and extends down to the periosteum, although the skin is not anywhere broken. The third toe has no nail, but a small depression, like an old punctured wound, instead; while the fourth toe has a rudimentary nail and a shallow constriction about its base.

A careful examination fails to detect any other deformity in other parts of the body. The child is the youngest of nine, no other one of which is in any way deformed. A cousin of the mother had double congenital talipes equino-varus. The mother experienced nothing unusual during her last pregnancy, and had a natural labor of only four hours' duration. Was attended by a midwife, whom the mother heard exclaim, "There are strings rolled about the child!" Nothing further can be learned about the case.

Dr. Lee remarked that the generally accepted theory concerning amputations in utero was ingenious, but thus far there had been no record of a case in which the severed extremity had been found. Its amputated portion was said to have been absorbed, but it was a significant fact that there should not be an exception to the rule. He believed, with many other observers, that the so-called amputations were the results of simple arrests of development.

Dr. Weeth asked if any experiments had been made with a view of testing the absorbent properties of the amniotic fluid.

Dr. Peaslee answered that the amniotic fluid was of such a negative character, and was so free from any remarkable absorbent properties, that it was used for preserving microscopical specimens.

APOPLEXY—LACERATION OF THE PONS AND HEMORRHAGE IN FOURTH VENTRICLE, WITH COMA, CONTRACTED PUPILS, TONIC SPASM, AND DYSPNŒA.

Dr. Peaslee presented the brain removed from the body of a gentleman, aged seventy-six years, who was suddenly attacked with the symptoms of apoplexy and died in the course of twelve hours afterward. The patient had been in his usual health until a few days before his death, when he complained of vague pains in his head, principally in the occipital region. At the time of his attack he was seized with a sharp, pricking pain in the forehead, immediately after which he became unconscious. This latter condition quickly deepened into coma, and death ensued in the course of twelve hours. The urine was found to contain a trace of albumen; the lower extremities were slightly œdematous. At the autopsy there was found a small amount of blood extravasated beneath the tissues of the pia mater, principally about the base of the brain and in the neighborhood of the pons. The fourth ventricle was entirely filled by a large recent clot, which had completely disintegrated the entire floor of said ventricle, and had converted the pons into a mass of detritus and clotted blood. The arteries at the base of the brain were atheromatous. The kidneys were small and atrophied. The epithelium in places was very granular, and the convoluted tubes contained an immense number of hyaline casts.

In conclusion, Dr. Peaslee remarked that the interest in the lesion of the brain was centred in the occurrence, during the coma, of contracted pupils, rigidity of the muscles of the extremity, and difficult respiration. The latter symptoms were not unfrequently noticed in connection with the lesion in question.

SCLEROSIS OF BRAIN, WITH DILATATION OF VENTRICLES.

Dr. Noyes presented a brain removed from a man who, at the time of his death, was forty-three years of age. He first saw the patient in April, two years ago, when he complained of loss of sight. The lesion upon which the loss of sight depended was easily recognized, and consisted in atrophy of the optic nerve. In one eye the vision had deteriorated to $\frac{1}{20}$; in the other eye it was nearly normal, being $\frac{20}{20}$. Very few symptoms of other lesions could be found. There were some little tardiness in passing water, very vague symptoms of numbness about the lower extremities, occasional vomiting and giddiness, and a disposition to sleepiness. So marked was this latter symptom that he would often drop into slumber while at places of amusement, and would be awakened with a great deal of difficulty. The patient admitted that within the few previous months his memory had failed, and that a certain tendency to stuttering, which had occasionally appeared in early life, had become marked and troublesome.

He was put upon the treatment of phosphorus and strychnine, but without marked benefit.

By the following September there had been a progressive loss of sight until the better eye was $\frac{1}{20}$. Aside from this, there was no other special symptom. In the following June, more than a year after Dr. Noyes saw him, he had an attack of partial uncon-

sciousness, in which he fell from his chair. In the following December he became totally blind, and he began to suffer from headache. It had been not only difficult for him to walk on account of blindness, but there was a peculiar unsteadiness in his gait. About this time his mental faculties became greatly impaired. A month afterward he took to his bed, had several convulsive attacks, suffered great depression of spirits, and on several occasions contemplated suicide. At the close of his life the symptoms which appeared were none of them of a strictly paralytic character, although there was less disposition to use the left arm and leg than the right. During the last month of his life the patient suffered from slight tremors of the right half of the body, and principally of the upper extremity of that side. Toward the last there was difficult swallowing and difficult respiration, but death ensued without special paralyses.

During the whole time that the patient was under observation his general symptoms were few, the ophthalmoscope showing progressive atrophy of the optic nerves. (Dr. Noyes exhibited charts showing the limitations in the fields of vision as the case progressed.)

Dr. Janeway saw the case during the progress of the symptoms, and was unable to make a positive diagnosis.

At the autopsy there was considerable turgescence of the dura mater and of the vessels upon the surface of the brain. The brain itself was unusually firm, and all its tissues were notable for their extreme pallor and firmness. The optic nerves were reduced in size and of a gray color. The ventricles of the brain were extremely dilated. After the most careful examination no other diseased conditions were found, and there only remained the theory that the enormous distention of the ventricles was in consequence of a hardening and shrinking of the whole bulk of the brain together. The effusion was ex vacuo in consequence of generalized sclerosis and atrophy.

Dr. Noyes presented a second specimen consisting of glioma of retina.

CASE OF DOUBLE GLIOMA RETINÆ—DEATH—AUTOPSY.

Dr. H. D. Noyes presented specimens of the above which were removed from a child, with the following history: At the age of six months the parents noticed a yellowish-white reflex from the pupil of the left eye. This attracted little attention until five months later, when the child was brought to the infirmary, where I saw it in November, 1878. The diagnosis of glioma of the retina was made; both eyes being affected. The left eye presented the most marked appearance of the disease, in which the growth was yellow and vascular, extending forward as far as the crystalline lens. Enucleation of the left eye was advised, but, not meeting the approval of the parents, it was indefinitely postponed.

During the summer of 1879 the child was taken to Germany, and while there Dr. Förster, of Breslau, was consulted. He confirmed the diagnosis, and advised and performed enucleation of the left eye in August. I next saw the child at the infirmary on January 5, 1880, and found the left orbit filled with the secondary growth, which was first observed by the parents two weeks previously. The intraocular growth in the right eye had increased in size, and could be seen with the naked eye encroaching upon the iris and anterior chamber. The child was etherized, and the left orbit thoroughly emptied of its whole contents. The tumor occupying the orbit was about the size of a small egg. A good recovery was made in about six weeks. This was followed by relief for three weeks, when the growth reappeared in the orbit, and was accompanied with severe pain in the temporal and frontal regions, and frequent vomiting. These symptoms pointed to cerebral implications, and operative procedures were deemed inexpedient. The pain was relieved with opium, and the nutrition sustained by proper nourishment. Death occurred March 18, 1880.

The autopsy was performed about twelve hours after death. The calvarium was removed and the brain exposed. Numerous adhesions were found between the dura and pia, chiefly in the region of the longitudinal sinus, on either side of the median line, and extending from the crista galli back to the tentorium. The brain substance was exceedingly soft, and was removed with difficulty. The optic nerves were divided near the commissure, and the brain placed in Müller's fluid for hardening purposes. The roof of each orbit was removed. The right eye was removed, and upon incising it the whole interior of the globe was found to be occupied by the intraocular tumor, which encroached upon the tissue of the iris and extended back into the optic nerve, enlarging it for about a quarter of an inch.

The left orbit was occupied by a tumor adherent to the floor of the orbit, projecting anteriorly, so as to cause considerable bulging of the eyelids, and extending back toward the brain, having caused absorption of the orbital plate of the greater wing of the sphenoid bone, leaving only the thickened dura mater between the tumor and the brain.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, March 22, 1880.

Dr. A. E. M. Purdy, President, in the Chair.

The Society was called to order at 8 P.M.

DUTY ON DRUGS.

The Comitia Minora reported upon the resolution introduced by Dr. Porter at the last stated meeting relative to additional tariff or duty upon any drugs or other substances used for medicinal purposes, etc., to the effect that it involved questions too important to be hastily considered, and under the assurance that Congress at its present session would not take further action upon the subject, recommended that the matter be postponed. Carried.

DELEGATES TO THE PHARMACOPŒIAL CONVENTION.

The recommendation of the Comitia Minora that delegates be appointed to represent the Society in the convention for the session of the U. S. Pharmacopœia to be held in May, 1880, was adopted.

RESIGNATION OF A MEMBER.

The Comitia Minora recommended that the resignation of Dr. Frank D. Beane be accepted, and that he be requested to return to the Society his certificate of membership. Adopted.

THE SEQUELÆ OF ACUTE DISEASES AND THEIR TREATMENT.

Dr. A. D. Rockwell read a paper on the above, in which he considered the sequelæ of several acute diseases, such as diphtheria, cerebro-spinal meningitis, and typho-malarial fever. He thought the profession at large had an inadequate idea with refer-

cure to the vast benefit accruing from the proper use of electricity in these cases. Dr. Rockwell then referred to twenty-four cases of diphtheritic paralysis seen during the last ten years, which, with only two exceptions, yielded promptly to the use of electricity — so promptly that there was no doubt as to the efficacy of the remedy. In the two cases which were not successful, the patients discontinued treatment almost as soon as it was begun. Of the twenty-two remaining cases many were of great severity, and only a few of them had been treated electrically, and, as a rule, with little regularity or intelligence. The history of one of the most interesting and instructive cases was given. A physician was attacked by diphtheria, and three weeks after the disappearance of the membrane from the throat he began to suffer from paralysis of the pharyngeal and laryngeal muscles, with absolute loss of sensation to the victim. In consequence, swallowing was exceedingly difficult, and regurgitation through the nares while drinking was unavoidable. The voice was weak and comatose. From the tenth day of the acute attack cardiac difficulty was indicated by a very feeble, slow, soft pulse, averaging 60 per minute. On one occasion, immediately after exertion, the pulse arose to 160 and as suddenly fell to 32, and resulted in what was regarded as an attack of angina pectoris that lasted for nearly three hours. The pulse remained at 32 for over an hour, when it gradually increased in frequency until it reached 58, where it remained. Four weeks after the disappearance of the patches painful fatigue was experienced in reading, and was relieved by a plus 38 spherical glass. At the same time the fingers became anæsthetic, with tingling and inability to handle small objects. The arms and legs were subsequently affected in the same manner. There was a marked tendency to constipation; numbness and hyperæsthesia of the external organs of generation. These symptoms persisted, without abatement, for three months, and were invariably increased by the slightest exercise. General faradization failed to give more than an agreeable sense of rest, and at the end of two or three weeks, the apparatus was transferred to the patient's house, so as to avoid the exercise incident to riding several miles in order to reach Dr Rockwell's office. The improvement after the change was at once marked, and all the apparent sequelæ, except that perhaps referable to the heart, had entirely disappeared at the end of the sixteenth week. Slight cardiac feebleness remained for about fifteen months. The train of symptoms which had followed

CEREBRO-SPINAL MENINGITIS,

and had been amenable to treatment, were those illustrated by a typical case. Mrs. A——, æt. 42, was attacked by the disease on the 20th of May, 1872. Her case was exceptional in its duration and severity, and she was confined to her bed for six months. Two years and a half after the subsidence of the more acute symptoms she came under Dr. Rockwell's observation, who found that she had submitted to apparently wise and judicious treatment until all the ordinary forms seemed to be exhausted, but without improvement. She was able to be about her house and to go out occasionally, but she suffered incessantly from some pain, beginning in the eyes, most pronounced over the back of the head and neck, and extending to the lower cervical vertebræ. The muscular stiffness present in the acute stage had never left her and gave her great distress. There was a chronic irritation of the intestinal tract from the mouth to the anus. For the symptoms more directly due to the meningitis, she was submitted to central galvanization as a general tonic, and for the relief of the digestive difficulties due to intestinal irritation, Dr Rockwell employed general faradization. Fifty applications were made in ten weeks. Under that plan of treatment alone the patient steadily improved, and made a satisfactory recovery.

In that connection attention was directed to the fact that sudden blows or shocks might in certain cases, result in obstinate circulatory derangement of the cerebro-spinal tract, associated with symptoms analogous to those following cerebro-spinal meningitis. The statement was illustrated by a case in which the patient had fallen and struck upon her sacrum, the immediate effects of the injury being severe pain, nausea, and slight motor paralysis of the extremities. At the end of three weeks recovery seemed complete. On taking cold, symptoms returned, but gradually disappeared. Subsequently she fell, striking on the hip. The injury aggravated all the former symptoms, and caused a perversion of vision, consisting in all dark objects appearing red. Some time elapsed before vision became natural in that respect. Central galvanization relieved the patient.

The paper concluded with the recital of the history of peculiar sequelæ following an attack of

TYPHO-MALARIAL FEVER.

The patient was a man æt. 24, who was taken sick in June, 1879, with acute dysentery, which was followed by typho-malarial fever. At the end of six weeks the fever had subsided, but the patient was quite helpless. In the following September, Dr. Rockwell saw him with his attending physician, Dr. J. O. Farrington, when he found the patient had general stiffness of all the muscles. Voluntary or passive movements were very limited. Deglutition was so difficult that solid food could not be taken with either safety or comfort. The muscles were wasted generally, and markedly in places, most apparent on the right thigh. Farado-muscular contractility of all the superficial muscles except the abdominal was greatly impaired. There were no symptoms suggestive of serious cerebral disease, but a strength of current ordinarily unendurable could be applied to the back of the neck without producing any sensation whatever. Under the use of general faradization, the affected muscles developed with astonishing rapidity; deglutition soon became natural, and complete recovery followed.

The differential indications for the use of the two currents were given as follows: First. "For the relief of the various paralytic symptoms that followed diphtheria, whether cardiac or of the voluntary muscles, the faradic current is almost always, if not invariably, indicated."

Second. "The galvanic current here is not only less effective than the faradic, but is not infrequently useless and occasionally harmful."

Third. "While localized faradization may prove sufficient in cases where the symptoms are mild and restricted in extent, general faradization should be used where the paralysis is more general and constitutional symptoms are manifest."

Fourth. "For these and analogous symptoms relating to the cerebral nervous system, the *true* constant current, or in other words, of so-called low tension and increased quantity, is preferable to the ordinary continuous current of higher tension.

The paper was accepted by the Society and being open for discussion.

Dr. Geo. M. Beard remarked that Dr. Rockwell's communication brought to mind one important general suggestion relative to the sequelæ of the diseases mentioned and that they are functional in character. It was true not only of diphtheria but also of cerebro-spinal meningitis, thermic fever (sunstroke), etc. These paralyses, whether local or general, whether of motion or sensation, were frequently functional in character and could all be treated in about the same manner. A general tonic plan of treatment would cure them. In some cases treatment was not essential to recovery; in others it would be required.

Another point worthy of notice was the difficulty in making a differential diagnosis of the sequelæ; that is, there were sequelæ of cerebro-spinal meningitis, sequelæ of thermic fever, cases of nervous syphilis, ordinary hysteria, some forms of anæmia with neurasthenia, and he saw no way of making a differential diagnosis of these conditions by the symptoms alone. The history was the only avenue through which correct knowledge of the case could be reached.

A person in absolute health, might, while walking in the street, become prostrated by heat, and for months or years present the symptoms of a hysterical girl. The same thing might occur as the result of cerebro-spinal meningitis and other affections.

With reference to treatment he had found that they were liable to relapses. The symptoms would yield to treatment up to a certain point, and then the patient would go back again. That was especially true of the sequelæ of cerebro-spinal meningitis and thermic fever.

Perhaps a patient who had suffered from thermic fever would be quite well during the winter, but always feel badly on a hot day in the summer, even when not exposed to the rays of the sun. Perhaps several years might be required to get rid of such sensations, and in some cases the impression produced by sunstroke was carried during life.

Another interesting feature in these cases was the susceptibility to stimulants and narcotics of all kinds. The person may have been accustomed to the use of tea, coffee, tobacco, etc., but, after being prostrated in this manner, cannot take even a teaspoonful without feeling the worse for so doing, or even smoke a mild cigar. It was also interesting to note that after recovery they get up to a plane when they can again use stimulants and narcotics.

There was another peculiarity in the sequelæ of those diseases, and that was the suddenness with which the symptoms might return. A physician under his care, wishing to get a medical journal, went a few blocks from his office, and while on his way back, without exposure to the rays of the sun, and on a day on which the temperature was only moderately high, suddenly became prostrated, and was obliged to stop in a drug-store and remain for some time before he could go further. He was not again suffering from sunstroke, but the heat suddenly brought him back to a lower plane, and special treatment was again required to get him up to the identical spot from which he originally fell.

Another fact concerning treatment of all these sequelæ was that it must be general as well as local. If a person came with local paralysis alone, and appeared to be pretty well otherwise, the natural tendency was to confine the treatment to the part affected, be it arm or leg. Physicians had done so, and probably would continue to do so, and yet oftentimes it was not the best treatment, whether electrical or otherwise. It was better to have general treatment regularly carried out, for another part of the body might, perhaps, be treated, and as good results obtained as if local treatment to the part in which the more prominent symptoms were manifested was the only form employed. The explanation was that the effects produced by the disease were more reflex than local. For example, application of electricity to the right foot might relieve paralysis of the left arm as well as if applied to the affected limb only. Probably, in ninety per cent. of the cases, the symptoms were reflex, and not more than ten per cent. were direct or purely local paralysis. If a clear idea was had in mind relative to reflex effects, better results would be obtained than where simply local treatment was employed.

PUBLICATION OF THE NAMES OF THE MEMBERS.

Under the head of miscellaneous business, a resolution was introduced with reference to the publication, semi-monthly, in two daily newspapers, of the names of all the members of the Medical Society of the County in good standing. On motion, it was referred to the Comitia Minora.

The Society then adjourned.

NEW YORK ACADEMY OF MEDICINE.

OBSTETRIC SECTION.

Stated Meeting, March 25, 1880.

Dr. Salvatore Cabo, Chairman; Dr. Henry E. Crampton, Secretary.

PELVIC CELLULITIS AND ABSCESS.

At a stated meeting held February 25, 1880, Dr. J. H. Merrill read a paper on pelvic cellulitis and abscess, in which he presented a resumé of the views entertained regarding the etiology, pathology, and diagnosis of the affection, and on motion the consideration of the subject was continued, and Dr. A. C. Post was invited to open the discussion on the treatment at the next stated meeting of the Section. The affection, Dr. Post said, had been fully recognized only by physicians of comparatively modern times. It might be circumscribed and occupy only a small portion of the pelvic cavity, or it might be more diffuse and occupy a very large share of the cavity of the pelvis. The cellular tissue around one organ only might be involved, or, more rarely, that around every organ in the pelvis might become implicated. The prognosis was usually favorable, so far as immediate danger to life was concerned, but in large pelvic abscesses in which suppuration was extensive, the consequences were apt to be very serious.

Treatment.—In the puerperal state, if the patient had previously been in good health, he believed that general blood-letting was beneficial. Leeching, followed by fomentations or poultices with absolute rest in the recumbent posture, was of essential service. A pillow placed under the pelvis to prevent gravitation of blood to the parts, was recommended. The bowels should be kept open with enemata. He emphasized the necessity of securing thorough evacuation of the bowels on the second or third day after confinement as a prophylactic. Diaphoretics and anodynes might be required. A nourishing diet, easily digestible, was essential. Blisters over the hypogastric region, and in certain cases an issue made with the actual cautery, might do good. In

more benign cases, when relapse had occurred, a mild mercurial course and vaginal douches of warm water had been beneficial. When suppuration occurred it was desirable to make an incision early. Examination by combined manipulation usually revealed in finding the abscess pointing above Poupart's ligament. In certain cases a considerable amount of swelling was found in the region of the fascia lata and the thigh was well flexed. In these cases an early incision was desirable and the point of election for the opening was near the anterior superior epinous process of the ilium. When spontaneous opening of the abscess occurred, the most favorable direction was through the abdominal wall or into the vagina, the next into the rectum. The unfavorable points for spontaneous opening were upon the thigh into the bladder the urethra, or the uterus. The most dangerous was the peritoneal cavity. Where no artificial opening was made, it was especially necessary to make free incisions. After suppuration was established a tonic plan of treatment was indicated. It was often necessary to inject the cavity of the abscess with carbolized water 1 to 10, but hyperdistention should be avoided.

Dr. Garretson recommended, in way of treatment, rest, ice-bladder in cases in which peritonitis was present, poultices, warm vaginal and rectal injections, and sitz baths, if the patient was able to take them. Tr. iodine, every third day, painted on the roof of the vagina, massage, opium, quinine, and opening the abscess as soon as matter could be detected. He used Bacqueliu's cautery in opening the abscess, thereby avoiding danger from hemorrhage. He did not use blisters, and regarded the prognosis in pelvic abscess as bad. In many cases it was difficult to distinguish between pelvic cellulitis and pelvic peritonitis, even at autopsy.

Dr. Gunsolus had used chlorine water instead of carbolized water, and with marked benefit.

Dr. Hunter recommended vaginal injections of hot water—hotter than the hand could bear—every two hours during the first twenty-four of the disease, and afterward at longer intervals. He also advised large doses of quinine from the beginning.

Dr. Champion suggested a rubber syringe with tubing made without metal, so as to avoid burning the patient when hot water injections were given.

Dr. Hanks mentioned aromatic spirits of ammonia—half a teaspoonful in a wineglassful of water every two hours—until the flow returned in cases of suppression of the lochial discharge with fever and pain, and other symptoms of pelvic inflammation. It was especially indicated when either a septic or malarial element was present.

The Chairman referred to a case as follows: An Italian woman, æt. 28, was delivered by a midwife of her third child on Nov. 3. She sat up the third day. She had a pain in the right side of her abdomen, with fever and chill, and was supposed to have taken cold. Three physicians treated the case as one of tympanitis and intermittent fever. Three months after her confinement she came under Dr. Caro's care, when there was constant vomiting, with diarrhœa, and the patient was greatly emaciated. There was great tenderness on pressure in the right side of the abdomen, with evidence of abscess. An exploratory incision was made, and then the tumor was freely opened and about four quarts of pus evacuated. The cavity was injected with carbolized water, one to forty, and quinine was given in doses of five grains every four hours. The patient recovered.

The Section then adjourned.

Correspondence.

ABUSES OF MEDICAL CHARITIES.

To the Editor of The Medical Record.

Dear Sir:—I trust I may be allowed to trespass upon your columns on this matter of abuses of medical charities, to answer the letter of Dr. A. L. Carroll.

First as regards the question of withholding names and places of those who perform a therapeutic discovery or act. I believe it to be a very great mistake. In my former letter I did not have Dr. Carroll in mind any more than the other gentleman who seemed to have been more directly stirred against. I think Dr. Carroll is quite right in declining to assume the championship of other people's quarrels, but this principle should not be extended to the publication of other people's ingenious, particularly when it relates to question the moral nature of some clinical teacher has under the imputation of doing a very reprehensible act. It is this lack of responsibility that I protest against, and where a man who has been injured declines to bring the wrong-doer to justice, I claim he has no right to grumble about the treatment nor to expect any sympathy.

The second part was about the duty of the surgeon to decline to treat patients because they were under the care of some other surgeon or physician. I have already said that he should refuse certain treatment, and upon that point Dr. Carroll and I are in accord. But I go a step beyond this, and maintain that the surgeon either in public or private practice is not bound to make any inquiry as to previous physicians. It may sometimes be wise to do so, but it is not a duty, nor is it imposed by any code of ethics I know of, nor, do I believe, is it generally done. I beg to call attention to the difference between enticing a patient away from another physician, and advising the patient if he or she has voluntarily sought the physician, attracted by his own personal reputation or that of the institution he serves. The question of the relation of physicians to each other needs revising and being better understood, and I trust the day is not far distant when we can dispense with a foolish code of ethics, which at the best is a stumbling-block to the profession, and to the laity foolishness.

I am, dear sir, very truly yours,

F. R. Sturgis.

16 West Thirty-second St., April 13, 1880.

POSTURE IN THE TREATMENT OF INTESTINAL COLIC.

To the Editor of The Medical Record.

Sir:—While reading the article by Dr. Burrall on "Posture in the Treatment of Intestinal Colic and Ileus," in the Record of March 27th, I was reminded of the first case of strangulated inguinal hernia which came under my notice, and which was about two months after my graduation. It was in 1844, and while a partner of my father.

I had been some hours with the patient, making taxis, giving enemas of tobacco, etc., all which had

but recently been made imperative in the lectures of Prof. F. H. Hamilton, at that time connected with Geneva Medical College, and not making progress toward the reduction of the tumor, I concluded that the wisest thing I could do would be to rid myself of the responsibility by sending for my father, then an old practitioner of forty years' experience. I did so, and shall never forget the relief which his advent into that house afforded me. As he came in, and without particularly examining the protrusion, he said, "Why don't you stand him upon his head?" My reply was, "That is not considered good surgery." Said he, "I don't care what your opinion may be as to its being good surgery; the result will show." At that he ordered a large, stout man, who had come in to see the patient die, to flex his (the patient's) legs over each of his (the laborer's) shoulders, and thus suspend the patient.

I don't now remember how many minutes such suspension required to effect reduction—certainly not many. I only know that in a short time it was complete—a much shorter period than was required of me to outlive the neighborhood opinion that "the young doctor didn't know as much as the old one about putting back *a breach*."

During the five years succeeding the period above spoken of, I well remember three cases where such a course was pursued with success.

D. Colvin.

Clyde, N. Y., April 8, 1880.

BROMIDE OF ETHYL.

To the Editor of The Medical Record.

Sir:—In view of recent utterances recorded in your columns, observations made in a single case at my public clinic here may possibly have some value. On Thursday, April 1st, I performed two comparatively trivial operations on the person of H. E. B——, æt. 19, from Holland, Mich., who appeared to be in excellent health at the time. The operations were circumcision for phymosis, and excision of part of the scrotum for varicocele.

My colleague, Dr. Victor C. Vaughn, having had a specimen of bromide of ethyl sent him from a manufacturing house in Philadelphia, induced me to use it, in this instance, in place of chloroform, which, in my experience of more than twenty years, has never disappointed me in any way, although I have used it very freely in all sorts of cases, and in patients of all ages.

The new anæsthetic was administered by a careful and experienced assistant, but the patient did not pass under its influence very rapidly.

In a short time my attention was called to the unusual appearance of the patient. His head was drawn violently backward, and his whole muscular system jerked spasmodically. The breathing had become extremely rapid, and the pulse small. It appeared to the gentleman who was administering the anæsthetic and to myself, that the symptoms were, to say the least, unsatisfactory, and I directed chloroform to be substituted. I did so, however, with reluctance, and not without serious misgivings that I had acted with undue and unjust haste.

Under chloroform the operations were soon accomplished, and the patient returned to his bed, where he very soon became conscious, and at the same time complained of feeling desperately uncomfortable. Headache, vomiting, high fever (104), sleeplessness, constipation, tenderness over the whole abdominal surface, scanty urine, great thirst, and utter inability to eat, together with the unmistakable aroma of the ethyl on his breath, were the principal phenomena which his case presented.

He was comforted at first by the assurance that his distressing symptoms would abate in a short time, but this assurance was *not* realized. For four full days, viz., from Thursday to Monday, this patient suffered from headache, vomiting, and general discomfort, to a degree that I have never seen approached by any case in which anæsthetics had been used. On Monday the aroma of the ethyl disappeared from his breath, and with it all his distressing symptoms, and to-day, April 9th, he is quite well. His wounds, strange to say, healed most satisfactorily.

The only commentary I have to make on the case here noted is, that any lingering scruples as to my having been too hasty in reverting to my old and hitherto faithful ally (chloroform), vanished completely upon reading the valuable paper of Dr. Marion Sims, published in your issue of April 3d.

I am, etc.,

Donald Maclean.

Ann Arbor, April 8, 1880.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from April 11 *to April* 17, 1880.

Horton, S. M., Major and Surgeon. After complying with instructions from these Headquarters, of January 28, 1880, to proceed to Ft. Douglass, U. T., and report to the Comd'g Officer for duty as Post Surgeon. S. O. 30, Dept. of the Platte, April 6, 1880.

Medical Items and News.

Contagious Diseases — Weekly Statement. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending April 17, 1880.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.

The New Building for the Manhattan Eye and Ear Infirmary.—On the morning of April 19th, at 7.30 o'clock, ground was broken for the new building for the Manhattan Eye and Ear Hospital at the site on the corner of Forty-first Street and Park Avenue. The building is to be of pressed red brick and Potsdam sandstone, four stories high, and with a dark-blue slate roof. The style of architecture is that of the English domestic architecture of the thirteenth century, with special modifications to insure plenty of light and thorough ventilation. The entrance will be on Park Avenue. On the ground floor there will be three suites of rooms of three rooms each, for the Departments of Eye and Ear

Throat and Nervous Diseases respectively. The second story will be divided into small bed-chambers, theatre, dining room, and its others, an apartment for the resident surgeon, and an assembly hall for the patients, well lighted and with a large open fireplace. Almost every room in the hospital will have an open fire-place, with a chimney-flue big enough to carry off the smoke of coal or wood. The third and fourth floors will be divided into larger wards, and with ample provisions for isolation of communicable eye diseases. The kitchen will be on the fourth floor. There will be a steam elevator for the use of the patients and the servants. The laundry work will be done out of the hospital. In the basement there will be the system of baths, including the Turkish bath, and an ample apothecary shop. There will be a library and laboratory, and other provisions for courses of lectures. The cost of the building will be nearly one hundred thousand dollars.

Medical Night Service.—A bill for the creation of a medical night service in this city has been presented to the State Legislature, and is in charge of Senator Strahan. It is framed after the Paris plan of such service, and in accordance with the suggestions offered by Dr Nachtel at the recent meeting of the New York Academy of Medicine. It provides for the registration at the police precincts, and at such other convenient places as the captain of the precinct may elect, the list of physicians, duly authorized by the Health Board, who are willing to respond to a night-call for $3.00. The latter sum is to be paid by the patient, or by the Health Board, on presentation of a properly authenticated certificate of such attendance signed by the captain of the precinct. Consultations, when necessary, may be obtained at the rate of $6.00 each, payable under conditions similar to those of ordinary visits. Each patient is to have preference for any particular medical attendant on the list, but as a rule the one nearest shall be summoned. The physician, within twenty-four hours after his attendance, must fill out a blank containing his name and address, the age, sex, residence and disease of the patient, and forward the same to the Registrar of Vital Statistics. The service is intended only for such as have no regular medical attendant, who are strangers in the city, and who require the immediate attention of a physician or surgeon. The sum of three thousand dollars is asked as an appropriation for the effective working of the scheme. The bill has received the indorsement of many leading medical gentlemen in this city, and will doubtless be passed without opposition.

The Kentucky State Medical Society will meet in Lexington, Wednesday, May 19, at 3 P.M.

New York Neurological Society.—At a stated meeting held April 6, 1880, the following officers were elected for the ensuing year: President, Dr. Thomas A. McBride; First Vice-President, Dr. L. C. Gray; Second Vice-President, Dr. V. P. Gibney; Rec. Secretary, Dr. W. J. Morton; Cor. Secretary, Dr. Mary Putnam-Jacobi; Treasurer, Dr. E. C. Harwood; Council, Drs. J. C. Peters, J. C. Shaw, Geo. M. Beard, E. C. Seguin, and Wm. A. Hammond.

Dr. Wm. J. Morton, of this city, has been invited to deliver the course of lectures on Diseases of the Nervous System in the University of Vermont, Burlington, during the present term.

The New Jersey State Board of Health received authority from the legislature, at its last session to look after the contagious diseases of cattle, and take measures to prevent their spread. It began its work by sending out a circular to farmers and dealers in stock. In this circular a plain statement of what the Board can and will do in the matter of preventing contagious diseases is given. Co-operation is asked for, and a brief account of the symptoms and nature of pleuro-pneumonia and hog cholera is given.

Two New Clinical Laboratories have been recently established in Paris. One is for instruction in mental diseases, the other in diseases of children. Neither of these branches have been taught in Paris, clinically, before.

The Epidemic is prevailing very extensively in Brazil. In November a commission was appointed by the government to investigate the disease, and the work is now in progress.

A New Board of Health was organized in New Orleans on April 8th. Dr. Joseph Jones was elected President, and Dr S. S. Herrick, Secretary.

The Physicians of Savannah, together with the city government have made a protest against the Harris bill, giving additional power to the National Board of Health. Dr. L. A. Fulligant, in an open letter to the citizens of the South, indorses this action, and criticises rather sharply some of the work of the National Board of Health. This, he thinks, should be confined more closely to studying sanitary questions, leaving matters of quarantine to local authorities.

In the same issue of the Savannah *Morning News* is a letter from Dr. J. G. Thomas, in which he comes to the defence of the National Board, and shows the advantages that have already been secured by its operations.

Health of New Orleans.—There have been no cases of yellow fever in New Orleans during the present year.

Small-pox appeared in Chicago a short time ago and caused considerable alarm. There has been a general rush for vaccination.

Oleomargarine.—The State Assembly has passed a bill to purify that all oleomargarine which is sold shall be plainly marked as such.

Compulsory Examinations for Color-Blindness.—The Connecticut Legislature has passed a law compelling all its railroad companies to have their employees examined for color-blindness before October 1st.

Aborting Whitlow and Erysipelas.—Dr W. W. Dawson states that he has succeeded in aborting both these diseases by the use of the elastic bandage.

The Election of a Professor of Gynecology by a *concours* at the Chicago Medical College, has been the subject of comment in all the English journals. The comments have been favorable, though there is an evident undertone of wonder that so marked an evidence of progress should be found in America—and in Chicago. It seems that the professors in the English medical schools are by no means all that they should be.

American Medical Association.—The Thirty-first Annual Session will be held in the city of New York on Tuesday, Wednesday, Thursday, and Friday, June 1, 2, 3, and 4, 1880, commencing on Tuesday at 11 A.M.

"The delegates shall receive their appointment from permanently organized State Medical Societies, and such County and District Medical Societies as are recognized by *representation in their respective State Societies*, and from the Medical Department of the Army and Navy of the United States."

"Each State, County, and District Medical Society entitled to representation shall have the privilege of sending to the Association one delegate for every ten of its regular resident members, and one for every additional fraction of more than half that number: *Provided*, however, that the number of delegates for any particular State, territory, county, city, or town shall not exceed the ratio of one in ten of the resident physicians who may have signed the Code of Ethics of the Association."

Secretaries of medical societies, as above designated, are earnestly requested to forward to W. B. Atkinson, M.D., Permanent Secretary, Philadelphia, *at once*, lists of their delegates.

To Preserve the Strength of Magendie's Solution, Dr. H. H. Kane gives the following formula:

℞. Morph. sulph. ..... gr. cclvi.
Acid salicylic. ..... gr. viij.
Aq. distil. ..... f. ʒ xvi.
M.

Heat the water to boiling-point, add the powder, stir, filter, and keep in a glass-stoppered bottle of green glass.

Taste of Quinine.—The following vehicle is said by Mr. Pennypacker to disguise the taste of quinine:

℞. Ext. taraxaci fl. .....
Ext. glycyrrh fl. .....
Elixi simp. .....ää.
M.

Editorial Change.—Dr. E. M. Nelson has been appointed editor of the *St. Louis Courier of Medicine*.

The British Army Medical Service and the Indian Medical Service have been united under one administration. This is causing much dissatisfaction, especially in the Indian Service.

A New Anæsthetic for Dental Surgery.—At a recent meeting of the Edinburgh Odonto-Chirurgical Society, Mr. W. B. McLeod brought to the notice of the Society a new combination anæsthetic which he had been using with great success. It consisted of a mixture of ethydene dichloride in nitrous oxide gas. The dichloride is poured on a sponge and then placed in the gas inhaler; the patient thus inhales the two gases together. The time of inhalation was about one minute, and the period of anæsthesia from one and a half to two and a half minutes. In the sixteen cases where he had used this mixture there had been no sickness, no lividity, and the pulse was slightly increased in force.

Recent Experiments with Aconitine by Dr. Oulment, physician to the Hotel Dieu, show that it is very efficient in certain forms of essential facial neuralgia. These forms are the congestive neuralgias, acute in course and generally due to a cold. The dose employed was from one-half to one and a half milligrams. If there is any regular periodicity to the attacks, it is well to combine quinine.

Dr. William Ellery Channing on the Laws of Health.—The famous Dr. Channing, whose centennial has recently been celebrated, conceived a novel idea while a divinity student. He cut down his diet to less than the actual requirements of his system, in hopes that he might thus be able to avoid the necessity of exercise, and might gain more time for study. The penalty which he paid for this was a life-long dyspepsia, due, as he was told, to a contracted stomach. This misfortune of Dr. Channing's led him to appreciate highly the necessity of a thorough knowledge of the laws of health. He is quoted as saying: "The universal disease of the human race is a sufficient proof that we have not yet discovered (you would, perhaps, say have lost) knowledge of the laws of God with respect to the body. To lose consciousness of these was, perhaps, the beginning of sin. Its first effect was to spoil the pure mind of its original holy instincts, and dim its powers of sense-perception. The last triumph of Christianity may be the discovery of a perfect hygiene."

Chicago Medical Society.—On April 5th, the following officers were elected for the ensuing year: *President*, Dr. R. G. Bogue; *Vice-President*, Dr. D. W. Graham; *Secretary*, Dr. L. H. Montgomery; *Treasurer*, Dr. F. H. Davis.

Hydrangea as a Solvent of Renal Calculi.—Dr. E. B. Freeman, of Barton, Ala., writes us in very glowing terms of the virtues of hydrangea in renal calculi. He states that he was a long time a sufferer himself from this affection and had tried many remedies in vain. He was completely relieved by the use of the drug referred to. He uses it in doses of a drachm of the fluid extract three times a day. It clears the urine and relieves all bad symptoms in a very short time. A case is related of a man, aged 45, who had been under competent treatment for a year for renal calculus, but was steadily growing worse. Under the use of hydrangea he was cured in sixty days. The drug has a specially solvent effect on lithate of ammonia. Dr. Freeman is anxious to hear from other physicians as to their experience with it.

[Hydrangea is an indigenous shrub whose virtues in calculous complaints have been reported on before. It was first employed by Dr. E. Butter while a missionary among the Cherokee Indians, forty or fifty years ago. It has since been recommended by different physicians at various times, among others by Drs. W. L. Atlee, Dr. Horsley, and John C. S. Monleur. Its chemistry and active principles are not well known.]

Our Expensive Charities.—The Board of Apportionment appropriated $58,963.50, on April 16th, for various city charities. The Commissioners of Charities and Correction sent to the Board a statement that the cost of food and clothing for the Department for January, 1880, was $105,722.91 greater than for January, 1879, and that unless the appropriation for 1880 should be increased, it would be exhausted before the close of the year. On the same day, Mr. Varnum's resolution providing that the State Board of Charities examine into the expenses of our charitable institutions, and report to the Legislature of 1881, was called up, and passed the Assembly.

The Rights of Authors and Lecturers.—In reference to the recent decision of Judge Donohue, given in the case of Putnam vs. Meyer, Messrs. Putnam have made an appeal, and it is expected that the case will be argued before the General Term early in May.

Incubation of Scarlet Fever.—Dr. F. E. Clarke, of West Brighton, S. I., sends us the history of

a case of scarlet fever, in which the period of incubation is exactly determined, and is a remarkably short one. The patient, a robust young man, called, on the night of February 10th, on some relatives who had lost a child from scarlatina neatness seven days before. He had not known of the death until the evening of his call. He stayed with the family several hours. On the following evening his throat became sore, and he did not feel very well. At this time he ate a bowl of soft-shelled clams. The next forenoon, about thirty-six hours after leaving the infected house, he was taken with violent vomiting, slight diarrhœa, headache, and sore throat. The next morning, two and a half days after exposure, the rash—first seen by the nurse—appeared. The patient went through the usual course of scarlet fever. At the end of a week he was convalescent, and his recovery was rapid and satisfactory.

Dr. Curie states that this was the shortest stage of incubation he had ever seen, and only knew of three others that were shorter. Two of these were reported by Murchison, the incubation being in one case one and the other twenty-four hours. Trousseau reports a case where the incubation was only seven or eight hours.

An Oakum Plaster Splint.—Dr Gregory Doyle, of Syracuse, N. Y., writes: "I am now using, and have been for some time, an application for fractures of the leg which I call, for want of a better term, an oakum-plaster splint. In applying it, the oakum is to be merely arranged in layers or sheets, say a third or half an inch in thickness. Then a mixture of plaster of Paris and water is to be prepared of the proper consistence. In this the sheets of oakum are to be well soaked and applied to the leg, which should first be well extended and covered with a loose bandage. The soft plaster and oakum should be carefully and evenly moulded to the limb, and the operation may be completed by applying an outside or finishing coat of soft plaster. When the whole is set it makes a very firm and neat dressing, preserving the natural contour of the leg, enabling the surgeon to detect the slightest deformity if it should exist. This splint could be made movable by first applying it to one side of the leg and allowing it to set, then greasing the edges and applying the other side, and when sufficiently hard a many-tailed bandage might be applied over the whole, thus making the apparatus removable at pleasure."

Dr. B. F. Dawson has been appointed one of the assistant surgeons to the Woman's Hospital, vice Dr. A. A. Smith resigned.

Drawing up a Black-list.—At the last meeting of the Alumni Association of Jefferson Medical College, a series of resolutions was passed in regard to the medical standing of the graduates of that school. It was decided to appoint a committee, who, by proper and designated methods, should secure the names of those alumni who had disgraced the profession and college by advertising themselves, or by selling patent remedies, etc. The recording secretary is to keep a list of these names.

It further provides that every graduate who receives a certificate of membership of the Alumni Association shall agree to return the same in case of expulsion from the Society by a vote of two-thirds of its members.

New Methods of Using Volatile Disinfectants.—In the Parkes Museum of Hygiene, at London, there are two apparatus for charging the air of a room with antiseptic vapor. One consists of a ramie cross towel circulating on two rollers, the lower of which dips in a trough filled with a solution of carbolic acid or any other soluble disinfectant. The other apparatus consists of a metal box filled with Norwegian tar. The lid of the box is provided with metal fasteners, which are immersed in the tar. When the apparatus is to be used the cover is raised, and the tar-covered fasteners are exposed to the air. The pleasant odor of the tar is very quickly perceptible throughout the room. A tube is fitted to the box also, which enables it to be used as a simple inhaler, and on applying the mouth to the end of the tube and drawing an ordinary breath, a very perceptible dose of the tar vapor is obtained.

Although it is improbable that anything like real disinfection can be obtained by the above methods, no doubt some benefit is derived, in many pulmonary complaints, from their use.—*Lancet.*

Frequency of Hematemesis in China.—Two members of the Chinese Legation in London have recently suffered from hematemesis to an alarming extent. Their condition, however, has caused no alarm or anxiety among their compatriots, because they say that vomiting of blood is exceedingly common in China, and very rarely fatal. Their view of the cause is that the Chinese are in the habit of eating largely, at wide intervals. This produces a hypersemic distention of the stomach, with erosion of the walls and rupture of the vessels. Tea-drinking is also thought to impair the nutrition of the vessel walls, when indulged in by persons whose diet is poor and scanty.

Home Cultivation of Quinine.—Mr. Wilkes Weaver, of Bogota, South America, has written a letter to the Agricultural Department advocating the cultivation of the cinchona tree in this country. He says that the coasts of Northern California and of Oregon would fulfil the conditions as to moisture; the slopes of the mountains would probably furnish hilly ground very similar to that occupied in its native habitat. The temperature is also nearly the same. The cost of a plantation of a hundred acres would be from $1,000 to $1,500 per acre, and some Indian plantations yield $8,000 per acre. The barks produced by cultivation are much superior to the natural ones. The success in the artificial cultivation of the cinchona tree in India will justify similar attempts in this country, and the Agricultural Bureau will probably try to initiate some movement in this direction.

Bill to Investigate the Insane Asylums of the State.—A bill has been introduced into the State Assembly, to create a temporary commission to investigate the lunatic asylums of the State. The commission will last one year, and report to the next Legislature.

Books Received.

Brain and Mind. By H. S. Drayton and James McNeil. New York: S. R. Wells & Co. 1880.

Students' Manual of Venereal Diseases. By F. R. Sturgis, M.D. New York: G. P. Putnam's Sons. 1880.

Catalogue of the Graduates and Officers of Medical Department of University of City of New York. Dec., 1879. 2d ed. Published by Alumni Association.

Rocky Mountain Health Resorts. By Charles Denison, A.M., M.D. Boston: Houghton, Osgood & Co. 1880.

Original Lectures.

THE ERUPTIVE FEVERS.

LECTURES DELIVERED

By ALONZO CLARK, M.D., LL.D.,

PROFESSOR OF PRINCIPLES AND PRACTICE OF MEDICINE, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

I.—SMALL-POX.

This class embraces, as I have already told you, small-pox, scarlet fever, measles, chicken-pox—the German measles, as it has been called here. (There are certain eruptive diseases, attended by fever, that come better under the class of skin affections.)

These are peculiar in several respects. First, they are contagious, and they all have a more or less definite time of incubation. This time relates to the period during which the poison, having been received into the system, lies dormant; in which it produces no symptoms that indicate disease; the period of incubation varying in different affections, and then comes the period of invasion, which is attended by fever of more or less grave character, and this varies very much in the different affections. In one of them it is only of a few hours' duration; in another, it is pretty definitely a two days' period. Then comes the eruption, and this has a varying duration in the different affections, longer and shorter. Then comes the desquamation—the period of desquamation. This varies in the different diseases that come under this class. And then come the sequelæ. And each of these diseases will have to be treated under these several heads: the period of incubation; the period of invasion; the period of eruption; the period of desquamation; the sequelæ.

First among them I will take small-pox, and I will first tell my reasons for thinking small-pox nowadays never originates *de novo*: never originates without contamination by the poison that has produced it from another case. A good many physicians are of opinion that it has an origin without the poison; but the poison travels in singular ways, and a person does not know when he is exposed to it, many times. Take, for example, an occurrence of small-pox in the town of Woodstock, Vt. I was there lecturing in the Vermont Medical College, and a case of small-pox occurred, and I was asked to see it. The man was catechized very closely in regard to whether he had been exposed to small-pox. He had not seen any small-pox, did not know of any small-pox, there had been none in town, and he had not been out of town. How could it have come? Had he received any articles of merchandise, and in that way got contaminated? No, he had not received anything; nothing but flour and groceries. He was sent off to an unoccupied house a considerable distance from the village, and the doctor visited him daily. He had an attendant that had had small-pox. Well, it came to pass that the selectmen of the town of Woodstock received a note from the selectmen of the town of Randolph six weeks later, saying that they must be guarded against a Canuck wagon containing a family of emigrants, travelling by a horse or donkey, for the family had small-pox. This man was asked if, on a certain day, he looked into a wagon that contained a family. Yes, he had, and he thought some of the children were sick. He lifted the wagon-cover and looked in. The source of the poison was then explained.

A gentleman, a superintendent of one of the mills in Lowell, Mass., took small-pox. He did not know that he had ever seen a small-pox case in his life. Dr. Greene, who was his friend and physician, undertook to work up the case. Nobody had known of small-pox in Lowell. Dr. Greene found, on careful inquiry, that an Irishwoman had come down from the upper part of the State with a child in her arms, and had gone to a tenement-house occupied chiefly by the Irish. There her child fell sick a day or two after she came, and the doctor ascertained that the sickness was small-pox. The people in the house would not allow her to remain there. She was almost forcibly ejected. Her husband was at work up at Worcester, and she went to him. She put the child under her apron, and took a car for Boston, and from Boston went up to Worcester. Dr. Greene ascertained in what car she went, and in about what part of the car she was seated; and he found, on inquiry of his friend and patient, that he went to Boston by the same train, that he was in the same car, and only two or three seats from this woman with the sick child. How many more took the disease from that particular source Dr. Greene did not ascertain, but the eruption came out at the proper time for exposure on that occasion.

I was myself in Ohio some years ago, and I went down toward the south-west on one road, to get on to another that ran north-west, and the trains did not connect, so that I had to wait two or three hours. While I was waiting, the train called the New York express came in, and this happened to be the station where the passengers got their refreshments. I stood on the broad platform that is there, and looked in the people's faces as they came out, thinking I might see some New Yorker; and one of the persons I saw struck me as having small-pox, and I approached nearer to him, and found it was the eruption of small-pox fairly out. I told the conductor he had a small-pox case there, and pointed out the man; and the man said, when I inquired of him, that he had been sick, but felt pretty well now. He had been very sick for several days, but thought the eruption that had come out on him had relieved him. He had been visiting in the northern part of Ohio, and was going home. I don't remember how far down, but a certain distance down the road. The conductor said, "What can I do with him? he has paid his fare; I cannot put him off; he has not behaved badly; has not broken any of the rules." I saw an empty freight car standing on a side track, and told the conductor to put this man in that, and take him as far as his ticket would carry him, and there drop the car. He adopted this plan. How many had been exposed to the contagion before this man was separated from the rest I do not know. They had not suspected there was any small-pox aboard. Here in New York, when small-pox prevails, it travels in every public conveyance. And women are travelling more than men with this disease; and whenever I see a woman in a car with other passengers, heavily veiled, I feel almost sure that there is small-pox under the veil. Then carriages carrying small-pox patients to the hospitals retain the poison, for nobody knows exactly how long; it may be for a good many hours at any rate, and if the same conveyance be used by a person who has not been vaccinated, he is very likely to get small-pox. It is not spread very often by means of fomites, but still fomites will carry the poison. I have no doubt it travels in the cars more than we know of.

Many cases similar to these might be cited in evi-

fact that, although a man cannot account for his having taken small-pox, the person has not originated with him, but has come from the body of another who had the disease.

One of our graduates, five or six years ago, wrote up a very excellent history of small-pox—the best I know of—as his graduation thesis. He found to his satisfaction that there were records of it eleven hundred years before the commencement of the present era in China, and that it gradually spread from China to India, and after fifteen hundred years it penetrated to Arabia, being carried by persons who were engaged in what was called the War of the Elephants. It was noted as occurring in Arabia the year after Mohammed was born, and it spread through Arabia and Eastern Asia; and when at length the Moors occupying the north of Africa made an invasion into Spain, he found that they carried small-pox with them into that country, and from that time it gradually spread over Europe and became a common disease. The expulsion of the Moors a long time after did not seem to expel the small-pox.

Now with reference to the history of a single case. I told you it has a period of incubation. That period is pretty definite, varying very little in different instances, and you may get a pretty exact idea about it when I recite to you this case. A patient—in 1869, I think it was—was received into Bellevue Hospital, into one of my wards, supposed to have the initiation of typhoid or typhus fever, whichever it might have been; but it was soon found that he had small-pox. The eruption made its appearance on a certain day, and I gave directions that he be sent to the small-pox hospital. This was rather late in the afternoon, and the boat had ceased to run. The next day was Sunday, and the boat did not run, and the chance of getting to the island was by row-boat only. There were but three patients in this ward. It was a fever ward, and the fever had about died out for that season. I thought the danger of contagion would not be very great, and he was therefore left until Monday afternoon—two days after the eruption appeared, and one day after the disease was easily diagnosticated. On walking out of the ward he passed the bed of a patient who was then sick in the third week of typhoid fever. His typhoid fever was light, and his convalescence was pretty rapid. Twelve days from the time that patient passed him in his bed, six feet perhaps from him, he began to complain of some fever, and feeling poorly. Two days after that the eruption appeared that could be recognized, or rather suspected, and a day later it could be recognized as the small-pox eruption. This man had been vaccinated, and so had the first. This second patient, also, was sent to the small-pox hospital, and both of the patients did well, having but a slight attack of the disease, and recovered pretty promptly. Now, there were just fourteen days between the occurrence of the eruption and the exposure; twelve days from the exposure to the time when he began to feel a little ill.

Physicians vary a little in their statements in regard to the duration of the incubation, but I think it is safe to say twelve days from the exposure to the occurrence of some fever, and fourteen days to the appearance of the eruption. There is nothing to characterize this period of incubation. The patient doesn't feel sick. The poison seems to have been received into his system and to be undergoing a certain change which will enable it, in a definite time, to produce symptoms.

The first stage of the actual disease is called the period of invasion, or stage of invasion, and that is the fever—and a pretty sharp fever. I remember a good many cases in which the fever was as severe, and the pain in the head as severe, as it is in meningitis—indeed more severe than it is in the majority of cases of meningitis in adults. The pain is more in the head than in the back and limbs, but these are also affected. There is occasionally a chilly feeling preceding the fever. The patient is brought to the hospital for fever; on the second day, his face is red; his pulse is full and rapid, and his headaches torment him; his tongue is slightly furred, the furr is of a whitish color; and perhaps he avoids the light on account of its hurting his eyes. This fever, which has nothing distinctive—you cannot distinguish it from the invasion of certain other fevers—will continue, ordinarily, two days. On the morning of the third day, if the fever began in the morning, you may expect to find the beginning of the stage of eruption, and the eruption is, in a great majority of cases, perfectly characteristic, so that in two days you can make pretty surely your diagnosis. It at first appears like little pimples, greater or smaller, along on the forehead from the point where the hair ends, downward toward the eyebrows, or on the neck—little red pimples, papillæ. You pass your finger over them and find that there is a distinct elevation. By the time the eruption appears the initiatory fever begins to abate, and by the time it is four days old, there may be very little fever, the pulse almost natural, and the temperature almost normal. This little pimple, or papilla, on the second day comes to have a little vesicle on the top of it—a very minute blister, not so large as the head of a pin; and in the course of that day, or by the next, that blister is extended and depressed in the centre. Now you have got your mark. The eruption—papilla in the beginning—a little red point standing out from the skin; hard, a vesicle forming upon it on the second day; that vesicle becoming umbilicated, as it is called—depressed in the centre on the third day. The diagnosis can be pretty distinctly made then. It is true that a form of ecthyma gives a pustule very similar to that of small-pox; but it is not umbilicated—it is level.

Now, to follow this pustule, or crop of pustules, to the full formation, we must take eight days—eight days from the beginning of the eruption. It increases all this time, and by the eighth day it has a form that is pretty well represented in this diagram. By the third day there is a white base to this little blister, and it looks as if there were pus in it. But it continues to increase; the boundary, the part of the skin immediately attached to the pustule, keeps a certain degree of redness. In the discrete small-pox it does not become very large—something between a quarter and half an inch. The umbilication continues, and even appears in the scab seventeen to twenty-one days after the beginning of the eruption. On the eighth day the pustule has attained its full size. The skin will become inflamed about it, and there may be even an erysipelatous state of the surface; but the pustule remains fixed, no larger than on the eighth day, and from this time it begins to dry up, first in the middle, then on the edges, and by the seventeenth day it is perhaps ready to fall off, a scab—or perhaps on the twenty-first day. When it falls off, the skin is left of a reddish color. You can see the vessels in the cicatrized part. There is a little depression, and the cicatrix is pretty well rounded, and there are little pin-holes in the bottom of it. This redness will increase if the person is exposed to the air—to the wind; and become a

pretty decided pink in all these depressions. But after three or four weeks the new vessels in the cicatrized part gain a little firmness and contract, and the redness or pink color no longer appears. There is left then the cicatrix. With that I suppose you are all more or less familiar, for everybody sees, in travelling the world over, a good deal of the cicatrization of small-pox. The depression does not always continue for any length of time. The cicatrices come up to the surface, and in some instances you will find several cicatrices running together—the pustules having run together. Here, then, is a running history of the eruption.

In this connection I must state to you that the disease is divided into two classes: one in which the pustules are single, not running together, each one forming separately; and the other in which they run together at their bases. The first is called discrete, and the latter concrete or confluent. And then there is a condition in which some of the pustules run together and others do not. That is often called semi-confluent.

With relation to the confluent pustules, you will have to bear in mind that they do not possess, as a rule, umbilication. Single pustules have it, but the concrete pustules do not. Concrete small-pox is very much more fatal than the discrete. Now, perhaps, you will get an idea from this plate of the course of the small-pox eruption. The eruption in bad cases runs into the mouth and down the air-passages, and to a certain extent down the œsophagus, and produces a cough, and occasionally a disease of the larynx that I have not mentioned to you (but probably Dr. Delafield has), œdema glottidis; so that, to anticipate a little, one of the dangers in small-pox is this œdema glottidis.

The fever of small-pox—the initiatory fever—nearly subsides, as I have told you, during the growth of the pustules; but when the pustules have attained their growth there is a diffuse inflammation of the skin extending from the pustules, and if they are numerous the whole skin may be inflamed, and the inflammation has an erysipelatous appearance.

There is now a new fever developed. It has been called the fever of maturation. And this is often pretty severe. It continues until the pustule has partly dried, and then, in a favorable case, abates. In a bad case, it may continue until death occurs. Death seems to be caused by several incidents: first, the depressing effects of the disease itself when the eruption is abundant; second, the erysipelatous inflammation that spreads from it to parts of the skin that are not invaded by the pustules; third, suffocation from œdema of the glottis, or the effects of the inflammation in the trachea; fourth, a kidney affection analogous to Bright's disease, but rarely attended with absolute suppression, but with albuminuria and casts. The sympathies between the skin and the kidneys are so alive that you can hardly suppose so formidable a disease as this upon the surface would not in some way affect the kidneys, and on examination it is found that it does. The period at which small-pox is most frequently fatal is the second week. Not at the time of the maturing of the pustules, but in the fever that follows that maturity. The amount of mortality from this disease can be better taught by figures than in any other way, and as I have some here I will read them to you. They are taken from the statistics of the small-pox hospital in London.

Mortality among those who had been vaccinated, 6.56 in 100 persons; and in those who have particularly good cicatrices, 2.52 in 100 persons; in the unvaccinated, taken as a whole, young and old, the mortality in the London Hospital is 37 in 100. But in the discrete small-pox the mortality is only four per cent. Observe the difference: of the slightly confluent, eight per cent.; and of the confluent small-pox, fifty per cent. Then there is a marked difference in the mortality depending upon age. In children not yet one year old, all die; the mortality is 100 per cent. In persons above sixty, the same thing. That is, if they have not been partially protected by vaccination. Children under one year of age do not recover; between one and two years, rarely (that statement is taken from Trousseau); persons over sixty almost never; and pregnant women very rarely. And in this connection it is proper to say that women having small-pox almost always menstruate, and sometimes pretty freely, whether it is their proper period or not. And there is some disposition to a hemorrhagic tendency in the affection, for there is a form of it called the hemorrhagic small-pox. I have been pestered with that a good many times, and I will tell you how. A case coming into a hospital that is devoted to general diseases comes as a case of fever, and on the day when the eruption should occur, if it be small-pox, it does not occur, and instead of it, little spots of ecchymosis, and it will be two or three days after the eruption should appear—perhaps four days after—before anything that can be called really suspicious as a pustule makes its appearance. Meantime the disease can spread. Persons lying near this sick person may take it. Persons who have charge of removing the patient may take it. I have several times, when perplexed with such a case, called specialists—those who devote themselves to skin diseases; and I have found that they were just as much puzzled as I was. The case has no characteristic marks except the spots of ecchymosis, and they are just about as numerous as the pustules should be. That hemorrhagic variety of small-pox has, in my observation, always been fatal. I met it in consultation in a case of a robust, healthy young woman, and I told the doctor who called me that I had never seen a case recover, but here was a good subject, and we would try our best to carry her through; if we could carry her to the fifteenth day, through the fourteenth day, I felt confident that we might hope for a good result. As we found her sinking we pressed the alcoholics, and kept up her pulse pretty well up until the evening of the fourteenth day, when it fell as suddenly as a bucketful of water would fall if the bottom were to fall out. She went right down. Dr. Bulkley, father of the Dr. Bulkley with whom you are acquainted, told me he had had one or two recover; but physicians generally perceive that these are almost inevitably fatal cases—those of the hemorrhagic variety.

There is a point here that has not been published in your books, and it may be of some use to you. In the experience that I had in the New York Hospital, as junior and senior walker and house-physician, which lasted two years, I saw quite a number of cases that were admitted for fever which turned out to be small-pox, and were sent to the small-pox hospital; and of all these cases not one left the small-pox behind it. No person who assisted the patient to get to the carriage, or to get to the hospital, took the disease; no patient lying alongside of him took it; and a great many years after I went to the superintendent of the hospital, and asked him what had been the experience after I had left it until then. He said it had been the same. There had been but one case in which the contagion

had been left behind, and that was a case of the hemorrhagic variety, in which the diagnosis could not be made until the third or fourth day. The same thing is true of Bellevue Hospital. All cases that I have observed there, received in the belief that they had fever and were afterward sent to the small pox hospital, have not left the disease behind them, if they were sent at the time of the beginning of the umbilication of the pustule. My conviction is strong that up to that time there are no emanations from the body that will poison another person. I see the statement made that small pox is contagious in the stage of attack during the fever. I do not believe it.

You will, perhaps, be some time consulted by a person who says "Doctor, I went to see my friend, Mr. So-and-so, and he was sick in bed, and I stood by the bedside for some time, and now they say he had small-pox. What can I do?" "How long had he been sick when you saw him?" "Well, three days—two days for the invasion and one for the eruption." "It is not, then, contagious, and you need give yourself no concern about it. If you have had no other exposure you will not have small-pox." At the same time he will be very likely to want you to vaccinate him. Vaccinate by all means, but not because he was exposed at that time, but that he may be again.

You see that this is a very formidable disease, and a curious portion of its history is, that the mortality from it has been, in the last two or three years, reduced in New York to almost nothing. I have a memorandum here of seven years' mortality of small pox, not including the last year, as the statistics are not yet published. In 1872 there was a mortality of 910 by small-pox alone, in a general mortality of 32,000. In 1873, 117; in 1874, 484; 1875, 1,280 in a mortality of 30,000; in 1876, 315 in a mortality of 29,000; in 1877, a mortality of 14 in 26,000 deaths from all causes; in 1878, 2 deaths only in a mortality of 27,000; and I believe it has not much exceeded that in 1879. I do not know why this exemption from the disease—for it is thought it will be mortal in a certain proportion of cases wherever it prevails. I do not know but it is due to the efforts of the Board of Health. When this large mortality occurred they busied themselves in causing the vaccination of everybody that would be vaccinated, and urging those who were reluctant. A corps of a considerable number have been busy every summer, urging vaccination upon the poor people. They may have effected a degree of protection that they probably never hoped for. In looking at the weekly bills of mortality, I find them running on for weeks without a single entry of small-pox, and so in the reported bulletins of weekly journals. There is published in some medical journals a weekly report of the prevalence of contagious diseases—small-pox, measles, scarlet fever, diphtheria, etc., and week after week there will be no report of a single case. I do not know how we can get that exemption, unless it is by the efforts of the vaccinating corps.

The amount of protection that vaccination gives was perhaps exaggerated by Jenner, who was its author; but it is a little too early to consider that.

Varioloid is small-pox pure and simple, but modified by a certain degree of protection that the system has received, either from a previous attack of small-pox, or from vaccination; and that it is small-pox is made apparent by the fact that persons who have varioloid diffuse the small-pox among the unprotected. The disease that comes from them is pure, unmodified small-pox, unless the modification comes from some protection in the system. I have already told you that the degree of mortality that occurs in this modified small pox or varioloid is about six and a half per cent. of those who are attacked, and the reason of that is that the supposed protection is really none. It is not a protection at all, either the vaccination was imperfect, or the protective power has died out, or the patient was more susceptible to small pox than the average of men, and one vaccination was not a protection against it. It happens, then, that in some who have been vaccinated the small pox is taken, and runs its regular course, subjecting these persons to the same degree of mortality that small pox itself does—viz., thirty-seven per cent.; but in much the greater number there is a modification of it that I can describe to you under three heads: 1st. A development of the disease such as you see indicated on the diagram I show you; an early termination, small pustules drying up quickly and leaving no cicatrix. That indicates the least degree of protection that is effective, and that is the form of disease that occurs in a good many who have been vaccinated. In others in whom the protection seems to be nearer complete, the papulous form; there will be but few of them, and a little blister will form on the top of them on the second day, and by the fourth day that blister has dried down into a little horny substance. It is not a very elegant phrase, but in the olden times there was a something called horny pox, and it was this. These little eminences are formed, having a dry scab upon them, and feeling hard, and with that the signs of the disease pretty quickly disappear; and then still in others papulæ form, and, without the production of the little blisters upon the top, shrink away and disappear. The first two of these are much the more common. There is no maturative fever in varioloid. The first fever occurs very much like the fever of small-pox, perhaps with equal vehemence, and then it dies away as an eruption appears, and there is no fever afterward. These several forms of modified small-pox, called commonly varioloid, you will see something of; and almost always, at least in the far greater number of cases, it will be the modification that limits, that diminishes the duration of the eruption, diminishes the size of the pustule, and does not let it go deep enough into the skin to produce cicatrices that will be enduring.

Now, a few words in regard to the treatment of small-pox. The first great fact that you are to remember when you have charge of such a case is, that it is a self-limited disease, and must run a course, and that your business is to keep your patient alive until its natural termination. In very many cases of small-pox that tend to recovery, really very little treatment is required. The general treatment may be almost entirely omitted; and those that do require treatment will require treatment for symptoms. If there is exhaustion, you would use your alcoholics in the same way that you would in typhoid fever. If there were a wide erysipelatous inflammation you would have the room kept pretty cool, so that the coldness of the air would modify the action of the inflammatory disease. If the patient be restless, if he have the irritative fever, give him opium to quiet the nerves. If he have suffocative symptoms, you will have to look into the throat, or feel the throat, and ascertain whether there is any œdema glottidis; and if there be, your duty will be to perform the operation suggested by the late Dr. Buck, to scarify the watery tumor upon the top of the larynx with a sharp instrument of some sort, the

blade of which is protected by winding something upon it, the point only left open to pass down upon your finger, and make little scratches into the bladder of water that constitutes œdema glottidis. There is no specific. It is not more than five or six years since that it was published to the profession that a certain plant would cause an abortion of the disease, and would cure it in every instance. The more it has been used, I believe, the less it has been found that the statement is true. We do not claim now, at any rate, that there is anything that will cut short the eruption; and the probability is that if you could find anything that would do it, it would do more harm than good. It is a loathsome disease—loathsome in the condition to which it reduces the patient, and in the effluvia that arises from his body. The only question of much importance in regard to the treatment is, can you produce a condition of the pustules that will not leave cicatrices? I believe that question can be answered affirmatively. But the particular treatment that you will subject these pustules to is of a very variable kind, if you follow the authority of one or another person. If early in the disease these vesicles be pricked with the point of a lancet, and kept empty, the cicatrization, it is said, will not occur.

LIPÆMIA AND FAT EMBOLISM IN DIABETES MELLITUS.

By LOUIS STARR, M.D.,

PHYSICIAN TO THE EPISCOPAL HOSPITAL, PHILADELPHIA.

In diabetes mellitus, death occurs in several ways. Thus it results very frequently from pulmonary consumption, and occasionally from local diseases, which in themselves are of little moment, but which end fatally in consequence of the slight resisting power of the system. Again, death may take place slowly from general exhaustion, or it may occur rapidly, being preceded for a few hours or days by marked respiratory symptoms, and by the condition known as "diabetic coma."

In examples of the last class, the alterations in the respiration consist of a moderate increase in the number of the respiratory movements, and a very decided increase in their fulness and depth; these changes being independent of any difficulty in breathing, and unaccompanied by the physical signs of pulmonary or cardiac lesion.

Diabetic coma occasionally appears suddenly, without any premonitory symptoms; at other times, after a short period of general agitation, breathlessness, and gastric pain, the patient becomes listless and drowsy, with a feeble, frequent, compressible pulse, and a cool skin, and gradually passes into a condition of profound stupor.

Setting aside the old idea of the coma being due to uræmic poisoning, and the breathlessness to pneumonia, there are two ways in which the occurrence of these conditions may be explained—first by the presence in the blood of acetone, produced by the fermentation of grape-sugar in the stomach, or formed in the cells of the liver; and, secondly, by the existence of lipæmia and fat embolism.

The theory of acetonæmia, supported by many authorities, but especially by Kussmaul,* is based upon the detection of acetone in the blood, the urine, and the breath of diabetic patients, and upon the fact that animals poisoned by acetone show, at first, symptoms of intoxication with slow breathing, and afterward become comatose, the respiration being slow, somewhat stertorous, unusually deep, and finally irregular. To produce these results, a large quantity of acetone is necessary, and although the features of poisoning do resemble those attending diabetic coma, it is questionable whether it is possible for a substance which escapes so readily from the lungs, to collect, under ordinary circumstances—that is, when generated in the system—in sufficient quantity to cause toxic symptoms. Kussmaul suggests, however, that the continued introduction of acetone into the blood may, in certain debilitated conditions of the nervous system, occasion a chronic poisoning, which may suddenly assume an acute form, just as chronic alcoholism in drunkards breaks into delirium tremens.

As a further proof of the dependence of the coma upon acetonæmia, Dr. Balthazar Foster† asserts that the peculiar creamy condition of the blood, often observed in glycosuria, can be artificially produced by the addition of acetone to healthy blood, and that this condition is not due to the presence of an excess of fat, as the appearance would seem to indicate.

The theory referring the coma and breathlessness to slow carbonic acid poisoning, due to fat embolism of the pulmonary vessels, in turn depending upon an abnormal quantity of fat in the blood or the state of lipæmia, originated with Prof. Sanders and Mr. D. J. Hamilton, who, in a paper published in the *Edinburgh Medical Journal* for July, 1879, detail the clinical histories and the results of the post-mortem examinations of several cases of diabetes, and summarize the data leading to their hypothesis in the following manner:

"1st. The lipæmic state of the blood present in all the cases known to us.‡ 2d. The anatomical evidence of fat embola, chiefly in the minute pulmonary vessels and capillaries, and to a less extent in those of the kidneys and other organs. 3d. The entire similarity of the histological appearances in the lungs to those found in fatal fat embolism from fractured bones. 4th. The analogy in the symptoms of dyspnœa and coma in fat embolism from fracture, as compared with the diabetic conditions. 5th. The quantity of acetone found in the blood in diabetes seems too small to account for the fatal symptoms. 6th. Acetone added to blood does not produce either the naked eye or microscopic appearance of lipæmia. In this respect our experiments entirely differ from those of Dr. Foster. The milk-like appearance in our cases was always proved to be due to oil, both by microscopic examination and by the removal of the milky appearance by the action of ether, as well as by the staining with perosmic acid. Nothing identical with this can be produced by adding acetone to blood. 7th. The phenomena induced in animals (rabbits) by administration of acetone are similar to those of alcoholic intoxication, and the labored breathing does not present the intensity of the severe diabetic dyspnœa. 8th. In animals poisoned with acetone the blood does not present any appear-

† Brit. Med. Journal, Jan. 19, 1878.

‡ The presence of an "abundance of fat" in the blood of diabetics, so as to give the serum, that separates on standing, a milky or chylous appearance, was long ago noticed by Dobson and Rollo, and has been confirmed by many subsequent observers.—Senator: Ziemssen's Cyclopædia, vol. xvi., p. 890.

an[illegible] albuminoid or mucous pus, like those of the peculiar blood of diabetes.

As the number of observations made by Prof Sanders and his co-laborer is far too limited to admit of a definite conclusion in regard to the truth of their theory, any additional evidence is valuable. Consequently the accompanying record of a patient recently under my care, is of importance, the case is also interesting on account of the unusual ophthalmoscopic appearances.

Henry W[illegible].* aged 20, white, born in Pennsylvania, a farm laborer, of temperate habits, was admitted to the Medical Ward of the Episcopal Hospital on November 8, 1879.

His family record was good. He had no syphilitic history, and, with the exception of a fracture of the left fore-arm in early boyhood, he had enjoyed good health until the fall of 1877, when the illness for which he entered the hospital began. His average weight previous to this had been 140 pounds. The first symptoms of ill health that attracted his attention were frequent micturition, together with a decided increase in the quantity of urine voided. There was at the same time a morbid thirst, and he soon began to lose flesh and strength, although he consumed an unusually large quantity of food. During the year preceding admission, his diet had consisted chiefly of mush, potatoes, and bread.

When admitted he was weak and much emaciated, weighing only 111 pounds. He answered questions slowly, his face had a heavy expression, his cheeks and eyes were sunken, his lips were pale, his hair was dry and lustreless, and his skin was harsh, scurfy, and cool to the hand. The edges of his tongue were clean, red, and smooth, while the centre was lightly coated with a yellow fur, the saliva was acid, there was occasional hiccough, intense thirst, and inordinate appetite. There was some flatulent distention of the abdomen, with a sensation of burning in the hypogastrium, and the bowels were obstinately confined. The pulse was 88, of very moderate force; the respiratory movements counted about eighteen per minute, and were regular and deep. An examination of the heart and lungs revealed nothing abnormal, there was no increase of the hepatic or of the splenic dulness, nor any enlargement of the superficial lymphatic glands. The urine was passed at short intervals and in large quantities, it was light colored, cloudy with mucus, acid in reaction, had a sp. gr. of 1.031, and contained a large amount of sugar, and a trace of albumen. The patient complained of dimness of vision, and cataract being suspected, he was sent to Dr. Albert G. Heyl, Ophthalmic Surgeon to the hospital, for examination. (See report.)

He was ordered for breakfast, two soft-boiled eggs, half a pint of milk, and one thin slice of thoroughly toasted bread; for dinner, twelve ounces of meat broth, a reasonable supply of roasted or broiled meat, and a slice of toast; for supper, one pint of milk, and a slice of toast; between meals he was allowed half a pint of milk. The quantity of water was not restricted, though he was directed to restrain his thirst as much as possible. In addition, a mixture of ten grains of bicarbonate of sodium and half a fluid ounce of compound infusion of gentian was prescribed thrice daily, and orders were given to keep the rectum unloaded by the use of simple enemata.

At the end of three weeks he had gained eight pounds in weight, but there was no change in the symptoms beyond the development of slight oedema of the feet and ankles. Another half-pint of milk, and a cup of either tea or coffee, without sugar, were ordered for breakfast, and as the bowels remained constipated, a pill composed of ext belladonna, gr. ¼, ext gentianæ, gr. 1, ext colocynth comp., gr. 1, and oleum cari, gtt. ss., was administered when necessary to secure an evacuation.

The oedema disappeared in three days, and there was no further change until December 8th, when it was noted that there were a number of minute pustules upon the chest and back and on the dorsal surfaces of the arms, and that there was a trifling dry cough, and a return of the oedema. A careful physical examination showed exaggerated pulmonary resonance, puerile respiratory murmur, and the presence of tenderness on palpation in the hypogastrium. The heart, liver, spleen, and lymphatic glands were normal. The respiratory movements were unusually deep, about 18 per minute, the pulse varied from 84 in the morning to 100 in the evening, and the axillary temperature from 97 to 98 F. The saliva was tested and found to be free from sugar. A portion of the contents of the pustules was also tested for sugar, with negative results.

On December 13th he weighed 117¼ pounds; he complained of headache, of a sense of weakness in the legs, and was more heavy and listless. The cough had ceased. On the 17th a large furuncle commenced to form in the right cheek. After this he steadily lost strength, his weight fell to 113¼ pounds, and on the 23d he was unable to leave his bed; small doses of opium—gr. ss. thrice daily—which had been administered in place of the alkaline mixture for several days, were discontinued on account of the increasing drowsiness, though, as the pupils were unaffected, this was probably an independent symptom. The respiration continued very deep, counting 20 a minute; the pulse was weak, 80 in the morning, 96 in the evening, and the temperature ranged from 96.5 to 97.5°.

On the morning of December 24th, he had severe pain in the left infra-mammary region, the pulse was 96, quite feeble, the temperature was 99.5 and the respiration 20, still deeper than before, and attended by movement of the nostrils. The decubitus was dorsal, with the head and shoulders somewhat elevated. There was greater somnolency and prostration. A flaxseed poultice was applied over the seat of pain, and digitalis and carbonate of ammonium administered. At 1 A.M., on December 25th, he passed into a condition of coma, and death occurred seven hours later.

During the patient's life several microscopic examinations of the urine were made by Dr. Simes, the Pathologist of the Episcopal Hospital, and by myself, resulting in the discovery of nothing more than sugar fungus.

The following table shows the results of seven analyses of the urine, the quantity of sugar being estimated by Roberts's fermentation test:

Date.	Quantity in 24 hours.	Color.	Reaction.	Sp. gr.	Quantity of sugar to oz.	Remarks.
	Oz.				Grains.	
Nov. 18.	181	Light yellow cloudy.	Acid.	1 031	28	Trace of albumen.
" 25.	108	"	"	1 031	29	No albumen.
Dec. 3.	118	"	"	1 034	30	"
" 9	80	"	"	1.030	25.5	"
" 12	48	"	"	1 032	27	"
" 16	58	"	"	1 032	25	"
" 22	56	"	"	1 029	22	Indican.

* Clinical history compiled from the ward notes of Dr. H. D. Harvey and Dr. T. H. Cathcart, resident physicians.

The next table shows the average daily amount of fluid consumed, and of urine voided for each week of treatment:

Date.	No. of oz. drank daily.	No. of oz. voided daily.
November 10–16, incl.	116.0	100.7
November 17–23, incl.	124.0	132.4
ember 24–30, incl.	115.1	108.5
ecember 1–7, incl	120.8	92.4
December 8–14, incl.	116.6	69.6
December 15–21, incl	114.0	60.8
December 22–24, incl.	117.3	64.0

The blood was examined on several different occasions, and always presented the same characteristics. On pricking one of the fingers, the blood flowed slowly, had a peculiar brick-red color, and when a drop had collected it was either traversed by one or two milky veins, or its upper surface became overlaid by a milky stratum. This milky appearance was somewhat more marked when pressure was made on the punctured finger to induce a greater rapidity in the flow. The blood coagulated very tardily and imperfectly. Under the microscope, with a power of 250 diameters, the rolls of red corpuscles were poorly marked, and interspersed with these were observed occasional large collections of fine granular matter. Upon treating with ether, numerous large oil-globules appeared scattered over the field.

On December 10th, my colleague, Dr. F. P. Henry, kindly made a count of the blood by means of Gowers' hæmacytometer, with the following result, viz.: number of *red* corpuscles to cubic millimetre, 4,205,000, the normal being at least 5,000,000; number of *white* corpuscles to cubic millimetre, 50,000, or 1 white to 84 red cells, the normal being 1 white to 350 or 400 red cells.

The *autopsy* was made twenty-eight hours after death. The body was greatly emaciated; the pupils were dilated.

The *brain* weighed forty-nine ounces. There were several spots of opacity, about one-fourth of an inch in diameter, in the pia mater on the convexity of the hemispheres, and the veins were distended with blood. The brain tissue was firm, and presented no gross abnormal appearances. An unusually large quantity of cerebro-spinal fluid escaped when the skull-cap was removed.

Upon making the incisions necessary to inspect the thoracic and abdominal cavities, it was observed that there was an absence of subcutaneous adipose tissue, and that the muscles were rather dry and brownish in color.

Lungs.—Left lung weighed twenty-five ounces. The upper extremity of the lower lobe seemed to be in a state of gray hepatization, a section being noncrepitant and sinking when thrown into water. This condition of hepatization gradually faded into one of intense congestion, and this again into healthy lung as the base of the lobe was approached, the whole area involved being equal to one-fourth of the affected lobe. A few flakes of recently-formed lymph were attached to the pulmonary pleura over the region of hepatization, and the costal pleura directly opposite was injected. The remainder of both pleural surfaces was normal; the pleural cavity contained nearly two fluid-ounces of salmon-colored, milky fluid. Right lung weighed eighteen ounces; there was moderate congestion of the posterior portion of the lower lobe, but no other alteration.

The *heart* weighed eleven ounces; its tissue was pale and flabby; the valves healthy. The left ventricle held a small post-mortem clot; the right ventricle a large anti-mortem clot, which extended far into the pulmonary arteries.

The peritoneal cavity contained a small quantity, estimated at three fluid-ounces, of clear, straw-colored liquid. The layers of the peritoneum were perfectly smooth and shining. The *stomach* was double the natural size; its mucous membrane was thickened, markedly mammillated, and showed numerous points of ecchymosis. The mucous membrane of the *small intestine* was congested, and this portion of the gut was filled with a thick, yellow material, having a vinous odor. The *large intestine* was filled with lumps of feces; its mucous membrane was also congested. The *mesenteric glands* were normal in appearance. The *pancreas* was unaltered. The *spleen* weighed seven ounces, and presented nothing abnormal. The *liver* weighed four and a quarter pounds, was engorged with blood, and was moderately firm in texture. The capsule over the upper surfaces of both lobes was thickened and opaque. The *kidneys* weighed together seventeen and three-quarter ounces; they were congested, apparently somewhat fatty, with non-adherent capsules. The *urinary bladder* was healthy. The blood, which flowed from the vessels and organs during the inspection, was darker in color than expected, that from the brain only being quite similar to the blood drawn from the finger during life.

A portion of the blood contained in the great vessels and viscera, a portion of that which escaped mixed with cerebro-spinal fluid on removing the brain, together with some of the liquid from the thoracic and abdominal cavities, and sections from the consolidated part of the left lung, from the liver, the kidneys, the medulla oblongata, and the semilunar ganglion, were carefully examined by Dr. Simes, with the following results:

REPORT OF DR. J. H. C. SIMES.

After standing for two or three days the several fluids presented different gross and microscopic appearances.

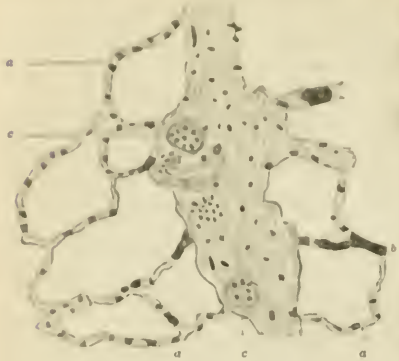
That from the peritoneal cavity was clear, slightly yellow in color, and contained a very minute amount of sediment, which consisted of leucocytes and epithelial cells, the usual elements of serous exudations.

The fluids from the thoracic and cranial cavities separated into three layers, the upper, an opaque, white, and thick liquid, contained numerous minute granules and oil-globules of various sizes; the middle stratum was formed by a red liquid, and the lowest, or sediment, was red in color, and was composed of white and red blood-corpuscles, with an occasional epithelial cell.

The blood from the great vessels and viscera deposited a dark red substance, consisting of blood-elements in large numbers; above this was a deeply colored, red fluid, and upon this again, floated a red, opaque thick liquid, in which the microscope revealed red blood-corpuscles, and numerous granules and oil-globules. The supernatant oily stratum in this and the former instances was equal to about one-sixth of the bulk of the fluid set aside for examination.

A thin section of the lung was made by the freezing microtome, after the alcohol used in hardening the tissue had been removed, by soaking in water. This was submitted to the action of one-tenth per cent. aqueous solution of perosmic acid. The object of freezing was to avoid the employment of wax and

oil as crystallizing agents, and so eliminate a source of error in estimating the effect of the staining. The section thus prepared was found to present the characters shown in the accompanying illustration.



It will be noticed that the capillaries in the alveolar walls have in their interior a material presenting itself in the form of small, generally spherical, collections (*a*), and stained deep black by the perosmic acid; a coloration proving the little masses to be fatty in nature. At some points the fat has accumulated in oblong branching masses (*b*), suggesting very evidently, the filling of the capillary blood-vessels and their collateral branches. Transverse sections of the small arteries (*c*) in the larger trabecula of fibrous tissue have their lumen congested, and among the blood corpuscles are seen globules of fat, stained black by the acid. The microscope, therefore, demonstrated the fact that the pulmonary blood-vessels were occluded by fat emboli, a result to be anticipated from the state of the blood.

In addition to the plugging of the capillary vessels, the examination of a carmine-stained section of the lung showed the characteristics indicative of croupous pneumonia. To determine that the appearances caused by the perosmic acid were not due to a fatty metamorphosis of the cells filling the alveoli—a pathological change well known to take place during the course of croupous pneumonia—a section taken from the lung of a patient dying of croupous pneumonia, at about the same stage of the disease, was similarly prepared. This presented none of the peculiar features observed in the lung of the diabetic.

Sections from the liver and kidneys were cut and stained in the same manner as that from the lung, and showed, under the microscope, an identical, though less extensive, plugging of the blood-vessels by fat emboli.

A section from the liver, stained by carmine, showed a marked degree of interstitial hepatitis. Both the inter- and intra-lobular fibrous connective tissue were found to be decidedly increased in amount. The cells constituting the parenchyma of the gland were more granular than normal; the nuclei, in many instances, being concealed by this granular condition of the protoplasm. A pigmentation of many of the hepatic cells, by bile coloring matter, was also evident.

In a carmine stained section from the kidney it was noted that the cells lining most of the uriniferous tubules were in an advanced stage of granular change. This change was so great in many of the cells that they had refused the staining and were yellowish in aspect. The interlobular tissue was much increased in amount, separating the tubules to a considerable extent, and its fibrous nature was very apparent. The adventitia of the blood-vessels was manifestly thickened; so, too, were the capsules of the Malpighian bodies. These alterations established the existence of interstitial nephritis, with granular degeneration of the parenchymatous cells.

A transverse section of the medulla oblongata, stained with carmine, presented very marked alterations of the nerve-cells. In place of the angular, polar, or multipolar, distinctly nucleated and nucleolated nerve-cells of the normal condition, there were seen round and oval, structureless or hyaline, slightly yellow cells without nuclei, nucleoli, or polar prolongations. The altered appearance of the cells was not confined to any special group, but was observed throughout the whole section. At the same time, although the change was general, it was not equal at all points. For example, in the gray substance of the olivary bodies the cells were all more or less altered, while in most or in all of the other gray masses of the section there were some cells possessing prolongations, having nuclei and nucleoli, and being free from hyaline change, in a word, being normal. The whole section gave an impression of being more granular than usual; this, perhaps, was due to the treatment necessary in preparing it for microscopical examination. The blood-vessels were thought to show increased cell-proliferation in their endothelium, for when seen in transverse section the number of nuclei, colored by the carmine, was greater than in vessels of the same size in health. The epithelial lining of the floor of the fourth ventricle showed nothing abnormal.

A section from the semilunar ganglion, stained by carmine, exhibited no pathological change.

DR. ALBERT O. HEYL'S REPORT.

The patient presented himself for examination on November 11, 1879. Examination with the ophthalmoscope showed that there were opacities in each crystalline lens; the pupils were dilated with atropia, and it was then found that the nucleus of each lens was opaque; the cortical structure, though sufficiently clear for examination of the interior of each eye, was traversed by radiating spikes of opaque lens tissue.

The moment my eye caught the details of the fundus, I saw the remarkable appearance which I shall endeavor to describe. The appearance was the same in each eye, and I was able, through the skill of Dr. Charles B. Nancrede, to obtain a very accurate painting of it. This picture was presented at a meeting of the Philadelphia County Medical Society, held January 30, 1880. I regret that it is not available for illustration of the following description:

The fundus was free from any evidence of the existence or pre-existence of inflammation; the nerve margin was well defined, the vessels were not tortuous; no retinal lesion, no hemorrhagic clots were seen.

The abnormal appearances which attracted attention were:

1. The abnormal color of the blood in the retinal vessels. As is well known, the retinal vessels are, with the exception of the optic papilla, the most striking objects seen in ophthalmoscopic examinations of normal eyes; the arteries being characterized by their small size and yellow-red color; the veins by their large size and dark, cinnabar-red color. Any

one not familiar with the actual appearances will easily recognize the distinction after a moment's examination of any good picture of a normal fundus. In this case, however, the vessels were all apparently of the same color; this color may be described as a light salmon. By color alone, then, the arteries could not be distinguished from the veins. This was the case when the light from the ophthalmoscope was thrown directly on the vessels; by rotating the handle of the mirror, so as to deflect the light, a dark axis could be seen in the large venous branches.

2. The apparently large diameter of the vessels. With regard to the exact mathematical increase in apparent diameter, a discussion at present would be out of place. The following general statement will suffice: the vessels appeared to have about twice the *normal* calibre.

This curious phenomenon may be explained satisfactorily in this way. When we examine the fundus of an eye we apparently see the full diameter of the vessels; accurately speaking this is not true. Could we examine the vessels under sufficiently favorable circumstances we should see a column of blood-corpuscles in the axis of the blood-stream, and surrounding this axial current a peripheral current composed of the plasma of the blood. Under ordinary circumstances this peripheral portion of the blood-current is invisible in ophthalmoscopic examinations; it can only be recognized by special search, so that what appears to be the diameter of the vessel is really the diameter of the axial current. Could we easily recognize the peripheral current the retinal vessels would seem to possess about double the calibre seen under ordinary circumstances.

In the case under consideration the serum of the blood was opaque, and therefore visible, by reason of the presence of fat in abnormal amount. Hence, the vessels appeared to possess double the usual calibre.

With regard to the general color of the fundus, the best idea of it may be obtained by taking Fig. 45 of Jaeger's ophthalmoscopic atlas to a well-lighted window, and allowing the sunlight to fall upon it. How much the lipæmia had to do with the general color of the fundus I cannot say; for the pigment of the fundus was sparse, and the patient, while not an albino, had very light, almost white, hair, light irides, etc. Under normal circumstances, of course, the fundus would have been of very light color. The examinations were generally made with an ordinary concave ophthalmoscopic mirror. The refraction of the eyes could not very accurately be determined, owing to the cloudy condition of the lens; it was, however, nearly emmetropic, perhaps a slight grade of hypermetropia existed. This condition, to which the name of *lipæmia retinalis* may be given, is therefore characterized by the light salmon color of the blood contained in the branches of retinal vein and artery, by the apparently large calibre of these vessels, and possibly by the very light color of the fundus oculi. These appearances being due to the presence of fat in abnormal amount in the serum of the blood.

This, probably, is the first case of the kind in which the fundus oculi has been copied and described, for after an extended examination of the literature of the subject I have failed to meet with a single reference to it.

While there can be no doubt of the existence of lipæmia and fat embolism in this case of diabetes, the share of the latter in producing the death of the patient is very uncertain, since, on account of his debilitated condition, the croupous pneumonia, though limited in extent, was quite sufficient to determine the fatal issue.

But the tendency to occlusion of the pulmonary capillaries may perhaps explain the peculiar depth and fulness of the respiration; characters which were observed on the date of admission, which slowly increased as the disease progressed, and which were greatly augmented by the onset of the pneumonia a short time before death.

The odor of acetone, described as resembling that of vinegar or stale beer, could not be detected either during life or at the autopsy, unless the vinous odor of the contents of the small intestine was of this nature.

ON THE RELATIONS OF NERVE AND MUSCLE.

By THOMAS W. POOLE, M.D.,

LINDSAY (ONT.), CANADA.

Why should it be taken for granted that the ordinary or extraordinary exercise of muscular contractile power is dependent upon a *stimulus* from the nervous system? Is there any *proof* of the alleged fact, and if so, where is it to be found? It will not do to accept such an opinion, because the response of the muscle to the will *seems* to justify it; nor yet because a few facts have been found, or perhaps, more properly, have been *construed*, to accord with it. On such a superficial view it might still be held that the sun rose and set, and we might be equally in error as to a great number of other natural phenomena, in regard to which appearances are notoriously deceptive.

The "stimulus" of electricity is often referred to as a counterpart of the "stimulus" of nerve-force, in its effects on the muscles. But where is the proof that electricity is a stimulus? Reasons why this agent is to be regarded as a paralyzer of nerve-function (while benefiting the muscle by exercising it), have already been given in the Medical Record (Nov. 1, 1879, p. 416), and need not be here discussed.

I am unable to point to any proof of the opinion generally accepted, that the relation of the nervous impulse to the muscle is that of a stimulus. On the other hand, there are a number of important facts opposed to it, and it seems apparent that all the relations of nerve and muscle may be much better explained on a very different theory and with very important practical results.

Among the facts opposed to the theory of the day (that muscular contraction is dependent upon a stimulus from the nervous system) the following may be briefly enumerated:

1. This theory fails to account for the actual contraction of the muscles in rigor mortis—a condition for which the myosin hypothesis fails to offer an explanation. (See recent article in Record, p. 451).

2. It fails to account for post-mortem muscular contraction, as when drowned persons are found clasped in each other's arms, or holding on to a cable or oar (Dr. Taylor's "Med. Juris."), or grasping straws, mud, or other objects; and for post-mortem muscular contraction in other cases of sudden death, examples of which will readily suggest themselves.

3. It fails to account for other remarkable post-mortem contractions in muscles and movements of limbs, numerous and well authenticated, particularly after death from cholera and yellow fever. (Dr. Carpenter, "Hum. Phys.," 7th Eng. ed., p. 763.)

4. The pulsations of the fœtal heart before the de-

velopment of the nervous system, or of nerves; the authenticated fact that muscular movements occur in anencephalic monsters, in whom the cerebro-spinal centres are wholly wanting; the occurrence of parturition as a post-mortem act, and its occurrence during life in the absence (from removal, or during paralyzing disease of the lower part of the spinal cord (Dr. Carpenter), are conditions not to be explained on the theory of the day.

5. The occurrence of muscular spasms, or "cramps," in the collapse of cholera, in the victims of poisoning by paralyzing agents, and in moribund patients from other causes, are facts antagonistic to this theory; for can it be believed that under such circumstances, the dying nerve-centres are generating and discharging an excess of nerve force wherewith to "stimulate" the muscles!

6. The "cramps" which so painfully knot in lumps the muscles of the limbs of the parturient woman, in the second stage of labor, owing to pressure on the pelvic nerves, must be regarded as due to an arrest, rather than to an increase, of nerve-force, and hence they supply a potent argument against this theory.

7. The spasmodic closure of the glottis from the poisonous inhalation of pure carbonic acid—a substance not shown to be an "irritant," and one certainly not conducive to the increased production of increased nerve-force, either directly or reflexly, is also a fact inimical to this theory.

8. The onset of spasms and convulsions when the motor nervous centres are deprived of blood, as in death by strangling, or from hemorrhage, or in the shambles, or on mere compression of the vertebral arteries, as in Sir A. Cooper's experiment, are facts adverse to this theory, because under these conditions nerve-force, instead of being unduly active to an extraordinary degree, must be regarded as undergoing a deprivation; for "it is a law in physiology that the functional activity of an organ is directly proportionate to the supply of arterial blood to the organ." (Dr. C. B. Radcliffe, "Lec. on Epilepsy," etc., p. 238.).

9. The counter-fact, that spasms and convulsions do not occur under circumstances favorable to the undue activity of the nervous centres (and consequently to increase of the alleged "stimulus" to muscle), namely, when "a determination of blood to the head" is artificially produced by ligature of the chief trunks leading to the extremities (Drs. Kussmaul and Tenner), or during a truly active state of the circulation (Dr. Radcliffe), is additionally adverse to that theory.

10. The theory of the day suffers materially from the fact that our best "antispasmodics" are "stimulants" Dr. Anstie), and that tremors, spasms (Dr. Radcliffe), and even tetanus (Dr. W. A. Hammond), are most successfully treated by "stimulants." If these states of muscular contraction depend on an excessive "stimulus" from the nerves to the muscles, the administration of drugs of this class, which are known to act specially on nervous tissue and to exalt its functional activity, would be not only injurious, but highly dangerous or fatal, instead of beneficial—a fact quite fatal to the theory.

11. The theory of the day necessitates the extraordinary and indefensible assumption that impure venous blood acts on the nervous centres in such a way as to prove more effectual for the generation of nerve-force than does pure arterial blood; as when Dr. J. Milner Fothergill asserts as follows:—"The more venous the blood, the greater the activity of this respiratory centre. The effect of venous blood is to augment the natural explosive decomposition of the nerve cells of the respiratory centre." ("Antag. of Ther. Agents," p. 80.) Accordingly, Dr. Fothergill almost makes it appear that having the vagi cut would be an advantage rather than otherwise, since thereby respiration is rendered "deeper and more prolonged, "fuller and more complete." So, also, defective "arterialization," we are told, results in "more perfect and extensive respiration" (p. 90). But, unfortunately, "rabbits, in which both vagi have been divided, commonly die before the end of the first day" (Dr. Burdon-Sanderson), a rather unfavorable consequence of the increased vigor thus given to their respiration.

The difficulty with the theory of the day here is, that as Dr. Burdon Sanderson shows, spasms and convulsions, not only of the respiratory muscles, but of the limbs and trunk, accompany the progress and mark the close of the asphyxiating process, and in the absence of other means for accounting for the extraordinary nervous "stimulus" required under the theory, to produce these contractions of the muscles, the presence of venous blood in the circulation is pressed into service and made to do duty as an assumed stimulant to the respiratory centre. But surely such an explanation is opposed to the plain teachings of physiology. Dr. Carpenter, while endorsing the idea that carbonic acid and venous blood act as a stimulus "to the pneumogastric nerves and to the respiratory centres," adds, "these parts are *unable to respond* to those impressions and to *originate motor impulses, unless duly supplied with oxygenated blood.*" ("Hum. Phys.," 7th ed., p. 327.) Dr. C. B. Radcliffe, F.R.S., denies that there is "any essential difference between the antecedents of convulsion from hemorrhage, and the antecedents of convulsion from suffocation. In the one case the vitality of the medulla oblongata fails as the blood streams away . . . . and in the other case the same results are brought about at a given moment by stoppage of the respiration and by the deficiency of arterial blood arising therefrom." ("Lec. on Epilepsy," etc., p. 116.) The "physiological law" of this author, quoted above, is also of special application here, and if it be true that "the functional activity of an organ is directly proportionate to the supply of arterial blood to the organ," then, in the face of these authorities and others which might be cited, it is difficult to see how the doctrine we are combating is to be maintained.

12. The theory of the day, when applied to nervous control over the muscular coats of the arteries, whereby their calibre is regulated, will be found completely out of joint with the facts of disease and drug action. For example, when the victim of cholera, or of aconite-poisoning is livid, cold, and pulseless, and the circulation is approaching a standstill, owing to undue contraction of the peripheral arterioles, these effects are attributable (on the theory) to *excitation* of the vaso-motor nerves, this being the assumed condition for vascular contraction. Indeed, Dr. Meryon, writing of the use of aconite in febrile states, says "it *stimulates* the dormant activity" of these nerves, and "by so doing diminishes the calibre of the arterioles." ("Rat. Therapeut.," p. 52). How absurd it is to assume an undue activity of any portion of the nervous system as the effect of a potent paralyzer, or amid profound prostration and collapse!

But more, an undoubted stimulant like brandy, which produces vascular dilatation and flushing, forsooth is a *paralyzer* of the vaso-motor nerves,—

for on the theory, arterial relaxation is the result of vaso-motor paralysis.

13. The theory now in vogue requires it to be believed that the arterial system is relaxed, or dilated when the nervous centres are destroyed, as by pithing, and it has been taught that such is really the case. The very opposite condition of arterial contraction and emptiness is here present, as the writer has proved by numerous experiments, and as Dr. Burdon-Sanderson's account of the experiment strongly confirms. (See MED. RECORD, Sept. 13, 1879, p. 248.) In other words, so far from the arterial muscle being dependent on nervous influence for its contraction, it contracts most effectually when the influence of the nervous centres is withdrawn, not only in death from pithing, but in death from general causes, for in death the arteries are invariably contracted and empty to the fullest extent possible (Dr. Carpenter).

14. On this theory it is impossible to account for the cure of congestive and inflammatory states—as pneumonia, for example—by the use of such drugs as aconite, veratrum viride, tartar emetic, morphia, and other "sedative" drugs, because (on that theory) the contraction of the dilated arterioles which it is desired to bring about, is to be sought for in *excitation* of the vaso-motor nerves, and these drugs are not excitors but paralyzers of nerve-function.

15. Dr. C. H. Bastian furnishes a remarkable illustration, not only of the absurdity of this theory, but also of the courage with which the theory is adhered to under unfavorable conditions. In his "Paralysis from Brain Disease," p. 27, he refers to a condition of the cerebral hemispheres in which the "nerve elements" suffer a functional "damage or derangement, which for a time hinders their proper life-changes, and so puts a temporary stop to their functional manifestations." That is, of course, a state of temporary paralysis. But associated with this condition, and depending on it, he finds the jerkings of chorea and the spasms of unilateral convulsions. Without pausing to reflect on this association of cerebral paralysis with muscular spasm, he rushes to the conclusion that "a large amount of nervous energy is liberated in the cerebral hemispheres"—just seen to be functionally paralyzed—"and a rapid down-rush occurs upon the motor ganglia." This sudden "down rush" or "discharge" of nerve-force, of course furnishes the necessary "stimulus" to throw the muscles into spasm or convulsion. And it is evoked from "nerve-elements" whose "proper life-changes" are "hindered," and whose "functional manifestations" have been stopped! And this is medical "science" as taught in the light of the theory of the day!

16. On this theory it is impossible to account for the results of the experiments of Dr. Brown-Séquard, in one of which it was shown that the lifting power of the muscles of a frog's hind leg was increased during some hours to nearly two and a half times, after division of its spinal cord, compared with its lifting power previously; and in another experiment the muscular irritability was increased (that is, the muscles were "seen to be more apt to enter into a state of contraction") after division of their principal motor nerve. As a result of these experiments, taken in connection with those of Sir A. Cooper and Drs. Kussmaul and Tenner, Dr. C. B. Radcliffe, F.R.S., arrives at the conclusion that "there is reason to believe that ordinary muscular contraction is associated with deprivation of nervous influence;" and even further, "that the power of muscular contraction is inversely related to the amount of nervous influence supplied to the muscles from the great nerve-centres." ("Lec. on Epilep.," etc., pp. 95, 100.) The conclusion thus arrived at found support from Dr. Anstie, editor of the London *Practitioner*, who, with these facts before him, wrote, "*the true action of vital force would appear to be rather that of restraining muscular contraction than of exciting it.*" ("Stim. and Narcot.," p. 70.) Here are facts from eminent experimentalists, and conclusions from thoughtful writers, in marked antagonism to the present theory of the relations of nerve and muscle.

17. Certain leading physiologists teach a doctrine highly unfavorable to the theory of the day. The "property of contractility" in muscle is said by Dr. Carpenter to be of two kinds—irritability and tonicity; the former denoting that form of contractility "tending to alternate with relaxation," of which the "most obvious and striking manifestations present themselves in the voluntary muscles and heart," and the latter—tonicity—distinguished by "a tendency to moderate and permanent [or passive] contraction." ("Human Phys.," 5th Amer. ed., p. 317.) Both of these forms of contractility are declared to be "an inherent property of the tissue itself" (p. 331).

Dr. Carpenter combats the doctrine "taught by some physiologists that muscles, though not dependent on nerves for their peculiar vital power [of contractility] are yet dependent upon them for the exercise of that power (Ib., p. 331). This is to assert that muscles are neither dependent upon the nervous system for their peculiar power of contractility, nor for their power to exercise it, which is a proposition antagonistic to the theory under discussion.

Drs. Todd and Bowman assert that "contractility is a property of the living muscular tissue as such;" and they "protest against the doctrine which assigns the spinal cord as the source of muscular irritability," and add: "It is contrary to all analogy to assign to one tissue the power of conferring vital properties on another." They say, "Surely, it is too much to suppose that a tissue like muscle, so complex in its chemical composition and so *exquisitely organized for the development of its proper force*, should be dependent on the nervous system, or a portion of it, for its contractile power." ("Phys. Anat.," Amer. ed., p. 303.)

These strong assertions of the Hallerian doctrine, that the property of contractility is inherent in the muscle itself, were the outcome of arguments intended to combat the views of Prof. Muller, Dr. M. Hall, Funcke, Eckhard, Jaccoud, and others, who maintained what many authors still maintain (Prof. Kuss), that the various so-called "excitants" or "stimuli" (such as a pinch, burn, corrosion of an acid, and electricity) which were found to induce muscular contraction, produce this effect not through their action on the muscle itself, but through the agency of the terminations of the motor nerves and their nuclei, which penetrate the muscular fibres. But in asserting so much, the physiologists just quoted, and their copyists, assert too much for the theory they elsewhere uphold. For if the property of contractility is thus amply provided for in the muscle, there is no need for it to be supplemented by the action of the nerve, especially since "it is contrary to all analogy for one tissue to confer vital properties on another."

The foregoing observations by no means exhaust the list of objections and difficulties which attach to the theory of the day on the relations of nerve and muscle. So far as the writer is aware, these objec-

tions have been fairly stated. If they are valid, that theory must eventually give way to one more in accordance with the facts, and to facilitate such an object, some suggestions in aid of a different theory will now be presented to the reader.

(*To be continued.*)

ON THE REMOVAL OF PARTICLES OF STEEL OR IRON FROM THE VITREOUS CHAMBER BY MEANS OF MAGNETS.

By EMIL GRUENING, M.D.,

SURGEON NEW YORK EYE AND EAR INFIRMARY, OPHTHALMIC SURGEON TO THE MT. SINAI AND THE GERMAN HOSPITALS.

THE passage of a foreign body into the vitreous chamber is justly regarded as one of the most serious accidents to the eye. Encapsulation or tolerance of the foreign substance is of very rare occurrence, and, in the vast majority of cases, not only is the injured organ lost, but its fellow threatened by sympathetic ophthalmia. Generally speaking, the indications in cases of recent injury, complicated with the lodgment of foreign particles, are, extraction of the body, and this failing, enucleation of the eyeball. Attempts at extraction by means of the instruments ordinarily employed (forceps, scoops, hooks, etc.) have so rarely been successful, that some surgeons disregard the first indication, and proceed at once to enucleate the injured eye. The most recent "Guide to diseases of the eye" (Nettleship) presents the status of the question as follows: "If it is certain that the foreign body has passed into the vitreous, whether through the lens or not, and whether by gunshot or not, it is scarcely ever worth while to attempt to save the eye."

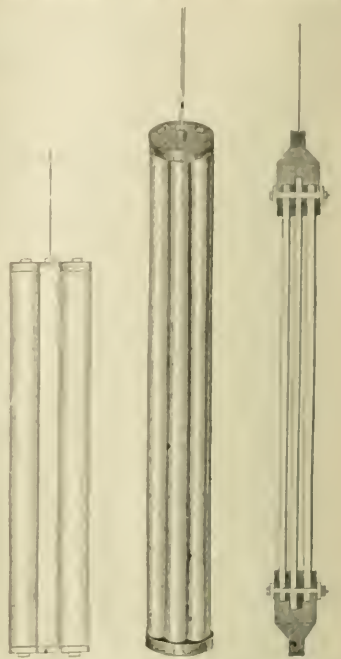
McKeown, of Belfast, was the first to introduce a magnet into the vitreous, for the purpose of extracting therefrom particles of steel or iron. (*British Medical Journal*, 1874.) Though he succeeded perfectly in removing the foreign body, and in saving the eye, yet his recommendation of the magnet as an extractor did not procure for it a favorable reception. In a subsequent publication (*Dublin Journal of Medical Sciences*, 1876) he reports two additional cases, the one terminating in atrophy of the globe, the other in suppuration. Manz, who made an abstract of the first of these cases (Virchow und Hirsch, *Jahresbericht*, 1875), remarked that although the object of the operation had been accomplished, the body extracted, and the eye but slightly injured, still the magnet employed could not be considered a trustworthy instrument.

The reason, then, why McKeown's method did not receive the favor which it merited, will be found in the circumstance that the particular magnetic instrument used by him was not suitable to the purpose. The magnet is described as being about eight inches long, one inch broad, one line thick, and tapering to a point at both extremities.

In 1879, Hirschberg (*Berliner Klinische Wochenschrift*, No. 46, 1879) successfully removed a piece of iron, 3 mm. long and 2 mm. broad, from the vitreous chamber, by means of an electro-magnet constructed for the purpose. The magnet consisted of a hollow cylinder of malleable iron, the two extremities of which were drawn out into long, fine points, like the branches of an iris forceps. The cylinder was surrounded by a coil which connected with a galvanic battery. Either of the poles of this electro-magnet easily sustained the weight of a small key, and attracted iron chips, 1 to 5 mm. long, at a distance of 1 to 4 mm.

Hirschberg's case excited much interest because it demonstrated clearly that a magnetic instrument, sufficiently delicate to be safely introduced into the eye, may still possess such powerful polarity as to extract particles of iron or steel from the vitreous without toil or trouble.

For some time past I have been experimenting with various forms of magnetic apparatus with a view of constructing an instrument that would concentrate the greatest possible magnetic polarity in the least possible dimensions. In my first trials I made use



of well magnetized solid steel cylinders, one extremity of which had been filed into a long, slender, needle-like point. The latter, however, never exhibited sufficient magnetic polarity for the purpose in question, and, owing to the hard temper of the steel used in making good magnets, showed itself as brittle as glass, and broke upon the slightest provocation. Discarding the steel point, I had a long and delicate piece of malleable iron fitted into one extremity of the magnet. This slight alteration produced a more satisfactory instrument. Not only did the induced magnetism of the iron prove itself (ceteris paribus) more powerful than that of the steel point, but the fragility of the previously employed instrument had been removed also. In order to add still more to the magnetic polarity of the point, I joined several magnets into a bundle, thus making a powerful magnetic magazine. The principle of constructing such a magazine is old, the application of the apparatus for

the removal of fragments of iron or steel from the vitreous chamber, new. As shown in the cuts the two extremities of a number of magnetized steel rods placed parallel to, and at a little distance from each other, are fitted into iron caps, one of which is provided with a delicate point of malleable iron, 32 mm. long, 1 mm. wide, and 0.3 mm. thick. This point is powerfully magnetic, sustaining, with ease, a weight of 15 grammes. Chips of iron weighing from 1 to 50 centigrammes, when placed into the vitreous of recently enucleated animal eyes, are attracted toward the point at a distance of 1 to 5 mm., and withdrawn with the greatest facility. The instrument thus perfected *equals* Hirschberg's electro-magnet in efficiency, but *surpasses* it in simplicity of construction, convenience of form, and lowness of price.

The figures represent three different forms of the instrument made for me by the Galvano-Faradic Manufacturing Company, No. 288 4th Avenue, New York.

Progress of Medical Science.

Amyloid Degeneration.—According to recent experiments by Mr. Budd, lardacein, or waxy substance, presents three distinct peculiarities, and the most peculiar of them all is its faculty for wholly resisting the action of ordinary digestive fluids. This, indeed, is its most specific characteristic. It exhibits a mahogany hue when treated with iodine, and is colored dark blue by the joint action of iodine and sulphuric acid; but the latter peculiarities (seeing that they are possessed by other substances also), are only specific in degree. Dr. Dickinson's theory explains only the brown coloration with iodine. He supposes that waxy substance is dealkalized fibrin (acid albumen, in fact), prolonged suppuration withdrawing large quantities of alkali from the blood. Mr. Budd found in the dystropodextrin of Seegen, a substance whose deterioration might easily lead to a morbid infiltration, answering to all the characteristics of lardacein. This substance is a dextrin, and is produced in large quantities wherever the amylolytic metamorphosis of glycogen takes place. Dystropodextrin is first set free in the liver; that organ is, perhaps, the commonest seat of waxy degeneration. The author thinks it quite probable that waxy deposits may be a mixture of perverted dextrins—dystropodextrin, however, predominating and lending to the compound its stubborn characteristics. Lardacein is stained dark brown by iodine, but upon the addition of an alkali the color vanishes. It may, however, be restored by the superaddition of acid. Dr. Dickinson argued that the brown coloration was due to the acidity of waxy substance, and inferred that this was neutralized by the alkali, and again renewed by the acid. Mr. Budd's conjoined chemical and microscopical investigations prove that the changes are due to the action of alkali upon iodine. Hence Dr. Dickinson's theory has been founded upon a misinterpretation of a series of simple chemical combinations. The formula which has been hitherto supposed to represent the composition of the infiltration is an erroneous one, representing a mixture of a morbid substance with original cell matter. Dystropodextrin, normally present in the blood, agrees with the infiltration in its most essential characteristic, viz., its total disregard for all fermentative influence.—*The Lancet*, Feb. 28 and March 27, 1880.

"Double-Staining" in Microscopical Investigation.—The employment of staining agents in the preparation of animal tissues for microscopical examination has been one of the most useful advances in this branch of science. Histologists were not long in finding out what might well have been predicted, that different tissues with varying chemical reactions are differently acted upon by various staining fluids, and this fact has for some time been used to assist them in the differentiation of tissues. The number of staining agents has of late years become considerably increased, and a good deal of attention has been expended upon perfecting their use. At a recent meeting of the Royal Microscopical Society, Dr. Gibbes explained the processes by which he is able to stain a single section in more than one color, getting each tissue in the section stained a different tint. Dr. Gibbes is able to get treble and even quadruple staining. Thus, among other specimens he showed transverse sections of the rat's tail, in which the bone, cartilage, nerves, tendon cells, muscle, and blood-vessels, which had different chemical reactions, were each stained a distinctly different color. For double-staining, successive immersion in solutions of picro-carmine and logwood may be used; or better, immersion first in a spirituous solution of roseine or aniline violet, and then in an aqueous solution of aniline blue or iodine green. To stain with more than two colors is much more difficult; the best results are obtained by first staining in chloride of gold or picro-carmine, and then in the spirituous and aqueous solutions of anilines. The value of these results will be apparent to all engaged in elaborate histological investigations.—*The Lancet*, March 20, 1880.

Acute Nephritis in Typhoid Fever.—At a recent meeting of the London Clinical Society, a case of this kind was reported. A porter, aged 21, was admitted into the Middlesex Hospital, under Dr. Greenhow's care, on Nov. 25, 1879, the fifth day of a fever, which set in with considerable severity, the second day of the attack being marked by vomiting, cough, and slight sore throat; and in the night he began to have painful micturition, and noticed that his urine was almost black in color. On admission, pulse 108; temperature 103.2°; urine, sp. gr. 1012, of a deep red color, from admixture with blood containing albumen—one-half, numerous blood-globules, blood and epithelial casts. He was very prostrate and suffered from muscular pains. There was impaired resonance with bronchial breathing and scanty crepitation at the apex of the right lung, but there were no râles elsewhere. The cardiac second sound was reduplicate. Abdomen was tympanitic, and there was tenderness and gurgling in the right iliac fossa. The liver and spleen were not enlarged. There were neither diarrhœa nor rose-spots. Cold sponging was ordered and fluid diet. At 9 P.M., pulse 126; temperature 104 6°. The illness ran a rapid course, prostration increased, the pulse-rate ranged between 100 and 130; temperature 97.6° to 104.8°. Restlessness and delirium passing toward the close into somnolence with occasional subsultus in arms and legs, were observed. Tongue became dry and fissured. Urine continued to be blood-stained, but the amount of blood and albumen diminished. The abdominal distention persisted, and characteristic diarrhœa appeared on the 27th, continuing until death, which took place on Dec. 8th, the thirteenth day of his illness. The autopsy revealed mitral thickening and enlargement of the

heart and marked pulmonary hypostasis. Two or three sloughing ulcers occurred at the lower end of the ileum, and one in the healing stage. Peyer's glands and the solitary follicles being elsewhere swollen. Liver and spleen greatly enlarged and softened. Kidneys, weighing twelve and fourteen ounces respectively, were intensely gorged, their secreting tubules were filled with swollen granular epithelium, and between the tubules there was small-celled infiltration. Dr Greenhow remarked that he had not met with a similar instance. Albuminuria, when it occurs, is usually a late event in typhoid fever, according to Liebermeister, not until the fever has reached its height; and Murchison says it rarely appears sooner than the third week, and is due either to congestion or to parenchymatous degeneration, not as due to acute nephritis. Dr. Murchison also says that when copious hæmaturia occurs it is generally associated with other hemorrhages. The points of chief interest were the concurrence of typhoid fever with such intense nephritis, the entire absence of dropsy, and the severe and rapid course of the disease.—*The Lancet*, March 20, 1880.

Melanotic Epithelioma of Penis. Dr. Gould reports a case of this kind where amputation, followed by recovery, was performed. A laborer, admitted to Westminster Hospital, had noticed nothing wrong with his penis until about five years before, when a small black spot appeared on the glans penis. It gradually increased in size; other similar growths had sprung up around the first. For a few months past he had experienced difficulty and pain in micturition, but with this exception, had been free from pain. No hemorrhage. No history of cancer or tumor in the family. On admission, the penis presented four or five raised black nodules the size of peas, ranged along the corona, while farther forward on the dorsum of the glans was a much larger black fungating mass, which quite obscured the glans. Two or three smaller tumors of the same color were seen higher up the penis, not projecting from the surface. No enlargement of inguinal or lumbar glands; no evidence of any growth in the lungs. Thickly scattered over the man's back were a number of pendulous warts and little molluscous tumors, nearly all of which were deeply pigmented, if not quite black. These, the man stated, had existed all his life. Amputation by the wire écraseur; rapid recovery. The growth, as determined by microscopical investigation, proved to be a melanoid epithelioma. The superficial epithelium could be traced growing down and becoming pigmented and continuous with the tissue of the deeper parts of the tumor. A peculiarity of the tumor was its early benign character. It had existed five years without any sign of lymphatic injection or secondary growth.

Clinical Hemometry. — From Drs. Baxter and Willcock's series of interesting papers on this subject, we extract the following: It has been supposed by many that the richness in hæmoglobin of the blood was always proportionate to its richness in corpuscles. The truth seems to be that although in health the two usually vary together, in disease the normal ratio between them may altogether cease to be maintained. Duncan first saw the possibility of anæmia being developed in one of several modes—by a diminution of the corpuscles, by an impoverishment of the individual corpuscle, or by a combination of the two. The first of these modes is called a *hypocytosis*, the second a *hypochrosis*. Hence, the obvious need of chromometry—the direct valuation of the hæmoglobin—to supplement the results of numeration. The normal average of corpuscles per cubic millimetre is usually put at 5,000,000, in conformity with Welcker's estimate. The authors are disposed to put it nearer 6,000,000. There is a striking absence of agreement on this point among authors, which ought, in large measure, to be attributed to instrumental error. Apart from this, it must be remembered that the proportion of corpuscles per cubic millimetre of blood is known to be affected by a great variety of conditions within the limits of health. The influence of age, sex, season, diet, purging, sweating, etc., all make themselves felt. Hence, clinical inferences should be drawn only in gross deviations from the normal standard, such as exceed the possible limits both of physiological variation and of instrumental error. The observations made by the authors are grouped under three heads: first, those made in acute febrile diseases; secondly, in chronic diseases, thirdly, in those pathological conditions in which the blood is either the primary seat of the morbid process, or, at any rate, the theatre of its most conspicuous manifestations. The general conclusions drawn from the various observations comprised in the first group, were of an unexpectedly negative kind. Enteric fever, even when it immediately threatened life, did not appear to affect either the number or the quality of the red corpuscles to any marked extent. In marked contrast to the immunity of the red corpuscles in all the pyrexial disorders, is their liability to destruction in malarial fever. In the malignant form of paludal fever, the rapidity of corpuscular disintegration is proportionate to the previous good health of the patient. On recovery from an attack of this kind, the restoration of the corpuscles is usually pretty rapid. The destruction of the red corpuscles is not dependent on the pyrexia as such, though it probably stands in close relation to the melanæmia, which is so frequent a consequence of the endemic fevers of marshy districts. The conclusions with regard to malaria are borrowed from Kelsch (*Arch. de Phys.*, vol. ii., 1875), the authors not having had an opportunity to substantiate them. In diabetes mellitus, an excess of red corpuscles, coupled with a low individual value, was observed. In internal cancer, the authors believe that the most extreme cachexia need not of necessity entail any marked impoverishment of the blood—at any rate, as regards its most important constituent. Decided diminution in the amount of hæmoglobin was found in chronic renal disease. The mere existence of valvular insufficiency did not necessarily entail impoverishment of the blood. In anæmia from hemorrhage, hypochrosis, as well as hypocytosis, occurred. In the order of recovery, the latter apparently took precedence of the former. As regards chlorosis, the statement is made that while hypocytosis and hypochrosis coexist, the latter is always in excess of the former, and that under the influence of iron the increase in the number of corpuscles usually precedes the increase in their individual value, though both factors are affected by the remedy. It is interesting to note that the patient's symptoms are always relieved when the number of corpuscles attains its normal level, even though their individual value show no corresponding improvement.—*The Lancet*, March 6, 13, 20, 1880.

Professor F. T. Miles has resigned the chair of anatomy in the University of Maryland, and has accepted the chair of physiology in the same school.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, May 1, 1880.

THE PHARMACOPŒIA CONVENTION.

THE convention that is to meet in Washington on the fifth inst., to provide for a revision of the United States Pharmacopœia will attract, from all parts of the country, gentlemen interested in the matter.

The delegates, judging from the names already published, are particularly well qualified for the task before them; in fact the convention will be pre-eminently an assembly of experts in materia medica and pharmacy. While some possess special qualifications and information in materia medica, embracing, as it does, the properties and actions of drugs, and others are experts in their pharmaceutical manipulation, still others are reasonably familiar with both these branches. There is no lack then, of requisite talent in the convention to enable it to properly care for the interests committed to its charge. These interests are by no means trivial, and are of special importance to the medical profession. A good pharmacopœia is the groundwork of successful therapeutics, as much as good building materials are the first requisites for the construction of a safe and substantial edifice. No matter how learned the physician, no matter how much knowledge and care he brings to the management of a case of disease, his success will be but indifferent if he have not ready access to the drugs best suited to his purpose, and preparations of them that best display their medicinal properties. These are the ends that it should be the object of the convention to secure. It may be safely said that our present Pharmacopœia is far behind the requirements of the day, and stands in need of very general revision and improvement. At present it is a work rarely owned and still less rarely consulted by the physician. It should be one that he would find practically useful, if not indispensable.

The need of pharmacopœial revision was first prominently urged on the profession a few years ago by a gentleman eminently qualified to give sound advice on the subject, and yet when the matter was considered in the American Medical Association, private interests came to the front and succeeded in defeating what appeared to be an important step in the right direction. The action, or rather lack of action taken by the association necessitates a continuance of the old plan of pharmacopœial revision. This plan, properly carried out, is not a bad one, as it brings together the representatives of the medical and pharmaceutical professions, both of which are interested in the scheme, each, however, from a different standpoint. It is to this body then that we are to look for action that will result in giving us a pharmacopœia worthy of the country, and one that every physician will feel it to his interest to possess. The mutual interdependence of the medical and pharmaceutical professions should lead both to seek to promote each other's advantage, knowing that the success of the one aids the advancement of the other. The interests involved in the present matter are too important and grave to be lightly considered, or to be decided in any other way than shall seem most conducive to the public good.

The chief work of the convention will be, we suppose, the determination of the principles that shall govern the revision, and the appointment of a committee to carry them out.

The constitution of this committee is important. It should comprise about an equal number of physicians and pharmacists, who should be selected on the sole ground of fitness for the work to be required of them, and its members should possess the requisite energy and willingness to do their entire duty, and not, like the last committee, shirk a portion of its assigned work without adequate excuse.

THE DISCUSSION ON THE PROBLEMS OF INSANITY.

THE obscurity of any question is generally a very good measure of the extent to which it is discussed. This is a fact which has been well illustrated recently by the prolonged debates upon the problems of insanity which have occupied three meetings of the Medico-Legal Society. The paper by Dr. Beard on the above subject, was a more than ordinary piece of work, as was shown by the interest it excited. The questions in the paper were treated with the acuteness and philosophic spirit which generally characterize the writings of its author. If he displayed at times more epigrammatic smartness than scientific accuracy, the paper was, at least, made no less interesting by the fact.

The discussion which followed it was, on the whole, an unsatisfactory one. It cannot be said that it settled anything, except the Gosling case. Mr. Abraham Gosling was decided to be insane, and he will either be dead, we are told, in about three years, or there will be one diploma less in this city. He is a brave man who dares take another view than this now. But, in addition to a fiat upon this matter,

the Society by its discussion, brought out a good many facts of interest regarding the various problems in the essay read before it.

We have not space to go over all the points taken up by the Society, but there are two or three which have an especial interest, and which may be worth referring to briefly.

To define insanity has been said to be, on the one hand, absolutely necessary, and, on the other, absolutely impossible. The necessity is a medico-legal one, and is felt every time that a case of insanity is brought into court. The impossibility is alleged to be due to the fact that insanity is an elusive and variable quantity. Dr Beard seemed to feel the necessity of a definition more strongly than its impossibility, and his solution proposed the following constant to the variable: "Insanity is a disease of the brain in which mental co-ordination is seriously impaired."

The criticisms which were showered upon this definition may be best indicated by an amended definition which was finally offered and which runs something like this: "Insanity is a manifestation of a disease of the brain in which, while consciousness is retained, mental co-ordination or responsibility is seriously impaired, perverted, or extinguished." While some of these amendments may be technically essential, they are none of them so important as to change the general character of the definition, or take from the author whatever credit it may give him. We believe it will be found, however, that the real defect of the definition is that it does not define at all, but simply puts an equally unknown term in the predicate. Insanity is the expression of mental inco-ordination. But what is co-ordination or inco-ordination? To this Dr. Beard says he cannot answer, nor, he added, could he do so, if all the kingdoms, and principalities, and powers of this earth were offered him as an incentive. Still, for all that, it was urged, we know what co-ordination is, although we cannot define it. But even if this is admitted, we can say very much the same about insanity. Most persons can tell it, although none can define it.

A definition must indicate the boundary lines of its subject. We do not define a thing when we predicate an undefinable synonym of it. We shall not deny that the definition under discussion may, when modified, prove a good working one in spite of the defects suggested. There is a specious clearness and simplicity about it, and before a court, the nebulousness of the idea which "mental inco-ordination" presents may be considered as due to a lack of scientific training on the part of the court. A medical expert is expected to define insanity; but when it comes to such a word as inco-ordination he may well assert that this is a thing of general lexicographical interest upon which he should not be called to show expertness.

Of the other subjects discussed there was one that calls loud to being satisfactorily settled. This was the question as to whether insanity is increasing in greater proportion than the population. The evidence on the whole was to the effect that such an increase is taking place in most civilized countries. Whatever may be the fact of the matter as regards insanity generally, there is no doubt of the alarming increase in our country, and our calculations and provisions must be based upon this fact.

The statement of Dr Beard that this increase is due in the main to the friction of modern civilization was not successfully confuted. But the statement is too general to be of much practical value. The specific charge, however, that woman's intellectual elevation is a potent cause of insanity as well as of race deterioration, will be hard to prove, and will meet no small opposition from a certain portion of the ladies.

But we have not space for enlarging upon this point now. Enough has been said to show the very suggestive character of the paper. Its influence will not be likely to end with the series of discussions which it evoked.

THE UNDERTAKER AS AN ARTIST.

It has been reserved for the present century to attempt an elevation of the undertaker to the position of an artist. Such an attempt may appear novel, but it is quite a legitimate one, and only indicates a natural awakening to the wider demands of our present civilization. The evolution of society from the homogeneous and simple to the heterogeneous and complex should not, and does not, exclude the undertaker in its readjustments. It may have been noticed that when it is proposed to discuss a subject philosophically, a popular custom is to announce that this particular thing is the barometer of civilization. It has in this way been discovered that civilization has a great many barometers. But we venture to say that none will give greater satisfaction than the undertaker, whom we now place on the list. The function and duties of this person have, as a rule, been simple or complex in accordance with the character of the society in which he lives. At present, when fashion coquets with death, and rules mortuary observances as strictly as the style of bonnets, the undertaker has to be a very live man to keep up with his work. It requires no inconsiderable skill to have everything done with decency and in good form. We are rather of the opinion, therefore, that the undertaker has not been credited with all that is due him. He is apt to be looked upon at present in a too lugubrious light—as one of the sad necessities that accompany extinction, or as answering, to a certain extent, the apostolic query: Where is the sting of death? He has never, by any accident, been looked at as an artist; and yet such, without doubt, is to be

the position of the undertaker of the future. This we have, to a large extent, on the authority of the State Board of Health of New Jersey, for it is in sanitary matters that his work is to expand to the symmetry and coherence of an art. The undertaker ought to know, and will know, when an artist, all about the facts of contagion, and the best methods of disinfection; he will be able to apply the tests of death; he will know how to prepare the body so that it will be inoffensive and incapable of spreading disease. He will understand the nature of cemetery soils, and will be able to tell how long a time will be required for the body's decomposition and disappearance. He will prepare and encase the body also, so that, according as may be desired, it will remain unchanged in its tomb, or will be rapidly absorbed by the surrounding soil. In fact, in addition to superintending the details of and preparations for an artistic interment, he will do everything that science requires to make the passage of the body from the death-bed to the tomb harmless to the living, and as little painful to the feelings of the bereaved or the æsthetic sense of the world in general, as possible.

It will be seen that in this new field there is now much for the undertaker to accomplish, both for himself and the community, if he will only learn. Undertakers are licensed in some States; as this tends to secure a more responsible body of men, it ought to be more generally the rule. In New Jersey, we learn, considerable interest has been shown by undertakers already, regarding the sanitary questions in which it is proposed they shall be instructed. A diffusion of this interest ought to take place, as it would undoubtedly tend to the security and health of the community.

THE REGISTRATION OF INFECTIOUS DISEASES IN ENGLAND.

In a report to the Parliamentary Bills Committee by its chairman, Mr. Ernest Hart, the progress of legislation upon the subject of registering infectious diseases is very elaborately given. The sanitary legislation of England is, on the whole, very perfect, the lack of a compulsory system of registering infectious diseases being perhaps its most prominent defect. Attempts have been made for several years to remedy this, and with some degree of success. The matter has been taken up by the British Medical Association, and as the influence of that body upon Parliament is daily growing stronger, it is to be expected that a thorough system of registration will before long be secured. There has been considerable opposition to the proposed legislation heretofore, because the idea of compelling a householder, or a medical man, to report upon the condition of a private family seemed something like the invasion of personal liberty and natural rights. This idea is, however, giving way before the evident advantage and reasonableness of having the existence of infectious disease at once made known and its dangers provided for. Already the system has been introduced into fourteen cities and towns, and its workings in these places have been eminently satisfactory. A number of bills to extend the law to other places were before Parliament at its recent session.

The English plan of registration differs from our own, as has been before stated in these columns, in its compelling the physician to give a certificate of the disease to the householder, who is then obliged to forward it to the proper health officer. The physician is paid from a shilling to a half-crown for his work.

The compulsory notification of infectious diseases almost always forms part of the sanitary regulations in our country, so far as such regulations exist at all. There are, however, some features in the English law which we might profitably copy. In the report before us a model clause is given for the benefit of communities desiring to secure legislation upon this subject. An examination of this model might be of much service to those interested in this particular question.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 1, 1880.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

A NEW TONSILLOTOME.

DR. FRANK H. HAMILTON exhibited a new tonsillotome, with preliminary remarks as follows upon hypertrophy of the tonsils, and supplementary to Dr. Leffert's excellent paper read before the Academy: From personal experience he regarded chronic hypertrophy of the tonsils as one of the manifestations of the strumous diathesis. He had scarcely seen it occur except in children who presented the general appearance seen in the condition called struma. He had noticed often that it was hereditary, and had known it to pass through several successive generations. He was not prepared to say that it generally had associated with it enlargement of the lymphatic glands in the neck. His impression was otherwise. Still, as he believed, that fact did not militate against the view that the condition belonged to the strumous diathesis. Again, the tonsils had a period of growth and decline. His impression was that the tonsils were seldom seen in early infants; they usually began to be seen at two, three, four, or five years of age, and reached the climax of growth from the tenth to the twelfth year, the period during which application was made to the surgeon most frequently for relief, and it was rare to see hypertrophy of the tonsils after the twentieth year of age, at all events, anything that demanded extirpation. The question of the removal of the tonsils was not in dispute, but perhaps the circumstances under which their removal was proper was yet at issue. He had been in the habit of saying that, inasmuch as they had prog-

ron and deafness, unless they occasioned serious inconvenience, there was no good reason why they should be removed. If, however they were the seat of frequent attacks of acute inflammation, or if they interfered seriously with deglutition or respiration when the child was lying down, or if they were subject to acute attacks of neuralgia, or if they interfered with hearing, or in any way interfered with the Eustachian tube, there was sufficient reason for their removal. With reference to hearing, it was well to consider whether the impairment was due to pressure produced by the enlarged tonsils or to continuous inflammation producing actual thickening of the mucous membrane of the tube and so preventing its action. He had noticed that removal of the tonsils did not at once improve hearing; but that a period of one or two years must elapse before the benefit was experienced. Removal of the tonsils when actually inflamed was not to be practised unless the patient was suffocating. Nor would he operate upon a person who was known to have a strong hemorrhagic diathesis, because of the liability to profuse hemorrhage. Dr. Hamilton then referred to three cases in which the hemorrhage was so considerable that it became alarming, all occurring in patients fourteen or fifteen years of age.

He then spoke of the different methods by which the tonsils have been extirpated, such as by the use of caustics, the ligature, and finally excision. He then described Velpeau's, Physic's, Warren's, Cox's, and Freman's tonsillotomes, and pointed out their defects. The instrument which he had employed, ever since beginning the practice of medicine and surgery, was a modification of Owen's tonsillotome, which he always suspected was really an instrument devised by that eminent surgeon, the late Dr. Alden March, of Albany.

The tonsil to be excised almost always hung a little downward. He had found it convenient to introduce the instrument into the mouth flatwise, with the face upward, then, after carrying it well back, turn it up edgeways, and in that manner the mouth was held open. He then passed his finger in, felt that the tonsil was properly engaged in the opening in the instrument, and when ready the guillotine was sent through the gland from *before backward*.

The President asked the indulgence of the Academy, while he referred to certain points in connection with chronic hypertrophy of the tonsils and its treatment. Inasmuch as no allusion had been made to one whose experience and extraordinary dexterity in manipulation had, perhaps, never been equalled, whatever may have been thought of his pathological views or practice, he would refer to the method of operating adopted by Dr Horace Green, because he thought that all that could be should be known relative to the operation for removal of the tonsils.

Dr. Green, after trying various methods, finally settled upon the following, which had been partially alluded to by Dr. Hamilton. His method was to seize the tonsil with a single hook, bring it forward, and then, with a bistoury, cut away the exact amount he wished to remove. He always operated upon the left tonsil first, standing in front of the patient, and cut from above downward. When the right tonsil was removed, he stood behind the patient, seized the gland, and cut from below upward. Scarcely ten seconds were required to perform the operation.

One fact which Dr. Green had noticed—and the President had made the same observation—was that the operation for removal of the right tonsil was the more painful of the two, and that there was more hemorrhage when the cut was made from below upward, than when made from above downward. Still, the removal of either tonsil was easily accomplished.

The President also believed the experience of all was, that in former times tonsils were often removed unnecessarily. He also believed that the tonsil had a period of increase, acme, and decrease. He had seen tonsils become very large, and in the course of a few years, the hypertrophy had entirely disappeared without special treatment. Furthermore, there were some objections to the operation for removal on account of the possible effect produced upon the voice. He thought removal was indicated not so much when the tonsils were simply hypertrophied as when there was disease of their interior structure, necessitating excision in order to effect a cure.

Dr. A. C. Post remarked that he had been in the habit of using the instrument made by Mr Freman, and had found that with it the tonsils could be removed with very great celerity, with ease to the surgeon, and but little discomfort to the patient.

NOTES OF FOUR CASES OF HIP-JOINT DISEASE IN THE THIRD STAGE.

Dr. A. B. Judson reported cases as indicated above, and presented three patients with the view to illustrate what could be accomplished by mechanical treatment of hip-joint disease. All were cases in which there was unquestionably complete destruction of the joint, and exaggerated evidence of general and local disturbance, and he thought that the results were sufficiently favorable to compare with the value claimed for exsection.

Case I.—A boy, seven years of age, had been diseased four years, when a long splint was adjusted without allowing the heel to reach the ground, and worn for one year. The constitutional disturbance was very severe, and cod liver-oil, ferruginous tonics, etc., were administered, and nutrition sustained to the highest possible degree. From the subsidence of the local disturbance, at the end of a year, it became evident that fixation was no longer required, and the patient was furnished with another instrument which he wore for three years, and walked with crutches.

Result.—An active, healthy schoolboy. Stiffening of the joint, but fast walking was not prevented. Motion at the joint limited to slight flexion, abduction, and adduction. Shortening half an inch distributed between the hip and knee. Limb smaller than its fellow. No evidence that the growth of the femur had been interrupted. Position of the femur that of slight flexion, but no abduction or adduction.

Case II.—Boy six years of age. Been under treatment eighteen months. Had worn short splint, been treated by means of weight and pulley, etc. Nine sinuses formed in the thigh. The long hip-splint was worn until it became evident that fixation was unnecessary.

Final result.—Marked limp in the gait, due partly to stiffness of the joint, and partly to shortening of the limb. No abduction or adduction. Motion in the joint limited to slight flexion and extension. Shortening one inch, distributed between the hip and knee. Limb somewhat smaller than its fellow, but its function was not materially affected. Spine free from curvatures. Slight discharge from one sinus.

Case III.—A girl. Defect in gait scarcely observable. What there was, was due to stiffness of the joint, and not to shortening of the limb. The position of the limb was good, with slight flexion, and no ab-

duction or adduction. Shortening one-fourth of an inch, part of which was in the tibia. Bones of the entire limb smaller than those in its fellow. No evidence that the development at the epiphyseal junction had been interrupted.

Case IV.—Boy nine years old. The case terminated fatally.

Out of sixty cases, chiefly in private practice, that had been under his observation, a number ceased to be treated, a few terminated fatally, and a number recovered. The four cases reported were in the third stage when he began treatment, and the results obtained he regarded as a fair average of what could be secured by mechanical treatment of a joint which might undergo destruction by inflammation that spared none of the tissues. The morbid action was not malignant. The open question was whether or not it was strumous. In two of the cases there was phthisis in the family. The principles of treatment were fixation of the joint for a time, protecting it from concussion and accident, general and hygienic treatment, such local treatment as might be indicated during the progress of the case, and trusting to nature to effect a cure. The results compared favorably with those obtained by exsection.

Dr. C. Fayette Taylor presented four patients, and commented briefly upon their history and the history of others whom he expected to be present.

Case I.—Mr. B——, a young man, came under treatment in 1871, and was discharged at the end of a year and a half. He had the history of hip-joint disease occurring four years previously, and was supposed to have been cured. He had two or three discharging abscesses, and one opened after treatment had been begun. His recovery had been remarkably rapid under the influence of mechanical treatment, and his cure was complete. In 1871, he was greatly emaciated, and his thigh was flexed at about a right angle with the trunk. He had perfect motion in the joint. As Dr. Taylor's memory served him, there was no shortening. He had found only a few cases in which there was not more or less difference in the length of the limbs, but if there was an inch shortening with perfect motion in the joint, it would not be observable. The case pointed to the curability of hip-joint disease with mechanical treatment after suppuration had been established.

Case II.—A boy came under treatment in 1876. He was still wearing what Dr. Taylor called the median splint, which was used particularly in cases in which a tendency to adduction was very great. The point of purchase in the median splint, a modification of Davis's splint, was against the pelvis upon the opposite side. The boy was recovering with anchylosis. There was considerable flexion.

Case III.—A lad came under observation in 1877, in the third stage of hip-joint disease. A number of sinuses discharged at the time treatment was begun, but all had closed. He had a fair amount of motion, and was still wearing the supporting apparatus. Dr. Taylor regarded it as important to protect the joint for considerable time after extension became unnecessary, and the median splint, or instrument, which the boy was wearing, was constructed for that purpose.

Case IV.—A boy, seven or eight years old, was, last summer, a fit subject for excision of the hip-joint, and the case bore directly upon the question, as to whether or not a patient could be restored to fair health after being in a condition which would have justified excision. His general condition had so much improved that he was looking very well. When treatment was begun, his legs were strongly adducted, and pus was discharging from several sinuses. All the sinuses except one had closed. He was wearing the long counter-extension splint on both legs, and the adjustment at the upper part was so made as to leave openings through which the discharge could pass without hindrance. His legs had been brought down parallel with each other, and the boy walked with crutches.

The cases were presented as average illustrations of what could be accomplished by mechanical treatment.

Dr. C. T. Poore thought that calling all cases of suppuration the third stage of hip-joint disease was an error, for suppuration might occur outside of the joint. Observers should, therefore, be more definite when speaking of the symptoms of the third stage.

With reference to excision, he was unable to boast of any very good results. But from his cases he thought several inferences might be drawn. He had excised the hip-joint thirteen times. *Four* of the patients were cured, and the remainder died. *One* died from phthisis, *four* from amyloid degeneration, *one* from cardiac thrombosis, *one* from tubercular meningitis, and *one* from exhaustion.

He thought the deaths from amyloid degeneration were due to constitutional causes. He had seen a patient with only a moderate amount of disease in the hip-joint, which soon showed evidences of amyloid degeneration of internal organs, and at autopsy, amyloid degeneration of the liver and kidneys was found. He had seen other cases which had had a duration of two or more years with profuse suppuration, and the patient had died from pure exhaustion, and at autopsy no amyloid degeneration whatever was found. Why the degeneration appeared early in one case, and did not appear at all in another, even after prolonged suppuration, he could not say, unless it was a constitutional condition. In all his cases of amyloid degeneration, there was a bad family history; and, in looking up cases of death from hip disease under treatment, he had been able to find in connection with amyloid degeneration a bad family history with regard to predisposition to tubercular disease.

He had collected forty-five cases of death from hip-joint disease not connected with excision. Of those, seven had tuberculosis, eight tubercular meningitis, sixteen amyloid degeneration, four were poor hospital cases, and ten died from exhaustion. These statistics showed that the danger of death in hip-joint disease was from constitutional disease, of course including the sixteen cases of amyloid degeneration as due to constitutional causes.

The treatment resolved itself into treating the predisposing causes. The cause being constitutional, the line of treatment to be followed in certain cases was readily determined.

With regard to family history, he thought that, in cases in which there was a bad history in that respect, the surgeon should guard as much as possible against profuse suppuration. With regard to results, what was desired was knowledge concerning those cases that passed from under notice. He believed that Mr. Holmes's remarks were true—namely, that one-third of the patients died, one-third were relieved somewhat, and one-third were cured. He thought all statistics pointed toward that conclusion.

With regard to excision, it must be remembered that in a vast majority of cases the patient had passed through the hands of gentlemen who did not believe

in the operation, and finally they reach a surgeon who performs it as a last resort. He believed that if good results were to be obtained from excision the operation must be performed early, and that then the patients would do better than to submit to long-continued mechanical treatment. It had been urged by those opposed to excision that the patients died after the operation; but he claimed that they died, not from the operation, but despite excision and from intercurrent disease, due to too late surgical interference.

He wished that there was a society where the worst cases could be exhibited. Only a certain class of good cases were usually presented, but what surgeons wished to see was the worst cases.

He believed that, when the joint had become disorganized, better results could be obtained by excision than by mechanical treatment, but as good results as were wished had not been yet obtained. Of late he had given up excision, and tried sending his patients where they could get a change of climate and sea air, but had not seen any change in results. He thought that his mechanical treatment had been good.

There was one condition which he thought had not been touched upon sufficiently in connection with hip-joint disease, and that was extension of disease into the shaft of the bone, and remaining as chronic osteomyelitis. Of course, those cases did badly.

He had seen one case of amyloid degeneration get well after excision. He thought that when the liver was enlarged from amyloid degeneration in connection with hip-joint disease, it was a case for excision rather than mechanical treatment.

Dr. L. A. Sayre remarked that he had nothing to add to what he had already published many years ago. He knew of no alterations or amendments that should be made to the following doctrine, which he believed and taught: Medicate according to the actual demands of each case, and not for the purpose of combating a theoretical morbific cause. See that the patient has sufficient food and that it is properly assimilated. Carefully study and regulate the hygienic surroundings of the patient. Give the parts involved in the disease absolute rest and freedom from pressure without materially interfering with the mobility of the joint. Extension in such a manner as to permit motion should be the object sought for in any mechanical appliance, except in cases in which the inflammation is so violent that *absolute rest* is required for a time. In cases in which the bones and cartilages are involved, and there is suppuration, spontaneous recovery is extremely rare. In such cases nature can be aided by dilating sinuses leading to dead bone, perhaps making free openings in various directions, inserting drainage-tubes, etc., thus facilitating the ready and complete exit of the discharge. "If, notwithstanding this treatment, the discharge does not diminish, but rather increases; if the disease, instead of improving, progresses despite all your efforts to subdue it; if symptoms of progressive caries develop; if the general health of the patient is daily becoming undermined, and there are no symptoms indicating repair, the only justifiable treatment left for the surgeon is exsection of the joint. More can be done in half an hour with the knife and saw in way of removing dead bone than can be done by Nature in many years."

Dr. Sayre then referred to the history of several cases, with photographs of the patients, in which there was much more motion than in any of the cases presented by Dr. Judson.

With regard to exsection, he had performed it in seventy-three cases, and in no instance had the patient died in consequence of the operation. There was no immediate danger in connection with the operation. In cases in which the patient was suffering from constitutional disease, the earlier the operation was performed, if done at all, the better would be the result, and if Nature did not show herself competent to remove the necrosed bone promptly, exsection should be resorted to rather than subject the patient to long-continued suppuration and the dangers by which it was commonly accompanied.

Dr. J. C. Hutchinson thought that it was impossible to fix the joint with any of the appliances exhibited. He maintained that it was impossible to fix the hip-joint except by apparatus extending to a considerable distance above upon the trunk. He also maintained that it was unnecessary to use any apparatus to produce fixation, because when the joint was diseased, it was firmly fixed by the constant action of the peri-articular muscles. He also maintained that it was unnecessary to use any apparatus to produce extension. He had not yet seen any apparatus that did not require constant attendance to enable it to keep up extension. But, even if extension could be made by any of the apparatus used for that purpose, he maintained that it was not necessary, for sufficient extension could be secured by the weight of the limb. [See Medical Record, vol. xv., No. 19.] A greater amount of extension could be obtained by putting a high heel and sole on the shoe worn on the well side and giving the patient a pair of crutches, than in any other way. He believed it to be impossible to separate the head of the bone from the acetabulum by any mechanical appliance, and all an apparatus could do was to prevent the head of the bone from jamming up into the acetabulum, and thus prevent pain.

THE NEW YORK THERAPEUTICAL SOCIETY.

Stated Meeting, April 9, 1880.

Dr. H. T. Hanks, President, Pro Tem.

OXALATE OF CERIUM AS A COUGH REMEDY.

Dr. Andrew H. Smith, Chairman of the Committee on Restoratives, reported cases illustrating the different degrees of success obtained in the use of oxalate of cerium in the treatment of cough. The report was based upon 84 cases furnished by the following observers: Drs. Hobart Cheesman, G. Bayles, H. W. Little for Dr. A. Hadden, F. A. Castle, C. E. Billington, Cameron, Purdy, and the Chairman. The sub-report made by Dr. Cheesman, of St. Luke's Hospital, contains a résumé of the literature of the subject, which the Chairman adopted as the introduction of the report, and it embraced references to Drs. Allport, La Roe, Morje, whose writings have already appeared in the Medical Record, to Simpson, of Edinburgh, who regarded the agent as a sedative and conserver of nerve-force, and to others.

Dr. Cheesman had used the remedy in hospital practice from July 1 to November 1, 1879, allowing it to take the place of all sedatives, including opium, and in the daily average of *phthisis* patients. It was uniformly administered in the form of a dry powder, and notes were taken in 69 trials. In 39, marked relief followed; in 19, the cough was moderately relieved; and in 11 no relief whatever was afforded. Of the

11 in which the remedy was entirely inefficient, 9 were in the third stage of the disease, and in 8 the Philadelphia preparation was used. In all the cases in which the cough was relieved, Merck's oxalate of cerium was used. The drug was given, as a rule, two or three weeks, and often intermitted, for a time, to test its efficacy. Five grains were given on waking in the morning and at bedtime, as average doses. In some cases the dose was increased in size progressively, perhaps to 10 grains twice a day, with occasionally a dose of 5 grains in the middle of the day, and with benefit. Dr. George Bayles had furnished reports of 3 cases of phthisis, in which doses of 5 to 10 grains were given with marked benefit. He also furnished reports of two cases of chronic bronchitis, which were markedly benefited by taking *three* and five grains in the morning, and 6 and 10 grains in the evening respectively. Of cases of acute bronchitis, one was greatly benefited by the use of 3 grains in the morning and 6 in the evening. Several cases of acute bronchitis were not benefited at all by the use of the drug. He also furnished reports of cases of the cough of dentition treated by the use of oxalate of cerium, in which doses of one or two grains in the morning and two or three in the evening were given with marked benefit. In two cases of pertussis, in which the patient received respectively 5 and 3 grains in the morning, and 10 and 6 in the evening, the effect was markedly beneficial. In several other cases no good effects were noticeable. He had also used the remedy in cases of spasmodic asthma in doses of 5 grains in the morning and 10 in the evening, with good results. He also furnished cases of other diseases in which the remedy was used with more or less of benefit. Dr. James R. Leaming had furnished the notes of three cases of phthisis in which he had used the remedy, and reported that it was, perhaps, the most valuable he had used, inasmuch as no unpleasant consequences followed, and it had a good effect upon the appetite. Dr. H. W. Little, of the Presbyterian Hospital, had furnished notes of three cases of phthisis for Dr. A. Hadden, and in none was any benefit derived from the use of the remedy.

At the close of the reading of the report, Dr. Hadden remarked that the cases reported as belonging to his service were hardly fair ones, because they were not thoroughly reported. In the first case, the patient had great irritability of the stomach, and had delirium, which he thought was partly due, at least, to discontinuance of opium that had been taken for a long time. The second was a case of fibrous phthisis, and was markedly relieved. In the third case the cough was relieved for a few days, and after that the remedy had no effect whatsoever. He had not used it in private practice, but now saw a reasonable basis for its trial. One reason for the incomplete report of the hospital cases, doubtless, was the fact that while using the drug his term of service expired, and the Visiting Physician who followed him did not continue the use of the remedy. Dr. F. A. Castle had furnished full notes of two cases of phthisis in which 6 grains administered twice daily gave marked relief from the cough. The second case illustrated, in a striking manner, the difference in the value of different preparations, Wyeth's being useless, and Merck's efficient. Drs. Billington, Cameron, and Purdy, had furnished notes of cases in which temporary relief was obtained by the use of the drug. The Chairman reported *five* cases of phthisis, in four of which temporary benefit was obtained by the use of the oxalate of cerium, in doses of 10 grains twice a day.

From the well-known sedative effect of the drug upon the stomach, it might reasonably be expected that it would benefit cough by allaying reflex gastric irritation. In addition to that, it was believed that it had a direct sedative effect. The conclusions reached by the Committee were the following:

1. Oxalate of cerium could be safely administered in doses of 10 grains, three times a day, for many days in succession.

2. The only unpleasant symptom, when so used, was slight dryness of the mouth that appeared after several days.

3. It was probably the most efficient when administered dry upon the tongue.

4. Its effects were not produced until two or three days after its use was begun, and lasted for two or three days after the remedy was discontinued.

5. It was most efficacious in the treatment of chronic cough, and the initial dose should be 5 grains.

6. In the majority of cases it had not proved an efficient cough medicine for any considerable length of time, but could be regarded as a valuable agent to be employed in alternation with other remedies.

7. It did not disturb the stomach; on the contrary, it relieved nausea and improved digestion.

8. Different preparations upon the market were not equal in value; and when success was not obtained by one, another should be substituted.

The President spoke of the uncertain action of the remedy in the treatment of the vomiting of pregnancy, and possibly it was due to the fact that he employed the Philadelphia preparations, and at the same time used small doses; whereas large doses of a more reliable preparation should have been employed.

THE NEW YORK SOCIETY OF GERMAN PHYSICIANS.

Stated Meeting, March 26, 1880.

Dr. H. J. Garrigues, President, in the Chair.

STEEL SPLINTER LODGED IN THE EYE—REMOVAL BY INCISION.

Dr. Knapp exhibited a patient on whom he had performed an operation for the removal of a small fragment of steel, which had entered the eye and lodged in the ciliary body. The operation was done thirty days previously, in the following manner: An incision was first made in the direction of the inferior border of the internal rectus muscle; an electromagnet connected with an ordinary battery was then applied to the foreign body, but failed to effect its extraction. Unsuccessful efforts were then made to dislodge the steel splinter by means of small hooks and curved forceps. It was finally decided to make a second incision, at right angles to the first, thus forming a scleral flap which at once revealed the body firmly fastened in the corpus ciliare. Excision of the splinter was practised and the flap sewed. During the operation, a slight quantity of aqueous humor escaped. The wound healed by primary union. The eyeball gradually regained its normal tension, this having been lost some time after the entrance of the foreign body. The retinitis formerly present had lost in intensity. The patient was now able to distinguish objects which were held near his eye. The steel splinter was presented for inspection, and the electro-magnet employed by Knapp demonstrated. It was called that of Hirschberg.

Dr. Gruening stated that for some time past he had been engaged in perfecting the construction of a magnet for a similar purpose. His own apparatus does away with the necessity for employing a battery, since it is constructed on the principle of the armature (vide page 184). This he considered a great advantage over Knapp's instrument, as it was thus readily portable, and might be added to the armamentarium of every oculist. He believed Dr. Knapp's apparatus to be essentially his own, and not constructed after Hirschberg's model.

Dr. Knapp replied that he had had no knowledge of the fact that the apparatus used was Dr. Gruening's. He had considered it as a Hirschberg instrument, and did so now.

PARTIAL RHINOPLASTY.

Dr. Gerster showed a patient upon whom he had successfully performed a partial rhinoplasty. The history was one of nasal lupus, destroying the right ala of the nose. A flap was taken from the forehead. It was four inches long and one inch broad. The terminal portion was turned upon itself to form a margin for the nasal opening. Three weeks after the primary healing of the flap, its connecting bridge was removed, and the patient's appearance was now greatly improved.

LIGATURE OF EXTERNAL ILIAC.

Dr. Gerster also exhibited a patient upon whom he had ligatured the external iliac artery, for a rapidly growing femoral aneurism. The case was of traumatic origin. The patient, 46 years of age, had syphilis five years previously. About fifteen months ago, while engaged in rowing a heavy boat, he slipped, and made a violent effort to prevent his falling backward. After three days he became aware of a distinct throbbing in the region of Poupart's ligament, and also noticed a swelling there, which subsequently became a pulsating tumor, about as large as a man's fist. His general health also suffered, he became anæmic, and entered the German Hospital on the third of January, 1880.

Compression by a pole, after Esmarch's method (vide "Esmarch's Surgeon's Handbook," p. 126), was tried, but failed to produce the desired effect. On the 17th of January, 1880, the operation was performed as follows: A long incision was made, because the extent of vascular degeneration could not be ascertained. Vessel ligatured by a firm carbolized violin string (E cord), superficial drainage established, sutures and antiseptic dressings. Wound healed by primary union, with the exception of its lower angle, where the drainage-tubes had exerted some pressure. Collateral circulation was rapidly established, the leg feeling quite warm in so short a time as three hours after the operation. Patient left his bed on February 17th, and is now able to follow his occupation. The site of the aneurism is at present occupied by a small hard mass, which is devoid of all tenderness.

SARCOMA OF KIDNEY.

Dr. Jacobi presented a specimen of a large sarcoma of the kidney, occurring in a child about four years old. The sarcomatous nature of the solid tumor had been suspected on account of the excellent general health of the child till shortly before its death. In cancerous disease this was not the case. The tumor was of congenital origin. The other kidney was found to be normal.

Dr. Wendt mentioned the occurrence in an elderly man of a similar, only very much larger tumor. The patient had died of progressive marasmus. The autopsy showed a solid sarcoma slightly adherent to the surrounding viscera. The other kidney was enlarged to double its natural size. The disease had run a remarkably long course, giving its first symptoms about five years before death.

Dr. Zinsser referred to a similar case, observed in a child four and a half years old. It had occurred in the practice of the late Dr. Krackowizer. The child had died during narcosis, established for purposes of examination.

Dr. Jacobi called attention to the possibility of mistaking empty intestine, when pressed against the abdomen, for the tumor itself—a mistake which had happened in his own practice. He also referred to the pseudo-fluctuation often found in these soft tumors.

Dr. Knapp spoke of cases of optico-ciliary neurotomy which had lately been reported by Schröler and Mauthner. Union of the optic nerve, after its section, had been anatomically demonstrated.

Dr. Gruening instanced a case of myxoma of the optic nerve where a portion of the latter had been removed. He believed that excision was preferable to simple section, when permanent results were desired.

Dr. Jacobi reported the history of a case of profuse cerebral hemorrhage. The symptoms had made the diagnosis waver between embolism and hemorrhage. The patient had complained for some time past of occasional attacks of severe headache and loss of consciousness. He had a slight mitral systolic murmur.

The fatal attack was ushered in by severe convulsions during loss of consciousness. They began at 4 P.M. and continued, with short intervals of repose, until 9, when a pause ensued. This lasted until 12. About this time the convulsions returned with additional intensity and at half-past one the patient died. During the intervals of repose, the patient appeared to be quite conscious and exhibited no indication of paralysis. The autopsy revealed a chronic superficial meningitis, and the presence of profuse hemorrhage in the left hemisphere. This had originated in the posterior cornea, and the blood had found entrance into the lateral ventricle of the opposite side. The microscopical examination revealed slight fatty degeneration of the blood-vessels and an abundance of miliary aneurisms. The bursting of one of them was the probable cause of the hemorrhage. The convulsions he regarded as of reflex origin.

Correspondence.

NITROUS OXIDE AS A THERAPEUTIC AGENT.

To the Editor of The Medical Record.

Dear Sir: Your issue of January 31st contains an article entitled, "A Preliminary Report upon the Use of Dilute Nitrous Oxide Gas in the Treatment of Melancholia and Nervous Exhaustion," intended by the authors as a sort of memorandum of discovery, or notice of priority. They say in the concluding paragraph: "At present we deem it our duty to suggest to the profession the employment of a remedy heretofore only used for surgical purposes, which in its new method of employment promises a great

deal." I desire to call their attention, if this has not been done already by another, to a little treatise published in Philadelphia in the year 1865, by J. B. Lippincott & Co., entitled "Researches on the Medical Properties and Applications of Nitrous Oxide, Protoxide of Nitrogen, or Laughing Gas. By George J. Ziegler, M.D., Physician to the Philadelphia Hospital, etc." They will there find a very careful and conscientious study of the "physiological influences and hygienic uses," and "medicinal properties and applications" of this agent.

The author is an enthusiast, and his views are somewhat rose-colored, but have undoubtedly a basis of sound, scientific reasoning. He is "convinced that protoxide of nitrogen will supersede, to a considerable extent, some of our most reliable and popular remedies, while at the same time it will render the prevention and resolution of many of the ordinary forms of disease more certain, speedy, and decided." Among the remedies which he thinks likely to be thus superseded is *quinia*. He ascribes to it, among other therapeutic properties, that of a "permanent chemico-organic, arterial, nervous, cerebral, and general stimulant," and "a superior hæmatic, neurotic, nutrient and tonic." With these views, it is not surprising that he should claim that "its power of averting and removing disease of an asthenic nature, more particularly . . . . is certainly very great," or that he should enumerate among the affections in which the happiest results might be anticipated from its use, "asthenic dyspepsia," "enervation," "neuralgia," "melancholy," and "a dynamic state generally," or that he should consider it "exceedingly valuable in adynamia of the brain and nervous system." He says: "Thus, in the numerous asthenic derangements of enervation and cerebration, manifested in the different forms and degrees of enervation, anæsthesia, neuralgia, imbecility, mental depression, hypochondria, delirium, and similar mental states, it is generally applicable. By regulating vital action, and intensifying all the functions of life, protoxide of nitrogen often proves very efficient as an anodyne, hyperotic, and general nervine, in correcting undue excitability of body and mind, relieving pain and suffering, promoting sleep, removing vital inertia and atony, and in restoring the healthy balance of the economy." I think these quotations cover all the effects observed by the authors of the article referred to. Shortly after the appearance of this little volume, if I mistake not, the "Compound Oxygen Treatment" made its appearance in Philadelphia. Dr. Ziegler's enthusiastic announcements fell very dead upon the intense and decorous conservatism of Philadelphia medicine. But not so upon all ears.

Was it that "fools rushed in where angels feared to tread"? Or rather, that wise, though not strictly ethical, men appreciated discoveries which "fools were slow of heart to believe"?

I happened about the same time to have some patients belonging to the Society of Friends, who exhibited, to a marked degree, the uncomfortable and altogether unwarrantable peculiarity of that sect of Christians of insisting upon doing their own thinking. These unreasonable persons expressed a strong inclination to try the new "oxygen" treatment. With a laudable desire to prevent them from falling into the hands of irregulars, I assured them that I could administer it myself. After a consultation with Dr. Ziegler, I procured the necessary materials and apparatus, and manufacturing both this gas and oxygen in my own office, exhibited them sometimes in combination, but, more frequently, the nitrous oxide alone.

One of these patients was a male, somewhat advanced in life, suffering from intense hypochondria: one was a female also, past middle life, with slight tuberculous deposit in one lung, and great depression of spirits; another was suffering from uterine disease with asthenia. In all of these cases, the immediate result of the inhalations was invariably to exalt the spirits and improve the whole tone of the system. They were all under treatment by massage and localized movements, so that their general progressive improvement could not be entirely attributed to the use of the agent in question, but it undoubtedly had its share in the favorable result. The two women continued permanently relieved. The man soon fell back into a despondent condition, although not to the same extent as before he came under my care.

I write, however, not for the purpose of detailing my own experience, but of claiming for a much neglected brother the "honor due unto his name." My attention was so closely occupied in other directions, that I neglected to pursue this investigation farther. It is a matter of congratulation that it has been taken up by gentlemen so competent to judge of the exact merits of the agent. In regard to its hypnotic value, I may add that, while I was manufacturing it, I was in the habit of taking a bag of the gas to bed with me, and that it never failed to procure for me a very delightful and refreshing night's sleep.

Respectfully yours,

BENJAMIN LEE, M.D., PH.D.

1503 SPRUCE STREET, PHILADELPHIA, April 20, 1880.

THORACENTESIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—The interest manifested in this operation is my only excuse for reporting the following (to me at least) interesting case: Katy F——, aged four years four months, while visiting in Jersey City in March, 1879, was taken sick and treated for pneumonia, left side. In about four weeks she was brought home. When I first saw her, she was pale, anæmic, had on an oil-silk jacket, and almost the whole back above the diaphragm was vesicated with turpentine. On auscultation of the lower portion of the chest, left side, there were distinct friction sounds, respiration somewhat humid, hacking cough, temperature normal. She remained much in this condition until the 1st of June, when there was evidence of fluid in the pleural cavity. No treatment relieved this condition. On the contrary, the fluid rapidly increased, so that by the middle of July the chest was much distended and the heart displaced. It seemed to be beating to the right of the median line. Cough constant; patient much emaciated. The only position in which she could obtain any sleep was on her side, with her knees well drawn up, her head and chest thrown forward. Her condition was indeed pitiable. With the assistance of Dr. Marvlag (July 17th) the aspirating needle was introduced between the sixth and seventh ribs. Fifty-three ounces of ordinary healthy-looking pus was withdrawn, with very great relief to the patient. For two weeks she was quite comfortable. The cavity, however, was gradually filling, and on August 16th she was again aspirated, when forty-two ounces of pus was removed. This operation failed to afford as much relief as the first. The cavity rapidly filled; she was again (Aug. 23d) aspirated for the third time, when thirty-two ounces

of much less healthy looking pus was removed; the needle was withdrawn, because of the severity of the symptoms. The cavity rapidly filled, the patient was becoming much exhausted, and it was evident, that if permanently relieved, the relief must come in some other way than by aspiration. I determined to make a free incision, and put in a drainage-tube. The place of necessity seemed to be below the ninth rib at about its junction with the costal cartilage. On the 7th of September, Dr Chadeck assisting, I attempted to make a free incision into the pleural cavity; I did not cut quite deep enough. The patient had decided objection to more cutting, so I directed a warm poultice. In about two hours the wound discharged copiously. A free discharge was kept up for several days, then each day it became less free and less pus-like. The wound in the skin was kept open by pledgets of oakum. For about six weeks the child improved rapidly, the discharge diminished in quantity and improved in quality, until only a few drops of pure serum would flow, when the patient coughed, or when the pledgets were removed, and finally, when the tents showed only a slight moisture on being removed, the wound was allowed to heal. It is now some months since this was allowed to close. The child has gained flesh, sleeps well, eats well, breathes well, and does everything that a healthy five year-old girl ought to do. There was no necessity for a drainage-tube, and the cavity was not washed out. Drs. J. S. Green, C. F. Stillman, J. N. McLean, and others, have examined her within a few weeks, and consider her lungs in a thoroughly healthy condition.

H. H. JAMES.

RAHWAY, N. J., April 3, 1880.

EXFOLIATIVE DERMATITIS OR PEMPHIGUS?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—J. G——, aged 52 years, previously enjoying good health, first called upon me October 10, 1878, for the relief of a sore throat and mouth from which he had been suffering a month. Upon examination I found an ulcerated condition of a large portion of the mucous surfaces of mouth, throat, and nares; this increased gradually, until the mucous membrane was entirely denuded from lips, gums, tongue, throat, palate, and posterior nares, leaving an ulcerated and angry surface considerably swollen, and the stench from which was indescribably and horribly fetid, scenting the whole house, and requiring powerful disinfectants and the keeping open of the windows of his room in the coldest weather. At this date, January 1st, the disease manifested itself in the scalp and upon different parts of the body, gradually extending until nearly the whole surface of the same was denuded of the epiderm. The hair coming out, finger and toe nails came off, followed by new ones. The cuticle also rapidly reformed, only to be again cast off.

At this stage, under the use of Fowler's solution, quinine stimulants, and cod-liver oil, the disease abated for a time; the mouth healed, new epiderm formed, appetite returned, pulse fell from 130 to 80, and the terrible fetor disappeared; but about March 1, 1878, the disease manifested itself again with greater intensity than before, involving the same tissues and extending to the bronchi and lungs, also to the stomach and intestines, the fetor, as before, being simply horrible. At this point I will endeavor to describe the appearance of the disease in the skin. It was that of circular blisters, some of which were several inches in diameter and coalescing, raising and filling with serum, spreading rapidly, the exfoliation being followed by a copious discharge of a purulent character. It would then change to a thin, green, finally watery exudation, then cease, and new cuticle commence in the centre extending outward; and at the same time the blistering process would go on at the outer edges, extending and being followed by the reparative process. *It was true there was pain* or disease of the glands, and but little increase of temperature. He complained of alternate flushes of heat and cold. The disease spread as before, until it covered every part of the body and extremities. When the bulla or blisters were removed, the derm beneath was angry and somewhat swollen, similar to the condition produced by a fly-blister. At this time there seemed to be a general want of nutrition and great prostration. Œdema of lower extremities and a feeling of the cuticle in the spaces not involved by the vesications, similar to that observed in cerebro-spinal meningitis, and it could be stripped off like that from the hands after scarlatina. The expectoration from the lungs became very copious, and of the same purulent and fetid character. Immense quantities were now passed from the bowels and bladder, and a sudden and very copious ones is occurred of dark, grumous, coffee-ground looking matter, after which he sank rapidly and died in a few hours. His death occurred April 6, 1878. As he had thought some months previous to his illness that there was a small tumor in his intestines which at times he could feel (but which was not mentioned to me until after his death), I proposed an autopsy, but it was not permitted.

Very respectfully yours,

R. S. HARNDEN.

WAVERLY, N. Y.

TESTS FOR COLOR-BLINDNESS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In the MEDICAL RECORD of April 10th, on p. 416, apropos of the circular by which the Secretary of the Treasury authorizes the examination of pilots for color-perception "by any respectable resident physician," is a paragraph relative to the use of Holmgren's test so misleading in its suggestions that I beg space for a word of warning.

The passage referred to is as follows: "A pile of worsteds, of various colors and shades of the same color, is placed before the person to be examined. A skein of worsted of a particular color is then selected and placed on one side; the examinee is then required to pick out all the worsteds which have any shade of this particular color. If he does this successfully, another color is selected and matched in the same way. It is generally sufficient to match two colors. Green and red are the ones oftenest used."

To test a person's ability to distinguish instantly and invariably a red light or flag from a green one is by no means so easy a matter as at first sight it appears; and an examination for this purpose by one who has not specially studied and practised its theory and method is worse than no examination at all, being liable to give a false assurance of security. So well is this understood in Sweden and Holland, that the railroad surgeons charged with this duty are all practically and personally instructed by Holmgren and Donders, the controlling experts.

Suppose a respectable practitioner, whose atten-

tion has never been particularly directed to this matter, called upon by a pilot for examination, and depending upon the hints above quoted. Although informed (incorrectly) that "green and red are oftenest used," yet seeing the statement that "it is generally sufficient to match two colors," he may suppose that *any* two will do. He selects perhaps yellow and blue—as a railroad official in Massachusetts did within my own knowledge. The result may be the same as it was in that case, in which the examiner passed, as having perfect color-perception, a person who is completely red-blind and *unable to distinguish red from green*.

In fact, for conclusive reasons which there is not room to detail here, the color first used in Holmgren's test should *always* be a bright, pure green. This, properly used, will detect the existence of color-blindness. The second color, for determination of the *kind* of color-blindness, is *not* "red," but medium purple, called by dealers "Magenta." The misunderstanding and consequent misuse of Holmgren's test have led to many errors on the part of examiners.

The use of the worsted-test, as explained in detail by Holmgren (the only English translation of whose complete instructions is given in Dr. B. Joy Jeffries's book on "Color-Blindness: Its Dangers and its Detection"), though very simple, requires a thorough practical knowledge of the subject; and any physician undertaking such examinations without that knowledge is in imminent danger on the one hand of certifying to the normal color-sense of really color-blind pilots, and on the other of refusing certificates to those not color-blind, but who from carelessness or want of familiarity with colors, appear to be so. Perplexing cases of the latter class are very common.

An experience of some months in the almost daily examinations for color-blindness which are a part of my official duty, and in witnessing hundreds of other such examinations, is my ground for cautioning my professional brethren against the risk both to the community and to their own reputation involved in undertaking, without careful special preparation, the examinations allowed by the Secretary's circular.

J. F. Head,
Surgeon U. S. Army.

Boston, Mass., April 19, 1880.

THE USES OF COCA IN SOUTH AMERICA.

To the Editor of The Medical Record.

Sir:—Your valuable journal, which has solaced many a weary hour, overtook me while on a journey into the very districts in which grows the coca of which you speak in your edition of February 21, 1880. I have been conversant with coca for the past eight years, and would say, from personal observation and experience, that the great encomiums lavished upon its use, are, to use a very expressive slang term, all *bosh!* I have read before of the experiments of Sir R. Christison, and believe that if he had taken a good stiff glass of brandy and water, Scotch whiskey, or a strong cup of green tea, he would have been just as much, if not more refreshed, than if he had taken a pound of coca.

Coca will relieve and in a measure prevent thirst; so will chewing a bullet. I do not think it will prevent hunger as well as tobacco. Given in the form of an infusion it will relieve colic; taken in the form of tincture or extract it promotes the digestion and excites the genital functions. All the so-called coca bitters, etc., only contain a small amount of coca and a large quantity of columbo, gentian, and other well-known vegetable tonics.

The food of the Indian here is composed largely of toasted corn and potatoes; he chews the coca the same as an American chews his tobacco, the Irishman indulges in his dudeen, the East Indian in betel, and the Chinese in tea and opium. The use of the lime is for sweetening purposes, as the Indian has a very great dislike for anything bitter. As far as my knowledge extends there is no nation which has not some form of intoxicant, narcotic, or excitant which has been extolled and from time to time adopted as an article of diet or medicine in civilized countries. Coca has a very limited use, and principally among the males of Peru and Bolivia who inhabit the higher altitudes of the Andes, the women rarely indulging in its use and the coast Indians hardly knowing its name.

When I return from my excursion I will give you some further particulars in regard to its use and effects. In the meantime I would only advise my professional brethren not to consider that the elixir of life has been found in the leaves of E. Coca.

My residence for three years in Cerro-de-Pasco,* the highest (I believe) inhabited city in the world, and eight years' residence among the Andes at an elevation of from 5,000 to 17,000 feet, enables me to speak with authority on the subject.

Yours, truly,
Geo. A. Ward, M.D.

Ambo, Peru, S. A., March 23, 1880.

New Instruments.

NEW HOLDER FOR SIMS'S SPECULUM.

By GEO. E. FRANCIS, M.D.,

Worcester, Mass.

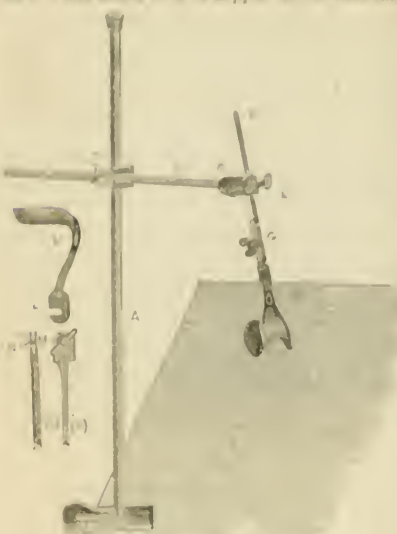
Having often desired to use the Sims's speculum in my office when I was unable to obtain, on the instant, the services of an assistant competent to hold it, I have constructed a mechanical holder, which, on trial, does the work so well as to lead me to describe and figure it for the benefit of those among your readers who have, for similar reasons, been obliged to use less perfect speculums in the diagnosis and treatment of uterine disease.

The woodcut shows at once the general construction of the holder. A is an upright steel rod, fixed to the edge of the table, and B a square steel bar, connected with A by the sliding-block C, which is furnished with thumb-screws for fixation. B supports at its expanded end, D, a socket, E, which can be fastened at any angle in a vertical plane, and which carries a round rod, F, which, in turn, can be fixed at any position of rotation or height by its thumb-screw. To the lower end of the rod, F, is attached the Sims's speculum blade H, by the joint G, and to the construction of this joint is due whatever claim to novelty and merit the instrument may possess.

As will be seen, the usual double Sims's speculum is cut in two in the middle of the shank, K, giving two single blades; to the cut end of the shank is fastened a notched plate, about an inch wide and

*Cerro-de-Pasco has an elevation of 14,500 feet; population, about 8,000.

constructed of steel rods, L, which fit snugly between two smaller parallel plates, M, fastened to the rod F. The notch in the speculum plate allows it to pass a quarter-inch screw, N, which serves to clamp the three plates immovably at any angle. A turn back of this screw allows the speculum to be set at a new angle, or to be slipped out for removal.



I use the holder in this way: the woman being in the usual lateral position on the table, the upright rod is secured to the left side of the table, about twelve inches from the end nearest the operator. I first make an approximate adjustment for height, etc., by the binding screws at C, the other screws being loose, and then introduce the speculum blade into the vagina, and while one hand holds it in the desired position by the shank plate, the other hand brings to it the clamp G, and the binding screws at G, D, and E are then successively tightened.

Once in place, the speculum gives the patient much less discomfort than when held by hand, and her muscles resist it less, while the steel rods are sufficiently elastic to allow considerable change in her position.

I have the usual series of speculum blades, and in order to utilize them, when not using the holder, I have had made a handle of ebony, with a clamp-joint like G, which is quite as serviceable as the usual double form.

To Mr. W. F. Ford, of New York, I am much indebted for advice and assistance.

NOVEMBER 25, 1879.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from April 18 to April 24, 1880.

MEACHAM, F., Capt. and Asst. Surgeon. So much of Par. 1, S. O. 74, C. S., A. G. O., as relates to him is revoked. S. O. 87, A. G. O., April 20, 1880.

HALL, J. D., Capt. and Asst. Surgeon. Assigned to duty as Post Surgeon at Fort Randall, D. T. S. O. 42, Dept. of Dakota, April 13, 1880.

WISSE, C. K., Capt. and Asst. Surgeon. When relieved by Asst. Surgeon Corbusier, to comply with Par. 1, S. O. 74, C. S., A. G. O., S. O. 32, Dept. of the Platte, April 14, 1880.

ARSWEGEN, P. C., Capt. and Asst. Surgeon. The operation of so much of Par. 1, S. O. 74, C. S., A. G. O., as relates to him is suspended until Sept. 1, 1880. S. O. 84, A. G. O., April 22, 1880.

MERRILL, J. C., 1st Lieut. and Asst. Surgeon. Relieved from duty at Fort Shaw, M. T., and assigned to duty as Post Surgeon at Fort Custer, M. T., relieving Asst. Surgeon L. S. Tenney, to enable him to comply with S. O. 74, C. S., A. G. O., S. O. 42, C. S., Dept. of Dakota.

STANNUS, W. C., 1st Lieut. and Asst. Surgeon. The operation of so much of Par. 1, S. O. 74, C. S., A. G. O., as relates to him, is suspended until Oct. 1, 1880. S. O. 87, A. G. O., April 20, 1880.

CORBUSIER, W. H., 1st Lieut. and Asst. Surgeon. Relieved from duty at Camp Sheridan, and assigned to duty at Fort Washakie, Wyo. T. S. O. 32, C. S., Dept. of the Platte.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending April 24, 1880.

Week Ending	Typhus Fever	Typhoid Fever	Scarlet Fever	Cerebro-spinal Meningitis	Measles	Diphtheria	Small-pox	Yellow Fever
April 17, 1880	0	5	41	5	92	46	0	0
" 24, 1880	0	2	58	7	103	32	0	0

A BIT OF STRAW IN THE CANALICULUS.—Dr. T. G. Vincent, of Mankato, Minn., writes: "A few days ago a gentleman called upon me to remove a foreign body from his eye. Making a careful search under both direct and oblique illumination without result, I was about to give up the search, when I noticed that the punctum of the upper lid was filled by a body that slightly projected. It was easily removed and found to be a bit of straw, one-eighth of an inch in length, which had worked its way into the canaliculus. The gentleman stated that a gust of wind had carried it into his eye about three hours previous to his visit. This being a very rare location to find foreign bodies entering the eye, it is worthy to be recorded."

THE LATE DR. CHARLES H. H. SAYRE.—At a meeting of the Bellevue Hospital Medical College, called for the purpose of taking appropriate action on the occasion of the death of the late Charles H. H. Sayre, M.D., an alumnus of this college, and the eldest son of Professor Lewis A. Sayre, the following resolutions were adopted:

Resolved, That the untimely death of our late professional brother has occasioned in the mind of each member of this faculty a feeling of deep grief, and

we tender to our beloved colleague, Professor Sayre, and to all the members of his family, our heartfelt sympathy in the great bereavement by which, in the inscrutable dispensation of Providence, they are afflicted.

Resolved, That in the death of the late Dr. Sayre, all who enjoyed his friendship will mourn the loss of one who had endeared himself to them by his noble and generous qualities; his afflicted father has lost not only a beloved son, but an able associate in his arduous duties, and the medical profession is deprived of a talented and skilful member.

Resolved, That a copy of these resolutions be transmitted to Professor Sayre, together with the fervent wishes of his colleagues for a speedy recovery from his present illness.

ISAAC E. TAYLOR, M.D., *President*.
AUSTIN FLINT, JR., M.D., *Secretary*.

BELLEVUE HOSPITAL MEDICAL COLLEGE.—Dr. A. A. Smith has been elected Professor of Therapeutics, Materia Medica, and Clinical Medicine.

AMERICAN MEDICAL ASSOCIATION.—At a meeting of the Committee of Arrangements of the American Medical Association, held April 9, 1880, Prof. T. Gaillard Thomas, M.D., was unanimously elected Chairman of the Committee of Arrangements in place of Dr. S. O. Vanderpoel, who recently resigned.

TO PRESERVE THE STRENGTH OF MAGENDIE'S SOLUTION.—Dr. H. H. Kane writes: An error occurs in the formula given at p. 471 of your journal for April 24th. The formula should be:

℞. Morph. sulph.....	gr. cclvi.
Acid salicylic.....	gr. viij.
Aq. distil.....	f ʒ xvi.

M., etc.

This is the formula of Dr. H. M. Keyes, he having called attention to its successful employment in Roosevelt Hospital, some years ago.

THE BILL TO REGULATE THE PRACTICE OF MEDICINE IN MARYLAND failed to pass at the recent session of the Maryland Legislature. The same fate met the "Bill for the Protection of Patients in Confidential Communication with their Medical Attendants."

THE REPUTATION OF BORACIC ACID in eye diseases is slightly on the wane. Much success is reported for it in inflammations of the various mucous membranes, as of the throat, urethra, vagina, and bladder.

DR. MATTHEW KEMPF, Professor of Surgery in the Kentucky School of Medicine, died from pneumonia on the 27th of March, at the age of 53. His memory was honored by a mass meeting of the profession of Louisville.

Dr. A. B. Cook has been appointed to the vacant professorship.

THE SANITARY COUNCIL OF THE MISSISSIPPI VALLEY met at St. Louis, April 22d. The Council voted in favor of increasing the efficiency of the National Board of Health. Dr. R. C. Kedzie, of Lansing, was elected President; Dr. Pinckney Thompson, of Henderson, Vice-President; and Dr. John H. Rauch, of Chicago, Secretary.

THE TYPE FOR SCHOOL-BOOKS.—Dr. Gaval, of Sarbonne, says: "Other things being equal, the legibility of a printed page does not depend on the height of the letters, but upon their breadth."

FOR SEA-SICKNESS.—A mixture of bromide of potassium and hydrate of chloral, taken effervescing with citrate of magnesia, has never failed but once. This is the experience of Surgeon F. W. Cory, of the Australian Mail S.S. Co.

WITHOUT ANUS OR PENIS FOR FIFTY YEARS.—Dr. Wheeler mentioned, at the meeting of the Surgical Society of Ireland, Feb. 13th, a case recorded by Bartholin in which there was neither anus nor penis, and all the ingesta were returned by the mouth for more than fifty years.

THE BILL TO PUT DOCTORS' BILLS on the list of preferred claims, which was before the Kentucky Legislature, failed to become a law. The opposition to it was quite extensive.

THE FOUR MEDICAL SCHOOLS OF LOUISVILLE have raised their price for professors' tickets to seventy-five dollars. The regulations in regard to attendance on lectures have also been made more stringent.

MAPLE SUGAR IN THE TREATMENT OF DIABETES.—Dr. H. Brubaker reports a case of diabetes mellitus in a patient æt. 70. The patient had been suffering for several years and was much emaciated. He had a fondness for maple sugar, and was finally told to eat it ad libitum, no restrictions being placed on this diet. From this time the sugar in his urine began to grow less, and finally entirely disappeared, as did the other diabetic symptoms. The patient died, however, from other causes.—*Clinical Record*.

PRESENTATION OF A BUST OF DR. J. MARION SIMS.—At a recent meeting of the Alumni Association of Jefferson College, a bust in bronze was presented to the Society by the surgical staff of the College Hospital. The presentation was made by Dr. Levis. The bust has been received by the Board of Trustees of the Jefferson College Hospital, and is to be placed in the hall of the hospital.

OUR INTERNATIONAL SANITARY CONFERENCE.—In a recent leading article the *Lancet* discusses the Sanitary Conference that is to take place under the direction of the National Board of Health in Washington this month. There is an inclination shown by the writer of the editorial to ridicule the Conference; and it is stated that the elaborate work of the National Health Board in the direction and for the securing of quarantine, indicates rather regression than progress. International Sanitary Conferences so far have been failures.

THE CONVENTION FOR REVISION OF THE U. S. PHARMACOPŒIA will meet in Washington, Wednesday next. IN PARTIES OF TEN a single railroad ticket is issued for *the ten* at the rate of $10.25 for the round trip to Washington and return; leaving New York *Tuesday* 4th, at 4 P.M., and, returning, leave Washington on Saturday morning.

NEW YORK ACADEMY OF MEDICINE.—At the meeting of the Academy of Medicine, 6th inst., a memoir of the late Freeman J. Bumstead, M.D., LL.D., will be read by George A. Peters, M.D., with a presentation to the Academy of a portrait. Also a paper by Dr. John H. Packard, of Philadelphia, On Some Important Advantages to be Secured by Oblique Section of the Skin in Surgical Operations.

AN OPHTHALMOLOGICAL JUBILEE.—Dr. Mooren, a celebrated German ophthalmologist, has recently celebrated at Dusseldorff a rare form of jubilee. He has entered on his list his 100,000th patient, having performed 16,765 great operations, 3,700 being for cataract. The town celebrated the event with festivities.

A British Dental Association has been organized by the registered dentists of Great Britain. The Association is a close copy of the British Medical Association, having established branches and undertaken the editing of a journal. The journal is called the *Monthly Journal of Dental Surgery*.

The Twenty Fifth Annual Report of the Cleveland Hospital for the Insane, for 1879, shows that 665 patients have been in the hospital during the year. The percentage of recoveries in the 227 patients admitted has been 43.8.

Presbyterian Hospital, New York.—Dr. F. A. Castle has been appointed attending physician, *vice* Dr. S. T. Hubbard, resigned; and Dr. Leroy M. Yale has been appointed attending surgeon, *vice* Dr. W. T. White, resigned.

There are two vacancies in the medical board yet to be filled, one occasioned by the death of Oliver White, and one by the resignation of Dr James L. Banks.

St. Luke's Hospital, New York.—Dr. W. T. Bull has been appointed attending surgeon to St. Luke's Hospital, *vice* Dr. G. H. Wynkoop, resigned.

College of Physicians and Surgeons, N. Y., Alumni Prize of Five Hundred Dollars.—The Cartwright Prize of the Alumni Association of the College of Physicians and Surgeons, New York, which amounts to five hundred dollars, will be awarded, subject to the following conditions, to the best essay on some subject in medicine or surgery: 1. The prize is open to the competition only of alumni of the college. 2. The subject is left to the option of the contributor. 3. The essay must present sufficient original, experimental, or clinical observation to make it a useful contribution to medical knowledge. 4. The essay, designated by a motto, must be sent to a member of the Committee on Prize Essays, accompanied by a sealed envelope inscribed with the motto and containing the name and address of the author, on or before February 1, 1881. Committee: A. H. Buck, M.D., 52 East Thirty-first Street; J. E. Janvrin, M.D., 120 Madison Avenue; W. T. Bull, M.D., 33 West Thirty-third Street. The Alumni Prize, also of five hundred dollars, will be awarded in 1882, subject to the same conditions.

The New York Physicians' Mutual Aid Association, in its eleventh annual report, states that its financial condition is very satisfactory, but it needs an increase in membership. The object of this society is an excellent one; it appears to be well managed, and its benefits ought to be appreciated by a wider number.

Locomotor Ataxia, according to Dr. S. Weir Mitchell, is best treated with large doses of iodide of potassium. Dr. Mitchell has devised some crutches to aid ataxic patients in walking.

Measles have prevailed to an extraordinary extent in Chicago. The cases have mostly been mild in course, however.

The St. Louis Medical College announces that hereafter all students who matriculate at that institution must take a three years' graded course in order to graduate.

Parisian Hospitals.—In a recent letter from the Paris correspondent of the *Louisville Medical News*, a very interesting, but far from flattering account of the Parisian hospitals is given. In the first place, the writer says the nursing is wretched; the Sisters of Mercy are untrained, and they give but a small part of their time to the personal care of the patients. Their chief duty seems to be to serve the meals, look after the linen, sit in their rooms, and go to chapel. In one ward four patients were found lying with old bed-sores which had just been discovered. The beds themselves are often filthy with vermin. The dressings are made by the assistant nurses, who are generally untrained, poorly paid, and prostitutes; night-nurses scarcely exist. The supply of water is small, and baths are rarely given. It is comparatively rare for the surgeons to wash their hands, and it seems to be the rule to wipe the instruments upon the apron. No screens are put around the beds of the dying or dead.

The surgeons themselves are, as a rule, more intent upon developing a particular idea than in looking after the general welfare of the patient. This is illustrated in the case of M. Dumontpallier, who for some time used to go about his wards sticking pins into the patients who complained of pain. This was to test his theory that pain is lessened by pricking the corresponding point on the opposite side.

All these evils are said to exist in the hospitals of France, "the most civilized country in the world," and the country where there is the least fault to be found in the education and standing of the physician.

A Summer Sanitarium for Children in Baltimore.—By the will of the late Thomas Wilson, $50,000 has been bequeathed for the establishment of a summer sanitarium for the sick children of the city of Baltimore. The trustees of the fund are still engaged in maturing plans for the best disposal of the money. It is probable, however, that a large hospital will be built at some elevated part of the country not far from Baltimore. Here the children will be conveyed and treated for a longer or shorter time.

A Summer School of Botany has been established in this city by the New York College of Pharmacy. It is to be under the direction of Professor Andrew Wood, and will consist of laboratory work and excursions. It continues from May till October.

The Arkansas Medical Monthly.—This is the title of a new journal which has just appeared. It is published at Little Rock, by Dr. Jonathan J. Jones. The first number is very neatly printed and contains several original articles.

The Maryland Medical Journal will hereafter be published twice a month instead of once. The form will also be changed to that of a two column journal. The *Maryland Medical Journal* has always been ably edited, and Dr. Ashby will doubtless have increased success in his new departure.

Bromide of Ethyl has just been brought before the Paris Surgical Society as a valuable local anæsthetic.

Dr. Henry C. Chapman has been elected Professor of the Institutes of Medicine and Medical Jurisprudence, in Jefferson Medical College, in place of Prof. James A. Meigs, deceased.

State Medical Society of Arkansas.—The Fifth Annual Session of this Society will convene in the city of Little Rock, at 10 o'clock, Wednesday, May 5th next, according to adjournment. The meeting will be held in the Hall of the House of Representatives of the State Capitol.

Original Lectures.

THE ERUPTIVE FEVERS.

LECTURES DELIVERED

By ALONZO CLARK, M.D., LL.D.,

PROFESSOR OF PRINCIPLES AND PRACTICE OF MEDICINE, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

SMALL POX.—LECTURE II.

THE topic that was occupying our attention at the close of the hour yesterday was the modes of preventing the scars of small-pox. I was saying to you that if the pock be emptied by the point of a lancet and kept empty, there is a report that no cicatrization will occur. Another method is, to open the vesicle and burn the papule with a stick of nitrate of silver, and repeat this from time to time as the vesicle forms anew. But it is a laborious practice, and the same results, it is reported, can be obtained in other ways. As, for example, by the application of the old mercurial plaster to the face; the plaster put upon leather and fitted to the face, and made to adhere by the adhesiveness of the plaster itself. The lead ointment, or lead plaster rather, warmed, becomes soft. Take some of the material before it is spread and mix with it a certain quantity of the oil of almonds, so that it will be soft, and can be easily applied with the camel's-hair pencil, or a simple brush, and coat the face over with that, and repeat it as often as it breaks away. This is another method. And there is another that is easier, and my impression is, it is quite as good as any of them, and that is the use of collodion blackened with animal-black. The animal-black gives a very fine powder, and, mixed with the collodion while the collodion is soft, and then applied with a brush all over the face, it adheres very well. And this, it is believed, will act in a way to cause abortion of the pustules upon the part to which it is applied. It will not do to apply it to any considerable part of the body, but the face is most important, and it is applied only to this part.

In enumerating the lesions of small-pox I omitted to say to you, and it is omitted in almost all the books that I have read, that occasionally the small intestines are the seat not of an eruption proper, but of a pustular appearance, caused by a whitish fluid in the solitary glands, which enlarges these glands. I have seen them very numerous, so that almost the whole of the intestine was occupied by them, like bladders of purulent-looking matter standing out from the inner surface of the intestine. The Peyerian glands, too, are sometimes elevated to a certain extent.

Regarding the treatment of small-pox—the very best treatment is to prevent. "An ounce of prevention is worth a pound of cure," in this case. Small-pox, I told you, has been traced to China at a period of more than a thousand years before the commencement of our era, and a mode of diminishing the mortality from it was discovered in China—how soon after the first history of the disease, I do not know. That was by inoculation. If the virus of small-pox be introduced into the arm, or any part of the body of a well man, it will, in a period corresponding to the common period of incubation, produce a mild small-pox—so mild that the mortality is marked at one per cent. only, while that of small-pox, as I gave you yesterday, is thirty-seven per cent. This marked mildness, this great diminution of the danger from the disease, came to be enticing, and the practice became very general. It gradually worked its way into the western portions of Asia (?) and reached Constantinople in 1701 of our era. It took it two thousand years, probably, to get as far as Constantinople. Slow travelling. In 1701 it was introduced by two enthusiastic physicians, one an Italian practising in Constantinople, and after a good deal of effort to overcome the destiny doctrine of the Mohammedans, it came to be generally practised. Mr. Maitland, surgeon to the English Embassy in 1720, saw some of this practice, and Lady Mary Wortley Montague, who was the wife of the Ambassador, interested herself very much in it, and when she went home in 1722 she had her own daughter inoculated, and she went through a mild small-pox, and was afterward as much protected against the disease as if she had had it in the natural way. But the Yankees got a little ahead of them. The distinguished clergyman, Cotton Mather, had heard of this thing in Constantinople and became quite earnest about it. And a Doctor Boylston, in Boston, inoculated children in 1721, the year before it was practised in London. It came to be a prevailing practice in England and in this country. I do not know exactly in what manner it was performed or done in England, but in this country a house out of the way of travel as much as possible, that might perhaps be unoccupied, or be hired, was found by the selectmen of the town, and as many as wanted to enjoy small-pox went into that house as boarders, were inoculated and went through the whole disease joyously, and when time had passed sufficiently to authorize the belief that they would not spread the disease, they were let out of the house and returned to their friends. Indeed, Lady Mary Wortley Montague speaks of the Turks as having a sort of festivity when they went into an isolated place to be inoculated, and having a good time all the way through the disease.

The marked advantage of this kind of artificial small-pox you will fully appreciate when I state to you that the disease is so mild that only one in a hundred of the cases proves fatal. But there is this very marked objection to it, that it spreads the small-pox. The persons with the inoculated disease are just as dangerous to those who have not had the small-pox as the persons who have it in the natural way, and Sir Gilbert Blaine estimates that in his time small-pox was more prevalent than before inoculation was practised. It was a practice, then, that was very decidedly beneficial to the individual, but unfavorable to the community, and when Jenner proposed vaccination as a substitute for inoculation, and the effects of it were seen, it was seized upon with great eagerness by all people. Another name for this inoculation is variolation, and perhaps in the old times one term was used as frequently as the other. Of late we hardly ever hear of variolation, though occasionally we hear talk of inoculation.

Now, in reference to the protective powers of the disease to which cows are occasionally subjected, and Jenner's connection with it. In 1770 Jenner was a student of his profession in the office of a Mr. Ludlow, I think, at Sudbury. A young woman came in from the country to be prescribed for at the office, and there was some form of eruption—very likely one of the forms of erythema—which induced some of them to speak of small-pox. She said, "No, I cannot have small-pox, for I have had the cow-pox;" and inquiries were made in regard to it, and Jenner's mind was awakened for the first time to the possi-

bility of their being a preventive for small-pox. He made inquiries in that district, and found it to be a general opinion among dairymen that if a woman for then was the time of milkmaids, a time now long past—milked a cow that had this disease, and had a scratch upon her finger or a crack in her hand, and some of the material that was shut up in these pustules had made an entrance into her system in that way, then she had a mild disease, occupying but a few days for its continuance, and ever afterwards was protected from small-pox. In this figure you see the udder of a cow, and there are upon it seven pustules, which look exactly like small pox pustules. They have the depressed centre, and they have the areola about them, and if you were to see them upon a person, and they were as numerous as small pox pustules, I do not think you could distinguish between them. [

Jenner did not make any practical discovery beyond this general belief in that region of England, for several years afterward. It was 1780 before he gave his time to the study of the matter so as to make it practical. Then there was brought under his observation a disease of the horse called grease, and a disease of hogs called hog-pox. He got an idea that this hog-pox was the same as cow-pox, and he vaccinated one of his own children, Edward—not William, who is now living,—with it, and discovered that his boy was affected just as if he had been inoculated with small-pox. He therefore concluded that it was a modification of small-pox that affected the hogs; the grease in horses is regarded as having more affinity to the disease of the cow. He experimented as far as he could without coming to the person of man, up to the 14th of May, 1796. He then inoculated a boy whose name was James Phipps, from some matter that he took from the hand of Sarah Nelmes, who was a milkmaid, and had these pustules upon her hand. He took some of the matter of one of these pustules and inoculated this immortal James Phipps. The disease ran a course very similar to that which had followed from the accidental inoculation from the cow; this was on the 14th of June. On the first day of July Jenner procured the matter of small-pox and introduced it under the epidermis of this boy in several places. The boy was unharmed by it; no disease at all was produced, except a little local sore, which passed away as if it had been a scratch. This was the immortal experiment; soon vaccination became pretty common. It had to meet with some opposition, as does every novelty, but in ten years it came to be a practice. Jenner did not publish his observations in regard to it until 1798. The book was in that year sent to Dr. Waterhouse, who was professor of practice of medicine in the University of Harvard, and directly afterward he published, in a secular paper, an article under the name of "Something New in the Line of Medicine," and gave reports, extracted from the book of Jenner, of his discovery. As yet none of the vaccine matter had reached this country, but in 1801 a physician of Bath sent some to this same Dr. Waterhouse. The next was sent by an English physician to Dr. Valentine Seaman, in New York. Dr. Waterhouse distributed the matter sent him; he sent some of it to Mr. Thomas Jefferson, President of the United States. Mr. Jefferson became a believer in the practice, and he and his sons-in-law vaccinated two hundred persons of his own family and of his neighbors. He became quite interested in the study of the progress of the thing, and after one year he writes to Dr. Waterhouse in substance: "I have given much attention to the question of at what time this particular matter has arrived at maturity and is most effectual, and I have come to the conclusion that the best period for taking the matter from the pock is eight times twenty-four hours," that is, a little past the eighth day. Now we fix it at the seventh or eighth day. Dr Waterhouse diffused this practice among the physicians of Massachusetts, and they blundered. They took the matter at the wrong time, and some of them took the variolous matter and inoculated persons with it, and of course it spread small-pox, and they were worse off than before. Then Dr. Waterhouse writes to a correspondent that he had gained some credit by following the footsteps of Jenner, but he had lost his way, and he wanted new directions. This was communicated to Jenner, and Jenner wrote to him and sent him some new matter. Some was also sent to Dr Seaman, of New York. Dr. Jenner wrote to Dr Waterhouse his views in regard to the time when the vaccine matter should be taken from the arm. He says essentially—you will remember it was nineteen years after the war of the revolution: "Entertain what views you please in politics, but entertain but one opinion in regard to the taking of the matter of vaccination, it must be taken not after the eighth day." The seventh day, I think, is a favored day by the vaccinators of New York now; up to the eighth day it is good, but after the inflammation occurs in the areola it produces a purulent deposit in the part, and then it is not good; and yet the dry scab is used where nothing better can be obtained. Vaccination has become almost universally practised in civilized nations. There have been attempts to oppose it, which have amounted to very little. A pretty strong feeling was brought against it a few years ago when it was ascertained that syphilis had been inoculated with it. This was observed in France; and Ricord, who was authority on syphilis, was convinced that syphilitic matter had been introduced into the arm, I think, of about six persons. There are now numerous instances of such transmission recorded. I do not know of any other form of disease that is transmissible by the same agency. You would, of course, in choosing persons from whom to obtain the virus, select the healthiest, particularly those who had not inherited syphilis. The young children, from whom it is pretty uniformly taken, are not likely to receive syphilitic poison in any other way than by its being transmitted from parents.

The way in which the virus is obtained varies in different countries and with different physicians. The most common one here is, if the vaccination is not from arm to arm, to prepare quills. Take a goose-quill, scrape off all the scaly matter, all animal matter, and make it perfectly smooth; using both ends of each quill, you will have six points, as they are called, after having been loaded, from one quill. "Have you any points?" one physician will say to another; that is, have you any of those quills that are loaded with the vaccine matter. Then, on the seventh or eighth day, take a pock that is perfectly sound and just puncture the top of it, and turn this quill around on it until you see the matter on all its circumference. Then turn it end for end, and, making another little puncture into the pock, turn that in the same way. By that time the first end will have become dry, and you will turn that in the lymph matter again, and so with the other end. Then, when it is perfectly dry, you may cut the quill into two parts, and split each part in three and sharpen the ends not loaded and drive them into the lower end of a cork, putting three, four, or six into one cork,

and then pass the quills into a vial through the neck, and cork up the vial. You then keep it protected from the air—that is, from all the air except what is in the vial. It is best to use it within a few days. In very warm weather it is supposed to lose its virtue in a short time. It will not bear freezing. Then, when you come to perform the operation with the lancet, you shave the part which you select, which is usually at the point of insertion of the deltoid muscle on the left arm, pinch up the skin and make it prominent, so that you can readily apply your lancet to it. Shave off the hair and some of the epidermis; scratch it so lightly that there will exude just a drop of blood and no more. You can cross the scratches or not, as you please. You then turn the armed end of one of these points in the blood, and wash off the virus that has dried there. One point is commonly enough—that is, to produce one pustule. But the question arises here, whether one or several pustules should be produced in a vaccination. One pustule is, to a very considerable degrèe, protective, but more are regarded as desirable—at any rate by the Prussian surgeons and physicians. They sometimes make as many as nine insertions at one sitting. I have here some facts that relate to that. The mortality from small-pox after vaccination with one pustule was 7.73 per cent; the number of cases, upward of 2,000. With two vaccinations, that is, with two pustules, out of 14,043 persons the mortality was 4.07 per cent.; with three pustules, out of 580 persons the mortality was 1.75 per cent.; with four pustules, in 514 persons, it was only one-half of one per cent., or 0.55 per cent. So you observe that if small-pox occur after vaccination, it is less severe in those who have multiple vaccination—multiple pocks.

Multiple vaccination, introducing the matter at four or more points, does not seem to protect a person from an attack of small-pox any more than one; but it seems to have this advantage, to make it more sure that the small-pox, if it do occur, will be of a mild character.

There are persons who decry vaccination, and think that it shortens men's lives. I know of but one answer to that, or at any rate I do not know of any that is so conclusive, as that vaccination has been generally practised in civilized nations for seventy years; it took it about ten years to acquire general favor, since which time almost everybody has been vaccinated. And the history of the last seventy years gives us a longer duration of human life every succeeding ten years (a less number of deaths in proportion to the number living); and if everybody be vaccinated, and everybody's life is made shorter by vaccination, you observe that this is rather a singular commentary. Every ten years is marked as giving additional length to human life (diminishing the proportion of deaths every year to the number living). I know no other commentary that need be made in regard to it.

The accidents that attend vaccination are sometimes a little grave. The most common is the production of erysipelatous inflammation, and it is sometimes of a serious character. It does not occur, probably, in one of two or three hundred persons who are vaccinated; but you should know that it is one of the things that may chance to occur. I had a case in which erysipelas occurred in a child a few days after vaccination, but it occurred in the other arm, and started just about the point corresponding to the one I had chosen for vaccination in the left arm, so that that can hardly be charged upon the vaccination. Bad sores sometimes occur, but that, I think, is due to the material that is used for vaccination. For example, nearly forty years ago we sent to England for some virus from the cow direct. It was sent over on something like a microscopic slide, with a little cavity made in it, over which was sealed a glass cover, which made it air-tight. We used it at the Northern Dispensary, and every vaccination produced a very bad sore, so that we were obliged to abandon it.

The question occurs with regard to the vitality of the vaccine matter; whether that which was introduced into this city by Valentine Seaman, in 1802, and has been propagated from person to person every week since that time, has the same vitality, the same activity, that the original vaccine matter from the cow has. I may say, in regard to it, that I do not know any difference in the protective power. But the vaccine disease produced by the humanized vaccine virus is less severe; there are fewer constitutional symptoms. The pustule is the same. There is less of red lines running from the vesicle to the central portions of the body; less of swelling in the arm-pit. I have confidence, then, in the matter that has passed through four thousand human beings. That is about the number that would result from the computation of the weeks since Dr. Seaman's experiments. It is quite the habit now to use the virus from the cow. In my early professional days a great many attempts were made to vaccinate cows, and they were almost all failures. There was a Dr. McGown who devoted himself very much to it. The corporation furnished cows and heifers, and he attempted to establish the vaccine disease in them by retro-vaccination, as it is called—vaccinating backward. He very rarely succeeded. I suppose they are more successful now, because several persons advertise to furnish fresh matter from the cow on order, at any time. You will, of course, exercise your judgment in regard to it, but I think you will be satisfied with the old vaccine matter.

In regard to the amount of protection that vaccination gives, Dr. Jenner believed that it was absolute; that a person who was once vaccinated, the matter having taken effect, would never have small-pox, no matter what his exposure. Dr. Gregory later adopted the rule, that if a certain form of cicatrix should be formed, that it was evidence of protection to the person. The first order for revaccination in the Prussian army adopted Dr. Gregory's description of the vaccine cicatrix, and assumed that every soldier who had that mark was protected. But very soon they found that the protection was incomplete; that it was necessary to repeat the vaccination in every person, no matter what was the appearance of the cicatrix. Perhaps you would like to know what is the appearance of the cicatrix described by Dr. Gregory. It is a little depression in the skin, one-third of an inch in diameter, with a well-defined boundary, smooth, shining, and with no depressions upon it except two, three, or four little pin-holes at the bottom. Those pinholes indicate the seat of the sweat-glands. They are sacrificed in the pustule, and, being discharged with the scab, they leave the holes that they occupy in the skin. You will remember the sweat-glands are on the inner surface of the skin. Of some hundreds examined some years after vaccination, it was found, in Prussia, that sixty-five hundredths had this particular kind of cicatrix; that is, more than half had it. And they found, also, that the small-pox modified would occur in these persons about as often as in those who had imperfect marks. But in those who had no mark at all, the

exposure was a great deal more. In the early part of my professional life, one of my medical college classmates established a vaccine institution here, and advertised that he would pay five hundred dollars to any persons that he had vaccinated to his own satisfaction, if they took small-pox, or any modification of that disease. He adopted the plan of vaccinating and letting the vaccine run its course, and then to vaccinate again, and so on as long as he produced a pustule or vesicle, continuing to vaccinate until the introduction of the matter left nothing more than a scratch to heal up. And so long as he continued the business, he had not a call for the five hundred dollars. The course more generally adopted is to vaccinate and trust to it.

Then the question comes, whether revaccinating is necessary. In 1852 the State Medical Society made me a sort of committee to investigate that matter, and I ran over all the European records that I could find, and made of the abstracts quite a little volume, which, however, was never published, and on that based my report to the State Medical Society in 1852. I found that a very considerable number of those who had been vaccinated did not have small-pox for a long time—not during the time they had been under observation, and in some cases this was forty years and more; that a smaller proportion did have varioloid, or modified small-pox, and rarely one would have the fully developed small-pox. And in tracing the relations to each, it appeared to me that passing through the period of puberty had some influence in diminishing the protective power of the vaccination; that a considerably larger number had the modified small-pox after puberty than before. I have no doubt whatever in regard to the propriety of revaccination; that is, vaccinating a second time when small-pox is prevalent. We do not think to do it when it is not prevailing. For my own part, I believe I have been vaccinated six or seven times, and every time the vaccine produces a sore. I do not remember the effects of the first vaccination, for the matter was introduced into my arm when I was a child. But the sore produced by each succeeding vaccination has been very much like that that was produced thirty years after the first. But I have given it up now; I think I am protected by age.

Small-pox is a disease eminently of young persons. It will attack anybody; but of ten persons of from forty to fifty years of age, exposed in the same way as ten from one to ten years of age, there is a very great difference in the number of the two classes that will take the disease. Almost all exposed to it in early life will take it.

In regard to the period when the revaccination should take place, I think it would be safe to say at about sixteen or seventeen years of age. I do not know but that repeated vaccinations will give just as much protection against small-pox as having the disease will. There is a story of small-pox in the revolutionary army. A soldier died of the disease, and the surgeons selected two men well marked by small-pox, to bury the body, and one of them took it in performing this duty. Every now and then we hear of persons who have had small-pox having it a second time. It is the same thing with scarlet fever, typhoid fever, and typhus fever.

A word more with regard to the preservation of the virus. I told you about arming the goose-quills, cleaning off all the animal matter, and making them smooth and clean, and then arming them by the puncture of a pock or pustule; then splitting them up into six pieces when the two ends are armed. Another way is to seal up the virus in a capillary tube. In that way it can be preserved for almost any length of time, if the air have not access to it. Another mode to which resort is had sometimes, is to preserve the scab; then cut it in the middle with a sharp knife, scrape off a portion of the maternal and moisten it either with tepid water or the saliva of the person who is to be vaccinated. That can be introduced on the point of a lancet into the scratches that have been made. The best vaccination is from arm to arm. In some of the Italian cities men are seen driving cows through the street, offering vaccination from the cow.

Thirty years ago I found, in transparent lymph of the pock of vaccina, numerous minute microscopic bodies floating free. They, in the last few years, have been seen by other persons, who regard them as of vegetable origin, and as being the contagious element. Dr. Roberts says they are "particles of biophasm whatever that may be to which the lymph owes its active properties." According to Dr Beale the pock of small-pox contains similar particles.

To sum up, I think we may say that the greatest medical discovery, after that of the circulation of the blood, is vaccination, and although Jenner did not work hard to make the discovery, he deserves all the credit for it.

There is a form of disease that has been sometimes regarded as a modification of small-pox, occurring almost exclusively in children, and not very prevalent,—varicella. Its name, you observe, is derived from the supposed resemblance to variola, a literal translation would make it a little small-pox. But it appears that it has no connection with small-pox whatever. That is shown in two or three ways. First, persons who have been vaccinated, or persons who have small-pox, are just as liable to have varicella as those who have not; and second, varicella furnishes no protection against small-pox; and third, the history of the disease is very different, as you will see. It has no febrile invasion. The first thing that is seen is little papular swellings that grow pretty rapidly into vesicles and die away, and the scab dries up about the fourth day. This is not the history of the small-pox pustule, as you see. Then, again, while this first crop of vesicles is drying, other vesicles will appear in the same neighborhood. New vesicles will form and run about the same course, and it is not uncommon for a third crop to appear, so as to occupy about twelve days in the course of the whole disease. There is no particular part of the body that is exclusively liable to this eruption. It occurs, however, more frequently upon the chest than anywhere else. The number of vesicles may not be more than half a dozen, or there may be a dozen dozen. The child's health is very little affected by them. It seems to eat, sleep, and play about as well as if there were no disease upon it.

It is regarded as contagious, communicable from one person to another—from one child to another, at any rate—and is not traced to any special condition of the stomach.

As the child's health continues to be good during the whole prevalence of the disease, you have very little occasion for treatment. Indeed, mothers who are familiar with it do not send for the doctor. They know that it is mild in its character. Its mortality is nothing, unless some complication occur, and the treatment is nothing.

The difference between the pustule, or rather the particular manifestation of the disease, and that of small-pox, is, as I intimated by the phrase that I

used, that the chicken-pox (which is a translation of the word varicella), forms only a serous vesicle. It is only in particularly bad cases that there is any purulent matter at all; and that, as I told you, dries quickly. The scab falls off and leaves no cicatrix, unless purulent matter formed there.

NERVOUS DISEASES CONNECTED WITH THE MALE GENITAL FUNCTION.

By GEORGE M. BEARD, A.M., M.D.,

NEW YORK.

(Continued from p. 556, Dec. 6, 1879.)

THE NATURAL HISTORY OF CONTINENCE—THE NERVOUS SYSTEM AS AFFECTED BY CASTRATION—PSYCHOLOGY OF OLD-MAIDISM AND BACHELORISM—SUDDEN CHANGES IN SEXUAL HABITS—FROM EXCESS TO ABSTINENCE, AND VICE VERSA—LATE MARRIAGES—ILLUSTRATIVE CASES.

IV.

The Natural History of Continence.—What is the effect on the nervous system of a life of absolute continence in the adult male? This is one of the hardest and complex of all the many difficult questions connected with this subject. The difficulty in answering this question is of a threefold character: First, in getting at the facts—that is, the habits of individuals or of classes in respect to continence; secondly, the difficulty in reasoning rightly from the facts after they are ascertained; and thirdly, the difficulty in studying the peculiarities of individuals; of idiosyncrasies, especially as they are developed under high civilization.

Any wholesale, absolute, briefly and dogmatically stated answer to this question would probably be erroneous. To say that continence in the adult male is entirely consistent with perfect health to the nervous system in old cases, or to say, on the other hand, that absolute continence is impossible for the adult male in any case, would be to say what is not sustained by facts, nor in harmony with the principles of deductive reasoning. My own studies on this subject, which include a careful and repeated inquiry into the habits of patients, conversation with very many physicians in regard to all the points involved, and an inquiry into the habits of savage, barbarous, and semi-civilized races, so far as is practicable, through all authorities on sociology,* bring me to these general conclusions:

1. Absolute continence is possible for an adult male, and consistent with health and longevity, with the relief that comes from occasional involuntary emissions, provided that the person is originally strong in his nervous system.

Involuntary emissions, as a means of getting rid of the secretion of the seminal fluid, are certainly unnatural—in the ordinary sense of the term unnatural—and when acting on a sensitive organization, are likely to do harm to the nervous system; the emissions will increase in frequency and will aggravate themselves, and induce a pathological state with a large number of symptoms. On the other hand, in a stronger and grosser temperament, such results may not follow; there may be no weakening, either local or general, that is perceptible, and the effects of continence may be of a *negative* character. Those who live in this way, or who know those that do live in this way, may infer that all persons could or might follow their example; but such reasoning would be deceptive and incorrect in theory and out of accord with the facts of observation.

2. Individuals of nervous and sensitive organizations find it usually difficult, and oftentimes impossible, to lead an absolutely continent life without suffering from nervous symptoms, which, in some cases, are of a serious and crippling character. The lower one is in the stage of evolution, the easier it is to be continent; the higher one is in the stage of evolution, the more difficult it is, other conditions being the same, to be absolutely continent without being thereby perceptibly affected. This general law sweeps through all the functions; delicacy and complexity of organization narrow the margin of endurance, so that both excess in indulgence and excess in abstinence become injurious; entirely abstaining or over-yielding, more quickly excite nervous symptoms than in the coarse and hard and phlegmatic temperament. The savage can go for days without eating, and when he eats can gorge himself, with but slight and temporary harm; the civilized man must have his three meals a day, and the neurasthenic patient sometimes requires to be fed every few hours, or even every few moments. In this brain-working, active, and nervous city, there are thousands who, if they abstain from a single meal, or even delay a meal much beyond the usual hour, are rendered irritable and fretful, and are liable to be attacked with headache, and various symptoms and are made incapable of effective work. The nervous man is dependent upon his food, upon the regular supply of it, and the supply must be frequent and regular; whereas, in the savage life, among all races of savages in all countries, irregularity of eating is the habit. To eat enormously or to go days without eating, are borne by them equally well. The negroes of the South, whose habits I have recently studied specially, in relation to an allied subject*—the causation of insanity and neurasthenia and other diseases of the nervous system—can, and will, for very slight compensation, row one of their heavy boats with awkward, ugly oars, all day, into and through the night, without anything to eat. If something is offered to them, they are glad to get it, but they can get along very well without it; and when, on getting something, they overeat, are very little harmed.

In this feature the reproductive system follows the same law as the digestive system; the more complex and sensitive and impressible the organization, the more likely are we to suffer from unnatural and prolonged abstinence. It follows, therefore, that there is no general, sweeping, universal cast-iron law upon this subject, fitting to all nations and races and conditions and temperaments and idiosyncrasies; in this, as in everything connected with the nervous system, each case is its own special study. There are individuals who need marriage, who cannot be well without a certain degree of normal sexual activity; and there are individuals who can bear—without, at least, serious or positive effect on the nervous system—prolonged sexual starvation. One

* The list of authorities can be found in my works on Stimulants and Narcotics, and Eating and Drinking. (Putnams.)

* In my paper on The Problems of Insanity, the habits of these negroes are more fully discussed.

reason, undoubtedly, why the coarser and phlegmatic temperaments can bear abstinence, even when their sexual power is very great, is that they have little imagination and their functions are not thereby so much excited, and are not so likely to become abnormally sensitive.

There is no question that true spermatorrhœa may result from prolonged continence in a nervously sensitive temperament, even when there is no self-abuse. This fact is, I believe, not understood, but it is as veritable as any fact of this kind can be. For such persons, who are more numerous in society than we may suppose, continence is impossible, except at the expense of the nervous system. Individuals of this temperament, also, are much more likely to be injuriously affected by slight excess than others; their margin of indulgence or non-indulgence is very narrow; whereas, the coarser and harder organizations bear, without immediate or traceable harm to the nervous system, either protracted abstinence or a very great indulgence.

The indiscriminate and off-hand recommendation, marriage, for cases of nervous disease, is as unscientific as the indiscriminate recommendation of any other hygienic or therapeutic measures. I see many of the best results of treatment in cases who do not get married, and who live a continent life; I also see cases who are decidedly better after marriage, to whom this, indeed, becomes the proper supplement to other medical and hygienic treatment; I also see cases, as all do, where excess in the marriage state—that is relative excess for the individual, by which I mean indulgence which is too much for that individual—brings on, in full force and in severe form, all the symptoms of sexual neurasthenia that have been supposed to be the exclusive property of young and unmarried men; morbid fears in immense number and variety, profound exhaustion, insomnia, dyspepsia, tremors, head and back pain, irritable eyes and the like.

3. Absolute and prolonged and permanent continence apparently reacts unfavorably on the mind, depriving it of some of its highest possibilities. The nervous system may be sound and free from perturbation, and at the same time be far below its possibilities of activity and fruitfulness. A person may be well and remain well all his life, without ever reaching the condition where the mind is at its highest stage of activity and productiveness. It is a part of the reactions and interactions of the different organs on each other, that the exercise of the sexual function, like the exercise of the digestive function, stimulates and sustains the exercise of the intellect; the higher nature is reinforced by the lower. The psychology of old-maidism and bachelorism is yet to be written, but an exhaustive and scientific essay on that subject would be an important and most valuable and very much-needed addition to the literature of the nervous system. The distinctive mental characteristics of persistent old-maids and bachelors—qualities which they would not have had if married—represent, when psychologically analyzed, not gain, but sacrifice. While a great quantity of excellent and useful work has been done and is being done, both by men and women whose reproductive natures have been little or not at all exercised, there is yet no evidence that any of the best intellectual work of the world in any department has been done by persons of this class. All the facts that can be obtained on so delicate and inaccessible a subject as this show that the most intellectual natures, in every department of intellectual activity, have not starved, but, on the other hand, very freely exercised the reproductive functions. Enough, certainly, is known on this subject, to make it clear that the free activity of this function is consistent with the supreme developments of the human mind. The very common belief that the mind gains by sexual abstinence is unfounded and is unscientific, as was the equally common belief that great thinkers were small eaters. Biography shows that the geniuses of the world have been prone rather to over indulgence, both of the digestive and reproductive system. Out of the vast mass of valuable work that has been done and is being done by those who, we have reason to believe, are continent, there is little record of any considerable amount of creative work which has directly changed, or is likely to change, the destinies of mankind.

The effects of castration on horses, bulls, and rams, is to render them docile, submissive, manageable,* but these desirable and indispensable characteristics are obtained at the price of the higher manifestations of brain-force in these animals; their ferocity, their ugliness and violence, are psychologically greater qualities, and indicate a better activity of the higher nerve-centres than those qualities that are needful in domestication.

With this decrease of mental capacity there is an increase of fat; the animal becomes larger and more unwieldy; it has good health and may live long, but the higher manifestations of force are no longer possible.

Eunuchs behave like castrated animals; the voice changes, the manhood declines, and there is an increase of fat.

Sexual starvation in man, at least, has, in a far less degree, the effects of castration, depriving the intellect of its supreme capabilities, while not interfering with the mild and routine operation of the brain or body, nor with the physical health. Priests are, with many exceptions, notoriously fat, and the married of both sexes very often, if not usually, begin to grow fat or to increase in weight between thirty-five and forty-five—just the time when there is observed, on the average, the beginning of a slight diminution of sexual power, and, in woman, the change of life takes place.

In my work on "The Relation of Age to Work," published some years ago, it was demonstrated that about all the original work of the world, in all departments of human activity, was done and had been done between the twenty fifth and forty-fifth year; original creative work is the best and indeed the only usable test of brain-force; we are most productive when we are most reproductive.

Mr. Lecky, in his "History of Morals"—a work that should be read and re-read by students of the nervous system—has the following passage to which especial attention is called: "But, in the eyes both of the philanthropist and of the philosopher, the greatest of all results to be expected in this, or, perhaps any other field, are, I conceive, to be looked for in the study of the relations between our physical and our moral natures. He who raises moral pathology to a science, expanding, systematizing, and applying many fragmentary observations that have already been made, will probably take a place among the master intellects of mankind. The fastings and bleedings of the medieval monk; the medicines for allaying or stimulating the sensual passions; the treatment of nervous diseases; the moral influences of insanity and of cas-

* See Dr. Lindsay's Mind in the Lower Animals, vol. ii., p. 382.

tration; the researches of phrenology; the moral changes that accompany the successive stages of physical developments; the instances of diseases which have altered, sometimes permanently, the whole complexion of the character, and have acted through the character upon all the intellectual judgment, are examples of the kind of facts with which such a science would deal."

4. Sudden and violent changes in sexual habits, especially in mature years, react injuriously and sometimes very seriously on the nervous system. Changes of this kind are of a three-fold character:

(1.) From masturbation to absolute continence.

(2.) From very long continence to excess, as in the case of those who marry in mature years—late in life.

(3.) A change from excess, or, at least, from regular activity to absolute continence, as in the case of those who are suddenly bereft of a companion.

All these three changes in a nervous constitution may produce important and complex and distressing symptoms of the nervous system. Those who have followed the cases that have been detailed in this series of papers can scarcely fail to have observed that, in the instances of young men who are afflicted with sexual neurasthenia, there is always a sudden stoppage of the habit of masturbating, followed by continence. Young men are very rarely affected with any of the symptoms referred to here, while they keep up the habit, unless the habit is carried to very great excess indeed; it is the sudden leaving off, caused usually by reading some books of charlatans, that brings on the unpleasant symptoms that drive them in despair to the doctor. There are those among the German writers, and others also, that claim that these young men always lie; that they are still keeping up the habit when they consult us. This is an inference which is not justified by the facts, and is certainly not correct for many of the cases; and in closely studying the histories of these young men, it is found almost always, that while they maintained the habit, even though for some years, they were not distressed particularly—were, indeed, in comparative health—but within a few months or years after stopping, then come on the morbid fears, the hypochondrias, the headaches, the insomnia, the fear of society, the profound exhaustion, etc.

In looking over lists of cases that I have treated, some time since, I became impressed with the fact that very many of those who are in middle life—that is, between forty and fifty—dated their symptoms from a few months to a year or more after the loss of a wife, and that after such loss they remained continent. In a strong, phlegmatic constitution, such a change of sexual habits might not be noticed; but in these nervous, sensitive temperaments, neurasthenic symptoms appear—in some cases, positive cerebral congestion or spinal congestion. I have also noticed, in quite a number of cases, that symptoms of melancholia and mental depression, cerebral congestion and neurasthenia, in all its phases, followed within a few weeks or months, or at most within two or three years, after marriage in middle life, of persons who had been previously continent. The number of cases of this kind illustrating both these forms of change—from continence to excess and excess to continence, in middle life—is so great that it cannot be a coincidence, and I am convinced that it is an operation of natural law.

The following cases illustrate this effect of the sudden changes in sexual habits, and make clear the points I wish to bring out better than any amount of elaborate statement.

Case XXIV.—A gentleman between thirty and forty years of age, married at twenty-three. At that time he was perfectly well, and for several years afterward, except an occasional attack of sick headache. He was of strong build and appearance, and of good inheritance. One year before consulting me he had lost his wife. Since that time he had acquired the habit of opium-taking, so severe had been his attacks of insomnia and of mental depression. He had travelled in Europe, where his sick headaches left him; but, as with the majority of such cases who go abroad for health, he had travelled so far and worked so hard that he came back worse, on the whole, than when he went. He told me that he had "shed barrels of tears," and that he had set the time for his death. He feared that he was going insane.

Evidences of cerebral congestion were very marked. Examination of the urine found a few spermatozoa and spermatic globules.

A case like the above, if taken by itself alone, would prove nothing; but it is presented here as a type of very many. The patient, I should say, positively stated that he had been continent after the loss of his wife, and while in the married state he had been unusually indulgent.

Case XXV.—A gentleman under thirty years of age, married at the age of twenty-five. In less than a year his wife died. Then came on symptoms of seminal emissions, though not especially frequent, considerable insomnia, a burning sensation in the region of the prostate and prostatic urethra. The urethra, on examination, was found exceedingly sensitive—in a condition of considerable hyperæsthesia, indeed; there was much pain in the lumbar spine.

It should be observed here, that at the time of marriage the patient was not specially strong; he had abused himself in early life but had stopped suddenly three or four years before marriage, and thus had become weakened through frequent emissions. Examination found a trace only of spermatozoa. This patient desired to get married again, which he was advised to do, after having first improved the local and general condition.

Now, in the above case, these two facts are clear: First, that during the marriage state he was in comparatively good health and had no symptoms about which he thought of consulting any one; secondly, after the death of the wife he was continent, and coincidently with his continence came on a number of symptoms—not so many, indeed, as we often see in these cases; still, of a positive character—indicating, in a mild form, sexual neurasthenia. The fatigue and labor of attending on a sick companion, and the mental anxiety following their loss, come in, we must all allow, to complicate these cases; but these mental influences and this physical exhaustion combined, would not produce, or would not be likely to produce, this special phase of neurasthenia we have described. Sexual neurasthenia is one of the sub-varieties of general neurasthenia, and, as I hope in time to show, has a group of general and local symptoms by which it may usually be diagnosticated.

Case XXVI.—A gentleman between forty and fifty years of age, only married a few years before he saw me. Within a few weeks after marriage was attacked with melancholia, which became very profound. I compelled him to give up his occupation. The patient wept so easily that it was impossible for him to state his case at first, until he became much calmed. There was much pain in the vertex and the genital centre of the lumbar region and the spine. Considerably before puberty he had contracted the habit of self-

abuse, which he had kept up for some time, and it is not impossible that this early excesse of the parts had imprinted a sensitiveness which may have become a permanent possession with him; but in spite of this he had been, with some exceptions, very well in his nervous system, up to the date of his marriage; indeed, he regarded himself at that time as a healthy man.

In the above case the effects followed so soon after the cause that there is little chance for error. A few weeks passed before the symptoms of brain-exhaustion came upon him in full force. All the more noteworthy was this case from the fact that the patient was a man of great strength of mind, great energy, force and will, and not disposed naturally to yield to fanciful or trifling symptoms.

CASE XXVII.—The following case illustrates both the appearance of nerve-symptoms after a change from indulgence to continence, and also the improvement on recurring to original habits:

A clergyman was brought to me by his physician with symptoms of pain in his head, in the back of the neck, and with attacks of insomnia and other evidences of cerebral congestion and exhaustion. After preaching on Sunday, he would be prostrated on the second day after—on Tuesday—in the morning. There were no evidences of myelasthenia or spinal exhaustion. He was very strong and muscular, could walk long distances. Four years before consulting me he had lost his wife. He was considerably exhausted by attending upon her. Shortly after that he found that symptoms came upon him which made it necessary for him to be very careful, which he had not been before. Then came the symptoms for which he was referred to me. He had married again and his symptoms had improved, and he was on the mend at the time that I saw him. When I last heard from him he was doing well.

The following case is more remarkable and instructive than any of the preceding, as illustrating the propositions contained in this paper:

CASE XXVIII.—A physician, at forty-three years of age, who had married five years before, came to me with a very long list of neurasthenic symptoms, which had compelled him, temporarily, to give up his profession, and which had driven him to desperation. The first element of difficulty in the diagnosis was, that he did not have, apparently, the nervous diathesis which a majority of these cases have; he was a strong, large man, and not especially nervous in the ordinary sense of that term; he would not have been selected as a person of a neurotic temperament. In my work on neurasthenia, I have indicated the means of making the differential diagnosis between functional nerve-symptoms, represented in neurasthenia and organic troubles, such as progressive muscular atrophy, locomotor ataxia, and the like. When this patient was tried by three of those tests it was clearly a case of neurasthenia, but by the fourth test there was doubt. His symptoms were very severe, and some of them were unusual, and one, at least, was unprecedented in its character and severity. The most remarkable symptom was a feeling as if drops of water were falling upon him all over his body, from the top of his head to his feet. Irritations of the urethra, especially near the meatus, will sometimes produce a sensation similar to this along the thigh; but I had never before seen a case where, in any form of neurasthenia, the patient felt as though he were in a mild rain-storm. The patient had twitching of the muscles all over him—that is, fibrillary contractions, so-called—a symptom which is laid down in all the books as indicating muscular atrophy. He had a diffuse feeling of coldness sometimes in different parts of the body. Insomnia was a marked symptom, and mental depression was so severe that he might almost be called melancholic. Fear of society—anthropophobia—was so profound in his case, that while he stated his symptoms to me he found it impossible to look me in the face, but was obliged to turn his eyes in all directions away from me. When I forced his head toward me, so that his eyes were upon me, I found it impossible for him to talk intelligently and satisfactorily. He stated that he had found this same difficulty with patients; that he frequently could not see patients; he was obliged to dismiss them, or have them go away without seeing him. A feeling of profound exhaustion would come upon him, when he would find it difficult to use either mind or body; he was also troubled with a feeling of formication or crawling of the skin; he had also sweating of the hands—palmar hyperdrosis—such as we often see in young men with sexual neurasthenia. Another very interesting symptom in his case was constant gaping as he talked. Critics of my writings on neurasthenia, and noticeably my friend, Dr Althaus, of London, have made much sport of this symptom; but it is, to those who study these cases and do not neglect them or laugh at them, just as truly, in some instances, one of the symptoms of neurasthenia, and also one of the most interesting symptoms of it, as patting is a symptom of small-pox. It appears to be a reflex phenomenon exerted in some cases by the effort of talking. It is not an evidence of fatigue as such, for the patient will gape in the morning just as well as at any time. In this case I never had any conversation with the patient when he did not gape. Another symptom of neurasthenia was *explosions* in the head—apparently in the back part of the head. A homœopathic practitioner, Dr. Searles, has lately published a number of cases where explosions of this kind occurred, and he has described these under the title of "A New Form of Nervous Disease." Rightly analyzed, these explosions in the brain are not masked epilepsy, nor are they epileptoid in any sense; they are merely symptoms of the neurasthenic state, particularly when the brain and upper portion of the cord are attacked. In this particular case these explosions occurred while falling to sleep. There are very many cases where the jerkings of the muscles, often throwing the body apparently up from the bed, occur, and these symptoms of explosions and jerkings may also appear at other times. Other symptoms in the case of this patient were, lack of mental control, neurasthenic voice—which was most noteworthy from the fact that he was a strong, vigorous-looking man—and attacks of frequent micturition. For two months he had had an attack of inebriety in a mild form, and was, to use his own language, "crazy for whiskey." From this attack he had recovered. Inebriety, as I have frequently urged, is one of the very many symptoms of the neurasthenic state. Neurasthenia, both of the general form and of the sexual variety, is one of the most frequent of the many exciting causes of the inebriety, a nervous disease that may attack those who have never been intemperate. As usual, in cases of this kind, this patient was especially nervous and debilitated in the hot weather of July and August.

Few patients that consult me are so difficult to diagnosticate, especially in regard to causation, as the above case. There seemed to be at first no reason why the patient should have these symptoms; they had come on apparently without any

traceable cause. He had had syphilis fifteen years before, and syphilis attacking the nervous system might give rise to many of these symptoms, but it would not give rise to the whole group. Malaria, we were obliged to exclude. I was compelled to see the patient two or three times before I got all his history in detail, or got a complete record of his symptoms. He had his urine examined by Dr. Mittendorf, and found absolute and clear proof of spermatorrhœa and oxaluria. On undertaking to pass a sound into the urethra, I found it was absolutely impossible to do so; he could not allow even a small sound to enter half an inch.

The whole history of the above case, taken together, made clear to me, beyond all question whatever, the diagnosis of sexual neurasthenia, caused mainly by a sudden change in sexual habits, a relative excess following long continence, and the hygiene and treatment were ordered accordingly. This patient, being a medical man, had read immensely on the subject, and the more he read, the more distressed he became. Pathophobia, or fear of disease, was one of the symptoms; he had made a diagnosis of liver disease, of heart disease, of locomotor ataxia, and of "softening of the brain," and was surprised, as well as relieved, when I told him that he could not have any one of those conditions. He very rapidly improved under treatment.

This case is very instructive, as showing that physicians, when they are attacked with neurasthenia of any kind, whether general or sexual, suffer more severely than any other class. They read; they read good books; they read German authorities; and the conclusion which they are obliged to draw from their reading is, that the symptoms indicate severe incurable organic disease of the brain or spinal cord, for the best authorities in the world tell them so, and it is not to be wondered that they become alarmed. One of the important medical wants of the age is the diffusion, through all the literature that the profession consult, of the points in the differential diagnosis of functional and organic disease. I have tried, as best I could, to make these points clear in other writings on "Nervous Exhaustion," and in this series of papers also; but, no matter how much may be written upon it, it must be many years before there shall be a thorough understanding on the subject in all ranks of the profession everywhere, and before our text-books on nervous diseases will have corrected the errors which they teach on this important theme.

A CASE OF
PERFORATING GUNSHOT WOUND OF THE CHEST—RECOVERY.

By RICHARD O. COWLING, A.M., M.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF SURGERY IN THE UNIVERSITY OF LOUISVILLE.

X., a lad eighteen years old, had suffered for many years with dyspepsia. He had been under the care of a homœopathic physician without relief. All food disagreed with him, milk least of all, though the digestion of this was painful, and he could take it by the spoonful only. In the summer of 1877 he had, in search of health, gone on a voyage to South America, and had received some benefit thereby, eating, for awhile, the ship's fare; but soon after his return he relapsed into his former condition. In spite of his meagre diet, his body was not poorly nourished. He weighed a hundred and eight pounds; could chop wood and undergo ordinary fatigue in hunting, with which exercises he strove to regain his health. He was of precocious mind, read continually and at late hours generally, with the effect of aggravating his dyspepsia. The ingestion of food, reduced again to milk alone, became more and more painful, and, in a fit of desperation, he determined upon suicide.

On December 29, 1877, he shot himself in the following manner: placing the muzzle of a fowling-piece against his naked breast, below the left nipple, and resting the butt on a low bench in front of him, he leaned forward and pulled the trigger. The gun used was twenty-eight inches in the barrel and of No. 14 bore. It was a "muzzle-loader," and was charged with three drams of powder and an ounce and a quarter of No. 8 shot, having been loaded thus heavily "for a hawk." The wadding was of paper.

He was alone in a room detached from the house in which his family resided when he committed the act. He does not remember hearing any report, and felt no pain, but rather as if he had been shoved backward with some force. He afterward walked to the door, called a servant who was passing, and returning, fell upon a bed and saw blood streaming from his breast. He never lost his consciousness. When the members of his family reached him, he recognized them and their distress, and remembers the summons for a doctor.

Dr. Chenowith, of the neighborhood, was the first to arrive, within an hour. Seeing the magnitude and situation of the wound, he considered, of course, that death was impending. Excessive pain had in the meantime come on, and the patient asked for chloroform. This was given him, and morphine, ¼ grain, was injected into his arm. The hemorrhage had ceased when Dr. C. arrived. No blood had been spat, nor did any come through the mouth during the progress of the case.

A messenger was dispatched to the city (the family resided in the country six miles away) for me, and not finding me, Dr. Kelly drove out. He found his condition unchanged. Pain was the prominent symptom, and this seemed to be increased by the air rushing into the wound. With the hope of giving some relief, the anterior opening was sealed with rubber plaster, and the morphine was continued.

I saw the patient first on the morning of December 30th, nineteen hours after the shooting. He was lying in the position he had first taken, half-way reclining upon the bed, his feet resting outside upon a chair. He was pulseless at the wrists and at the brachials. His temperature was 96½°. His voice was clear, and he complained of excessive pain. More morphine was given, and his clothes, which, with the bed-coverings, were saturated with blood, having been removed, we put a clean shirt upon him and laid him upon a fresh lounge. He bore the handling well, and expressed some comfort at his new position. No hemorrhage was started by the movement.

The anterior opening of the wound was concealed by the plaster. Through the posterior one the air rushed in and out with a snoring sound. The noise worried the patient much and depressed him. To prevent this, we agreed to seal the posterior wound also, until the discharges should commence—if, indeed, the patient should survive so long. The sealing of the wound did give temporary relief. Besides the plaster it was agreed that large linseed poultices should be kept to the wounded side embracing both openings; hypodermic morphine be given as re-

quired, and the patient be fed with milk at short and regular intervals. He could take none of the ordinary stimulants and we gave him tea as a substitute.

Dr. D. W. Yandell saw the patient with us on the afternoon of December 30th. Dr. Kelly continued in the case a few days. Afterward it fell to Dr. Chenowith and myself. I remained with the patient thirteen consecutive nights.

On the third day the plasters were removed, and I had my first view of the anterior wound. It was about an inch and a quarter in diameter, slightly oval. The top of it was two inches below the left nipple. The inner edge on a perpendicular line dropped from the nipple. The part for two inches or more around were badly burned. The discharge had passed in below the fifth rib, cutting the sixth in two. The posterior opening of the wound was apparently an inch below and to the outside of a line passing directly from the front aperture to the back. It was not so large as this by fully one fourth. The shot had passed clear through the chest, and, as I subsequently discovered, had lodged in the ceiling, covering an area of about eighteen inches in diameter. The relative position and size of the openings at first did not seem to point to the anterior one being the wound of entrance, as the accompanying burn indicated—and as the patient subsequently, when he was able to answer our questions, informed us. I found, however, by experiment (with an empty gun), that in leaning over the piece in the manner in which the shooting had been done, the course of the charge would apparently be in the line taken in the case in hand. I found, especially, that in leaning over to reach the trigger, the body was necessarily twisted, and the muzzle was directed outward.

I resume the history of the case. On Dec. 31st, there was still no pulse. The temperature was 97½°. On January 1st, seventy-two hours after the shooting, the pulse became perceptible, though then extremely faint. The temperature was 98½°. The discharge of pus began on this day, and the plasters were removed. On January 2d, the pulse could be counted 180; temperature, 99½°. On January 3d, pulse, 160; temperature, 99°. The temperature remained at this point during the progress of the case until the third week, when it became normal—never having mounted to 100°. The pulse improved in number and quality of the beats until on the tenth day it was at 125, ranging up and down ten beats or so during the day. At two weeks it was under a hundred. The discharges which commenced on the third day soon became excessive, necessitating the removal of the poultices every few hours. Their fetor also was intense, in spite of every disinfection, and caused one of the chief complaints of the patient.

The wound enlarged greatly during the progress of the suppuration, and at the end of a fortnight was seemingly of sufficient size for the patient to have been easily spitted through it upon a broom-handle. Beyond the chest-walls it was excavated in all directions. The ends of the cut ribs, before and behind, could also be seen, and the patient complained greatly of their movement, "as if they were being thrust into his flesh." With the beginning of the third week a marked change took place in the wound. The fetor suddenly left, and became less and less profuse. Granulations sprung up so rapidly that by the twenty-first day the anterior opening was bridged entirely across, and by the thirtieth it had fairly cicatrized. At the same time, the granulations around the posterior opening, which had nearly closed, began to pout, and a spicula of bone was discharged. Two or three weeks subsequently I extracted two other small and sharp splinters, after which no other foreign bodies came or were taken away.

A curious change took place in the patient's appetite during the progress of the case. The milk, which at first was somewhat forced upon him, was called for after the first week, and taken in continually greater quantities. Soup was then added to his diet, and gradually eggs, porridge, oysters, fish, game, mutton and beef were placed upon his bill of fare by his own direction. One day near the end of the third week it was announced to us that his breakfast had consisted of coffee, six buckwheat cakes and a "porter-house" steak—provender even the taste of which he had gone for years without knowing.

I was led to believe from this improvement in his digestive powers that his dyspepsia would not return; that his digestive organs, which had perhaps lost much of their powers through long suspension of their functions, having regained them under the stimulus of the drain which was now producing an appetite with the necessity for food, would continue to hold on to them after recovery from the wound. That ability to eat and digest would come by eating and digesting, just as sometimes the lame learn to walk by walking. The event proved the truth of this prognosis in part—another factor interfering with its whole accomplishment.

During the first three weeks of the patient's confinement he had been harassed with a continual cough, caused by the exposure of the lung to the air. It ceased when the wounds were closed with granulations. His forced position, too, upon his back, was excessively annoying, and the frequent dressings severely taxed his endurance, though they were done from first to last with the exquisite tenderness of a devoted mother. With annoyance and discomfort severe pain continued a prominent symptom for a number of weeks, and the patient had generally a third of a grain of morphine by hypodermic injection every six or eight hours.

On Feb. 3d he was removed from the room in which he was confined to the house in which the family resided. On this day he stood upon his feet for the first time, and a few days later could leave his bed for a few hours at a time. He continued to improve in strength—and kept his appetite for several weeks. The morphine habit had grown upon him, however, and he could not or would not leave off the injections. Apparently as a result of this, his former nervousness returned in a degree—he had frequent sick stomach, with occasional vomiting—and his loathing for food in a measure returned. I made an attempt to combat the effects of the morphine, but my surgical services being at an end, the patient preferred to return to his old love for medical treatment, and so I saw him no more. He was ordered to the seaside, as I learned, and after an absence of several months sent me a photograph of himself which represents quite a healthful-looking youth. After two years, as I have been informed, his general condition, though far from being of the best, is a great improvement upon his former state.

The vast clinic of the civil war presented so many examples of gunshot wounds of the chest received at every point upon its area—and from missiles of such varied description—and all questions connected with their prognosis and treatment have been so well discussed in the surgical records of the army, that it would be vain in a double sense to offer any such remarks from the text of the single occurrence which is here presented. I simply wished to put upon

record a case which I think will be found curious even among the curious, for while the chest has been perforated time and again with almost every missile known to war-killing, it has not often happened that an ounce and a quarter of bird-shot have passed through the lung so near the heart, to the apparent improvement in the condition of their owner. If I were asked what particular factor I thought tended most to the recovery of the boy in the case narrated, I would say that it was the perfect drainage which the direction of the wound made possible; but then we know that during the war there were earnest and able advocates of a position which destroyed drainage by sealing the openings of the wound. There is one point, however, upon which I think every surgeon, as the result of his own experience and a study of his records will agree—that in no class of surgical injuries does each case determine its own laws more than in gunshot wounds of the chest.

LOUISVILLE, KY.

ON THE RELATIONS OF NERVE AND MUSCLE.

BY THOMAS W. POOLE, M.D.,

LINDSAY (ONT.), CANADA.

(Continued from page 484.)

IN continuation of this subject, let us take our leading physiologists at their word, and admit the inherent endowment of muscular tissue with the property of contractility, "with all that the term implies." Their evidence (already quoted) is none the less valuable or reliable, because given—like the favorable admissions of an adverse witness—in support of a different *plaidoyer*.

Since muscle has been shown to be "so exquisitely organized for the *development* of its proper force"—contractility—and since a nervous "stimulus" is not needed to do for muscle what it can do of itself; nay, more, since the foregoing facts show that nervous agency is a hinderance to muscular contraction, and that the latter occurs to the best advantage in proportion as the influence of the nervous centres is withdrawn, the conclusion is obvious that the function of the motor nerves is to *restrain* muscular contractile power, and that a *release* of this "proper force" of the muscle occurs when the will, acting through nervous agency, directs co-ordinated muscular movements.

This is not a new doctrine. It was suggested nearly fifty years ago by Dr. West, an English physician, in an essay then published. Sir Charles Bell gave countenance to Dr. West's views, in a lecture at the Royal College of Surgeons, London, in which he said "that *relaxation* might be the act, and not contraction; and that physiologists in studying the subject had too much neglected the mode by which relaxation was effected." (See Dr. C. B. Radcliffe's "Lecture on Epilepsy," Appendix, p. 277.)

Before proceeding to point out how fully this theory explains the conditions noted in the previous article, in which the theory of the day proves a failure, and how plainly consistent it is with other physiological and pathological facts, it seems desirable to set at rest, at the outset, what may be regarded as an objection of importance.

AN OBJECTION ANSWERED.

It will be asked: If the function of motor nerves be to restrain muscular contraction, why do not the muscles at once contract when their motor nerves are cut, by accident or design? In reply it may be stated that, in the case of involuntary muscular fibre, it really appears that muscles of this class *do* contract when their controlling nerves are cut or paralyzed. Take the authenticated experiments in which the pneumogastric nerves of the rabbit have been cut "below the pharyngeal and above the œsophageal plexus," as detailed by leading physiologists. Here the pharyngeal and upper parts of the œsophageal muscles are still under nervous restraint and food is passed downward. When the bolus reaches the lower œsophageal region, of which the motor nervous supply has been severed, it is "suddenly rejected by a peculiar kind of regurgitation." (Dr. Dalton, "Phys.," p. 473.)

Does this result imply *paralysis* of the muscular fibres of the gullet, as has been asserted by our physiologists? Far from it; the ejection of the bolus is the result of contraction of the muscular coats of that tube, which contraction is especially active in that part of the organ from which nervous restraint has been withdrawn by section of its nerves. The lower end of the œsophagus is not a mere flaccid tube in a state of "paralysis," otherwise the bolus could not be first delayed and then ejected in the manner stated. Indeed, Dr. M. Hall found that "the simple contractility of the muscular fibre (of the œsophagus) occasions a distinct peristaltic movement along the tube *after its nerves have been divided*, causing it to discharge its contents when cut across." (Dr. Carpenter's "Phys.," 5th Amer. ed., p. 404.)

Nor does the evidence point to "paralysis" of either the cardiac sphincter, or of the stomach, as a result of this operation. The absence of distention in the latter, and the fact of the ejection of its contents, shows the continued activity of the gastric muscle; while it is well known that "the reopening of the cardiac orifice, *on pressure from within*, is one of the first of that series of reversed actions which constitutes the act of vomiting" (Dr. Carpenter), and is therefore no evidence of paralysis of this muscle.

Dr. J. Reid has shown that section of the gastric branches of the vagi "may cause, in the first instance, vomiting." (Drs. Todd and Bowman, "Phys. Anat.," p. 493.) Here the gastric muscle is no longer adequately restrained, and contracts accordingly, just as it does when deprived of nervous restraint by the shock of a fall, by a blow on the head, by the depressing agents known as emetics, and in *the vomiting of pregnancy*, owing to the monopoly of nerve-force by the uterus in consequence of the unusual development there taking place. How naturally this explanation serves to explain these several conditions. No one who has suffered the horrors of sea-sickness, or the deadly nausea which tobacco is apt to produce in those using it freely for the first time, will doubt that vomiting is essentially dependent upon nervous paralysis rather than an excessive development of nerve-force "stimulating" the gastric muscle.

In Valentin's experiment a portion of intestine was shown to contract so effectively after the severance of all its nervous connections as to expel its contents through a perpendicular tube inserted in one end of the portion experimented on. Drs. Todd and Bowman show that involuntary discharges from the bowels and bladder are not due to paralysis of the sphincters, but to increased pressure from "the parts above," which overcomes the resistance of the sphincters. ("Phys. Anat.," p. 180.) Here, again, it is the nerves which are "paralyzed," and not the muscular fibres of the intestines or sphincters. The

contractions of the uterus and of the arterial tubes, under the influence of ergot, acetate of lead, and other drugs, may fairly be claimed to admit of a similar explanation. These drugs are inimical to normal nervous life, and certainly no one would think of them as stimulants. It is, therefore, a rational explanation of their action that by paralyzing nerve-force they withdraw its restraint over the arterial and uterine muscles, which pass into contraction accordingly in obedience to their inherent property of contractility. If ergot were a stimulant to nerve-function, it ought to quicken the pulse and dilate the arterial system as other stimulants do. Dr Radcliffe says of it, "In spasmodic ergotism, so far as we know, the pulse presents no sign of excitement throughout the whole course of the malady." ("Lectures, etc.," p. 226.) And it is well known that ergot lowers circulatory activity by a general contraction of the arterioles throughout the body.

Without delaying over minor facts and illustrations of similar import, enough has probably been advanced to justify our theory so far as the involuntary muscles are concerned. These, as is well known, are chiefly supplied with nerves from the sympathetic system, in the peculiar relations of which to its muscles there may be, and doubtless are, material differences not yet appreciated, compared with the relations of the spinal motor nerves with their muscles.

It will not do to compare the motor nerve-trunks to a tense cord, holding the muscle (like a bent bow) in restraint, and expecting the bow to straighten the moment the (nerve) cord is severed. If the motor nerve-trunks are nothing more than mere carriers of nerve-force, what is the meaning of their motorial end plates, with their prolongations studded with granules and nerve-nuclei, which penetrate the microscopic fibres of the muscle? What are these but local magazines of nerve-power, which for a time continue to control the muscle after the generation of nerve-force has ceased in the nerve-centres—as on the somatic death of the body—or after the influence of these centres fails to reach the muscle, owing to section or injury of the nerve-trunk?

When a motor nerve is cut (its molecules in the terminal end plates being at the time adjusted for muscular relaxation), the muscle cannot contract until the molecules of the terminal nuclei are reversed, or their static condition modified by trophic or other changes, not even when the muscle is separated from the body. If now a pinch, burn, a drop of dilute acid, or an electric shock be applied to the peripheral end of the nerve-trunk or to the end plates and nuclei in the muscular fibres, the static condition of the nerve-molecules is overthrown and the muscle set free to contract. If the process is repeated, or has been at first intensified, the time comes when the muscle contracts as much as it is capable of doing, and then makes no further response. It is then erroneously said to have lost its "irritability," whereas it is still capable of passing into the rigid contraction of rigor mortis. How could it ever have entered a physiologist's mind that a pinch, burn, a drop of acid, or even a rude touch, could play the part of stimuli to microscopic nerve- or muscle-fibres? Is it not, on the contrary, obvious that such rude assaults upon the integrity of nerve-function (whether applied to the nerve-trunks or to their endings in the muscular fibres) arrest the power of these attenuated fibrils—put an end, temporarily or permanently, to their restraint over the equally delicate muscular fibres which pass into a state of contraction accordingly?

In ordinary wounds the integrity of the nerve and its functions are speedily restored; but, if otherwise and nerve-function remains inert, molecular changes may confidently be expected to occur, as experience shows, and the muscle passes into a state of contraction.*

But it must also be borne in mind that most muscles have their antagonists, and when the flexor contracts the extensor must yield, and *vice versa*. The normal action of the rival muscle has therefore to be considered as a preventive to the contraction of the muscle whose motor nerve has been divided, as has also the possible intervention of other nerves not included in the section.

In justification, if such be needed, of the explanation just offered, I quote the following remarkable sentences from Dr. Thomas Laycock, Professor of Medicine, Psychology, etc., in the University of Edinburgh: "We must not forget . . . . that not only do the tissues themselves undergo normal vital changes, independently of the nerves or of the nervous system, but also that *nerves and nerve-fibrils perform their appropriate functions independently of the nervous centres*. Nerves are produced anew in organized plasma, and join on to the general trunk in accordance with the order of embryonic development of the nerves *from the periphery toward the centre*. MM. Phillipeaux and Vulpian made numerous researches which prove that *nerves separated wholly from the nerve-centres*, and completely altered as to nutrition, may become regenerated, *although remaining separate*, and recover all their vital functions. Numerous experiments on the nerves of muscles show that these motor *nerve-fibrils have their own inherent properties in entire independence of brain, spinal cord, or nerve-centres*, and not only in separate limbs, but in muscles that have been cut from their limbs." (*Med. Times and Gazette*, 1871, pp. 595, 211; *Brinth. Retros.*, January, 1872, p. 58.)

If the question be asked, would a similar explanation as that given above for the continuance of muscular *relaxation*, after section of a motor nerve, apply also to muscular contraction—that is, would the muscle if contracted at the moment of cutting the nerve, remain contracted, owing to the continuance of the static condition of the nerve-molecules which are then adjusted for contraction of the muscle? The answer is that mental emotion in the conscious subject would vitiate any such experiment, and its conditions could not be realized during artificial anæsthesia. But there is abundant and striking evidence of muscular contraction present in the last moments of life, continuing to be maintained in death; and while such facts confirm our theory, they are highly embarrassing to the theory of the day.

HOW THIS THEORY ACCORDS WITH GENERAL FACTS.

The explanation given above serves also to show why the muscles do not at once pass into a state of contraction on the somatic or general death of the body. Nerve-force holds its sway for a time in the motorial end plates and their nuclear terminations, and as it gradually dies out, the muscular contractile power thenceforth asserts itself till the exquisite organization of the muscle for the development of its proper force is destroyed in advancing putrefaction.

This gradual cessation of nerve-force, releasing one fasciculus or one muscle after another, accounts for those remarkable post-mortem movements of parts, or limbs, already referred to as wholly unaccountable on the theory of the day.

* Drs. Mitchell, Morehouse and Keene: "Gunshot Wounds," Case 87.

This theory accounts for post-mortem parturition; for parturition occurring (as vouched for by Dr. Carpenter) in cases where the spinal cord is paralyzed or destroyed; and for after-death evacuations of the intestines and bladder. During life, nerve-force restrains these hollow muscles; but when nerve-force becomes extinct, they assert their power, and if the necessity is present, expel their contents. The *paralysis* of sudden fear in men and animals, as is well known, not unfrequently results in similar involuntary evacuations.

Muscular spasms and convulsions, so generally associated with nervous paralysis, find here a ready solution, and these spasms will be tonic or chronic in proportion to the intermittent or persistent freedom of the muscles. What is called muscular "paralysis" is really a state in which the influence of the will is prevented from reaching the muscle, but in which the muscle is still contracted by the spinal nerves, the influence of which prevent it from passing into contraction, which it will do if finally freed from nervous restraint, as occurs in "late rigidity" and in rigor mortis. The term "paralysis," as applied to muscle, is therefore a misnomer.

The theory here enunciated explains the cramps of the limbs of parturient women, and the occurrence of spasm and convulsion in states of exhaustion and in death from hemorrhage. It shows why convulsions occur when the basal ganglia are deprived of blood—from nerve-exhaustion, and why they do not occur under the opposite conditions—when the nerve-centres are amply nourished and nervous restraint over the muscle duly maintained.

It explains why arterial contraction is found present whenever nerve-force is at a low ebb, as in cholera and aconite-poisoning; and why arterial contraction is complete in death when nerve-force is extinct: because, as nerve and muscle are antagonists, the withdrawal of one of the rivals leaves the more persistent action of the other unopposed.

It explains why a stimulant, as brandy or the nitrite of amyl, dilates the arteries—by increasing vaso-motor nerve-force (the antagonist of contractile power of the muscles of the arterial coats); and why a stimulant becomes our best antidote to spasm by similarly reinforcing motor nerve power, and so relaxing, by restraining, the muscles which had temporarily gained their freedom.

This principle accords admirably with what Dr. F. Anstie wrote of convulsions from narcotic agents. He states: "It is a fact that, so far from being an evidence of excitement, muscular rigidity under chloroform is one of the regular symptoms of chloroform narcosis with many patients. It is characteristic of the moment when communication between the nervous centres and muscles is about to be cut off, owing to *the temporary death of the nerves*." ("Stim. and Narcot.," p. 81.) How is this striking fact to be accounted for on the theory of the day, which demands a "stimulus" from the nerves as a condition of muscular contraction?

(To be continued.)

Changes in City Asylum Management. — Dr. Franklin, late of the Hart's Island Lunatic Asylum, has been appointed superintendent of the New York City Asylum on Blackwell's Island. Dr. A. E. MacDonald, who had been temporarily in charge here, has had his duties limited to the Asylum on Ward's Island. Dr. Healy, who was Dr. Franklin's former assistant, has been appointed to the Hart's Island branch Asylum.

Progress of Medical Science.

Tonga: a Remedy for Neuralgia.—Drs. Sydney Ringer and W. Murrell have used this remedy in eight cases of neuralgia with gratifying results. Mr. Ryder, a gentleman residing in Fiji, placed the remedy in their hands, with the following account: It has been used for several centuries by the aborigines of the Fiji Islands. A European learned the secret of its composition, and gave the drug to Mr. Ryder, who requested the authors to test its virtues. This gentleman also stated that the remedy consisted of parts of at least two plants, whose botanical relations, however, he did not know. The parts of the plants are broken up into a coarse powder, and then wrapped up in the inner bark of the cocoa-nut tree. Messrs. Allen & Hanburys have prepared a liquid extract containing one part of the drug to one part of the extract. Of this Mr. Ryder recommends a drachm three times a day. He and his friends have tried the remedy extensively, and find it most successful. It generally cures by the second or third day. In eight or ten days the pain may return, when a few additional doses will permanently remove it. It has been used in Sydney with great success. This remedy, according to Ringer and Murrell, produces no toxic symptoms. They gave two half-ounce doses of the liquid extract at half an hour's interval, and repeated it again in two hours without producing any effect beyond slight drowsiness. To another person they gave three two-drachm doses at half an hour's interval, with the same result. These doses did not affect the pupil, nor increase nor lessen the secretion of the mouth or skin; neither did they affect sensation of the skin supplied by the fifth nerve. Tonga does not affect the pupil when topically applied to the eye.—*The Lancet*, March 6, 1880.

Spirillum Fever.—An interesting paper on the experimental pathology of this disease was read at a late meeting of the Royal Medical and Chirurgical Society by Dr. Vandyke Carter. It contained details of the successful inoculation in the monkey of the contagion of spirillum fever. The author's experiments were made by injecting the blood of fever patients beneath the skin of the common Indian monkey. The main conclusions arrived at are: 1. That the spirillum fever (relapsing fever) of man is directly transmissible to a quadrumanous animal. 2. That there occurs a non-febrile infection of the blood prior to "fever." 3. That though the blood spirillum was never seen in the monkey without fever ensuing sooner or later, yet the pyrexia is secondary in time, and is susceptible of highly varied manifestations; and the spirillum disease might be defined as essentially a *mycosis sanguinis prope cum febre*. These inoculation experiments have been repeated in Germany with success (*Deut. med. Woch.*, June 21, 1879, p. 327). The question as to the constant presence of the spirillum in the blood in this fever was raised by Sir Joseph Fayrer, and Dr. Harley believed that in the specimens forwarded the "spirillar" filaments were portions of fungous growth. Dr. Lewis, as is well known, found the spirillum in some cases, but not in others, and concluded that the occurrence of the spirillum in the blood was not essential to the fever. Nor did there seem any evidence from the experiments to show that the spirillum was the cause of the affection (*The Lancet*, Feb. 28, 1880). In a note on relapsing fever, Dr. Enke, of Magdeburg

(*Practical Week*, Feb. 28, 1880), writes that he had occasion to observe 136 cases of this affection. The constant presence in the blood of spirillum was particularly emphasized. In some instances these vibrios were only discovered after repeated examinations of the patient's blood. The author furthermore concludes that the spirillum is to be regarded not only as a constant concomitant of the disease, but as its true cause.

Human Filariæ and Mosquitos.—The new investigations of Dr. Manson, communicated recently to the Queckett Club, appear to afford positive proof of a singular habit on the part of the filariæ. These microscopic worms periodically pass in and out of the circulation. Dr. Manson gives a table showing the hours of the day and night at which they are either present or absent in the blood. The worms are remarkably punctual in keeping to their appointed times. The evening inrush to the circulation commences about half-past seven, the overcrowding attaining its maximum at midnight. Numerous infested mosquitos were shown.—*The Lancet*, March 6, 1880.

Transplantation of Bone.—At a recent meeting of the Glasgow Pathological and Clinical Society, Dr. McEwen showed a boy on whom he had operated for necrosis of the humerus. The whole shaft had died, and was removed subperiosteally. New bone was produced at the upper and lower ends, but a gap of about two inches and a quarter was left in the middle, in which no bone formed. About a year after the operation, it was resolved to transplant a wedge of human bone into the gap. The bone to be transplanted was taken from the tibia in a case of osteotomy, and it was cut into small pieces before being introduced into the arm between the parts of the humerus. This was done antiseptically, and the wound healed without pus. There was still a gap, but it was much less than formerly, and the result was so favorable as to lead Dr. McEwen to repeat the operation.—*The British Med. Jour.*, March 6, 1880.

Tinea Imbricata.—Dr. McCall Anderson, at the same meeting, showed drawings and microscopic specimens of the parasite. Dr. Turner, in the first annual report of the Samoan Medical Union in 1868–9, referred to a disease under the name of herpes desquamans, occurring in both sexes and very contagious. Dr. Turner described it as a scaly disease, much more like ichthyosis in its general appearance than any other skin disease. The scales, however, ran in concentric circles, and might be well represented by taking a sheet of stout card-board and shaving the upper layers of it in such a way as to make it curl up in circles. The rings of desquamating cuticle were about a quarter of an inch apart. It was associated with heat and intense irritation. The same disease was apparently described, under the name of tinea imbricata, in a pamphlet by Dr. Patrick Manson, who said it was principally met with in the Straits of Malacca and islands of the Malay Archipelago. He had also demonstrated its parasitic nature, which Dr. Turner supposed. The specimens presented were forwarded by Dr. Manson. He had succeeded in inoculating the disease after an incubative period of about nine days. The fungus was seen as a brown mass under the epidermis, which was slightly elevated. This mass, growing larger, burst through the epidermis, leaving a brown rim, very slightly raised, and about one-sixteenth of an inch in breadth. When the entire ring thus formed had attained the diameter of about half an inch, a brown patch again formed in its centre; this, in its turn, again cracked the young epidermis over it, and a second ring was formed inside the first, and so on. Unlike ordinary ringworm, it did not usually attack the hairy parts of the body; and if it did, the hair-follicles were not invaded by the fungus, and the hair continued firm, glossy, and natural. In tinea circinata, the fungus was scanty, the spores few in proportion to the mycelium, and they were globular, with the mycelial threads short, and having numerous irregularities of outline. In tinea imbricata, the fungus was very abundant, and the chains of spores much more numerous than the mycelial threads. The spores also were oval, rectangular, or irregular, very rarely globular, and the mycelial threads were generally long, straight, or gently curved.—*The Brit. Med. Jour.*, March 6, 1880.

Treatment of Chronic Dysentery.—Dr. Raefo gives an analysis of thirty-eight cases of this disease, observed at the Seamen's Hospital, with fairly satisfactory results of treatment. Castor oil and a mixture of bismuth or hæmatoxylon were found quite serviceable. The author believes that the castor-oil treatment may be advantageously employed in all stages of the disease. With respect to the dose, in twenty-one cases two drachms of the oil were administered every alternate night. Of these, six were discharged cured. In the remaining seventeen cases the oil was given twice a week in half-ounce doses, and the number of cases discharged cured amounted to eleven. Each dose of the oil was guarded by the addition of eight drops of laudanum. The administration of castor-oil does not usually lead to an immediate diminution of the number of stools, its first effect being to improve their character. By the end of the first or second week the stools become more feculent and less offensive, and the tormina and tenesmus are less urgent. The stools then gradually fall in number, preserving often a regular gradation, interrupted, however, by repeated relapses; each relapse, if treated promptly with ipecacuanha, being more manageable and of shorter duration. In four cases turpentine was administered in conjunction with the oil. Turpentine seems to be indicated in large ulcerated surfaces, and when the discharge is offensive. The results of topical applications by injections were not encouraging. Ipecac powder is indicated whenever, in the course of treatment, the stools that have become feculent begin to lose that character and are accompanied or preceded by abdominal pain and tenderness. The necessity of watching for the earliest indication of a relapse is strongly urged. As essential to the cure, rest and strict attention to diet are insisted on.—*The Lancet*, Feb. 28, 1880.

Fibroma Cutis in Transition to Sarcoma.—Prof. J. A. Estlander reports the case of a man forty years of age, who noticed, on the posterior surface of his thigh, one of those hard tumors of the skin which occur so frequently, and are generally not so large as a pea. About seven years later, it suddenly began to enlarge, and in a little more than three months it was as large as a hen's egg. After extirpation it was found to have a compound structure, nine-tenths being fibromatous, and the remaining tenth spindle-celled sarcoma. The latter portion was closely united, but not grown together with the former.—*Finska läkaresällskops Handlingar*, Bd. 19, S. 265.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, May 8, 1880.

THE INTERNATIONAL SANITARY CONFERENCE.

THE *London Lancet* of April 8th has an editorial upon the International Sanitary Conference proposed by the United States National Board of Health, which shows that the writer does not fully understand either the purpose of such conference or the organization and duties of the Board. A few words of explanation, therefore, seem in order.

The proposed conference is not for the general discussions of the sanitary relations which should exist between nations. As is properly stated by the author of the article referred to, several such conferences have been held, and the results have been small.

The conference proposed has a perfectly definite object. It is to see whether it is possible for certain powers, more especially interested in yellow fever, to agree upon some method for giving trustworthy bills of health to vessels leaving ports liable to suspicion on account of this disease. At present the great majority of such bills of health are unreliable, and the statements made in them do not command credence. For example, a Havana bill of health is always a clean bill—even though the vessel may have a case of yellow fever on board at the time of sailing.

Whether the object sought can be obtained by means of the conference we do not certainly know, but it is a very definite one—a very desirable one—and one which cannot be attained so well in any other way.

The *Lancet*, however, is particularly hostile to quarantine, and says that "Few things have excited so much surprise in this country, in connection with the administration of the United States Board of Health, as the prominence which it has given, and is still giving, to measures of quarantine in its suggestions for the limitation of recent prevalences of yellow fever. . . . . true to the old quarantine fancies, the *possibilities* of infection, however remote and inconsistent with our actual knowledge of the mode of dissemination of communicable diseases, are made to govern the practice."

Evidently the writer thinks that he has sufficient actual knowledge of the mode of dissemination of yellow fever to be sure that quarantine is useless against it.

This is a matter of opinion, but those physicians in the United States who have seen most of yellow fever think very differently.

However that may be, it will perhaps diminish the surprise of the *Lancet* that the National Board of Health has been busying itself about quarantine, if it will remember that in the first place the Board is required to do this very thing by law—by a law which it did not originate and which it has never, as a body, recommended; and in the second place, that all the regulations advised by the Board have been for the purpose of inducing local authorities to do away with non-intercourse quarantines or other like measures which interfere greatly with commerce, and to which most local authorities have been much too prone to resort on the slightest rumor of danger.

The quotation made by the *Lancet* from the bill now before the house is so presented as to give the very reverse of the real meaning of the bill.

The object of the bill is not to cut off all communication between the infected place and other States—that will be done fast enough by the surrounding States under the present statutes; but it is, on the other hand, to keep up such communication in accordance with the methods best calculated to insure safety and the least interference with commerce. We are not, however, surprised that the *Lancet* should have made this mistake, seeing that some professional men in this country have fallen into the same error.

English experience as to quarantine is of absolutely no value whatever as regards yellow fever, and we do not know enough about this disease to speak positively as to the effect of hygienic measures on it. Be this as it may, the poverty of our Southern seaports, and the character of their municipal governments, is such that there is no hope of their being put in satisfactory hygienic condition for years to come.

ON THE INTERNAL USE OF WATER FOR THE SICK.

IT would hardly seem possible that a discourse on the subject of water could present anything that is not trite and interesting. It has been the theme of poets and temperance orators for many years, and scientists have exhausted the side which ethics and æsthetics do not touch. Nevertheless, a contribution to practical medicine of genuine value is given by Dr. Meigs in his recently delivered clinical lecture on the internal use of water for the sick. He states it to be

his belief that this use of water is much less than it ought to be, and that unnecessary suffering, as well as actual injury, are produced thereby. The view that water should be employed more extensively is enforced with many illustrations from his wide experience, as well as with great literary skill and a mustering of numerous scientific facts. Water forms three-fourths of our organism. The French colonel, therefore, to give the quotation of Dr. Meigs, was only one part colonel and three parts water. Water is the universal solvent that allows free play to the nutritive changes. It distributes itself into every tissue, unites as a solid with some and assists the metamorphic and functional processes in all. It carries off effete matter, and regulates the vital heat of the body. Man can live two weeks or more without food, but he has been known to die in four days from lack of water.

These are sufficiently familiar facts, but their repetition may enforce the lesson that it is dangerous to withhold from the sick a fluid so essential to every vital process. A healthy person takes about eighty ounces per day, and he will feel distress if any less than the normal amount is given. In all febrile conditions, as well as in the alvine fluxes, the amount needed is greater; therefore, the physician should be on his guard that the patient gets an increased supply. Dr. Meigs measured the quantity of fluid given to three fever patients, and found that in a continued fever with the temperature at 103° or 104°, the daily amount was from 110 to 120 ounces. This was the quantity that the patient took when allowed to have just as much as he wished.

A striking illustration of the use of supplying all that the system craves is found in a study of the physical side of the question. One of the great functions of water is to regulate the temperature. This it does by carrying off heat through evaporation from the cutaneous surface and the lungs. About thirty-six ounces of water are evaporated in this way every day, that is, the temperature of this amount of water is raised, by the animal heat, to the point where it becomes a vapor and leaves the body. The daily amount of heat thus carried away is about two million foot-pounds. This would be equivalent, according to Professor Haughton, to raising the person's body five miles vertically every day. When a person has a moderate fever, the extra heat of the febrile condition, if transformed into force, would lift the body one mile higher, or in all six miles vertically into the air. With this tremendous drain on the system we can easily see the necessity of keeping it well supplied with the necessary fuel.

We should remember, at the same time, that in supplying the organism with water we are giving it one of the most active stimulants to combustion. As has been shown by Parkes and others, water increases the metamorphic changes in the body. Assimilation and disassimilation are promoted. In healthy persons the stimulus to assimilation is greater, and the bodily weight increases. In weakly persons, however, according to Ringer, the disassimilation is proportionately so much increased by taking large quantities of water that a febrile condition is sometimes induced. It is necessary to remember, therefore, that in fevers we are feeding the flame as well as supplying a necessity of the system. It is a fire that we dare not lessen by cutting off the fuel, lest the machinery itself be consumed.

Dr. Meigs asserts that the best and only indication for the amount of water that should be given is the thirst of the patient. Let the sick man have all he wants, provided his stomach will retain it. Even when there is vomiting, it may often be advisable to let the patient continue to drink. When he has become insensible and comatose from his disease, the rule suggested is to keep up the supply which was being given before unconsciousness set in. As stated, from 100 to 120 ounces in the twenty four hours appears, from Dr. Meigs's experiments, to be about the necessary amount in a moderately high fever.

Many physicians will, perhaps, take exception to this plan of allowing the feelings of the patient to be the guide as to the quantity of fluid. It is very authoritatively laid down in some works that fever patients, if left to themselves, will always drink to excess, impair their digestion, and, perhaps, produce flatulence or even diarrhœa. That this is a possible result of putting no limitation to the amount of liquid, every one will admit; nevertheless, we are inclined to side with Dr. Meigs, and believe that there is more danger, as there is certainly more distress, in giving too little than in giving too much. The agonies of those old times, when water was peremptorily denied, and the half-desiccated patient moaned and tossed himself about till an early delirium or death overtook him, are not repeated now, and never will be. But something of the old idea that there is danger in water still hangs about the profession and among the laity; and the remarks of Dr. Meigs in advocacy of water have, therefore, a pertinency and value that cannot well be overestimated.

THE EXCLUSIVE SOCIETIES OF PHILADELPHIA.

The Philadelphia County Medical Society is becoming quite famous as a close corporation. We do not mean to say that this is all the reputation it has, for we are reliably informed, by certain members who attend the meetings, that occasionally some very creditable work is done. Others who read the official organ of the Society are of the opinion that it is the leading medical organization of the country; but, as such readers are principally the members of said society who have their papers and remarks printed in full, they can hardly be considered im-

partial witnesses. It has been darkly whispered that many years ago the Society conceived the idea of publishing its transactions regularly in a leading medical journal. Several periodicals were tried, but each became weary in well-doing and ignominiously broke faith. Finally it was resolved to make a contract to publish good and bad alike, and, as a reward to the journal for so doing, to give it the exclusive right to act as the organ of the organization. No one should blame the Society for insisting upon the contract being kept, as it is certainly the gainer by so doing. No outside journal must be allowed to come in when it chooses and take the tidbits. If such were the case, some of the members might slyly drop their subscriptions to the organ of the Society, and perhaps seriously damage that publication. The firmness with which both parties to the contract adhere to it is a pleasant and instructive picture. The dog is satisfied with the manger, and the manger with the dog. If both are let alone no one will probably starve. We half suspect that curiosity more than hunger prompts the meddlesome interference of certain journals into what are strictly private matters. From a recent number of the *Clinical News* we learn that the Pathological Society of Philadelphia is another exclusive organization which refused any reports to that journal because of the same kind of contract. Verily the members of these societies are on a fair way to fame and extended usefulness. The injunction for all people, good, learned, and true, to let their light shine, has no application to the societies in question. The bushel is not a very large one, but it effectually covers the light.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 14, 1880.

DR. T. E. SATTERTHWAITE, PRESIDENT, IN THE CHAIR.

DERMOID CYST OF OVARY.

DR. G. F. SHRADY presented a specimen of dermoid cyst of ovary on behalf of a candidate for admission to the Society. It was removed by abdominal section, and contained sebaceous material mixed with long curled hair. The patient made a good recovery.

DR. SATTERTHWAITE presented a specimen of locomotor ataxia, with sclerosis of the posterior columns.

POST-OCULAR TUMOR.—EXTIRPATION OF EYE.

DR. JOSEPH W. HOWE exhibited a post-ocular tumor with the following history:

Daniel Callaghan, aged 57, occupation laborer, was admitted to St. Francis' Hospital on Jan. 31, 1880, suffering from a post-ocular neoplasm and protrusion of the eye. He stated that his grandfather died at the age of seventy-two, with some tumor involving the eye. His father died at seventy-eight, with what was called "cancer of the nose-space." His mother also was afflicted with a tumor of the nose, which was removed by an operation. The tumor, however, returned and destroyed her life at the age of forty-eight.

Patient has not been addicted to the use of stimulants, and has never had any form of venereal disease. Thirteen years ago a papule appeared on the upper portion of the left side of the bridge of the nose. In a few months this papule softened, and an ulcer took its place, which increased very slowly, running toward the inner canthus. In October last caustics were applied—the ulcer was destroyed, and cicatrization of the whole surface took place. About one year ago his left eye began to grow prominent and painful. The pain was lancinating and intermittent. The protrusion and pain gradually increased with some loss of vision. Six months ago the sight in that eye was completely lost.

On admission the patient complained of intense pain through all the branches of the fifth pair of nerves on the left side. The pain being particularly intense in the orbit. The eye protruded very much beyond the lids. There was little or no pain on pressure.

February 4th.—The patient was etherized, and an incision made in the outer canthus, preparatory to exploring the orbital cavity. The conjunctiva was then opened and the finger introduced behind the eye. The tumor was found to surround the optic nerve, and to be firmly attached to a small portion of the floor and inner wall of the orbit. It was then decided to remove the eye as well as the whole of the morbid growth. The eye was enucleated in the usual manner, and the tumor removed, together with a portion of the floor of the cavity. On the inner angle of the orbit there seemed to be a small connection of fibrous tissue extending from the tumor to the edge of the cicatrix at the inner canthus, and forming a link between the two.

The patient bore the operation well, and has made a good recovery.

The tumor was examined by Dr. Wendt, who made some fine drawings from the specimen. It is a rare form of neoplasm, called a cylindroma. It is, however, also known as a tubular cartilaginous tumor, tubular sarcoma, mucous cancroid, plexiform sarcoma with hyaline vegetations, cancroid or adenoid sarcoma. On account of the characteristic variously shaped cylinders and dendritic protuberances, Billroth's term cylindroma seems to be the most appropriate designation. In this case, according to Dr. Wendt, the tumor consists essentially of a stroma of small round-celled sarcomatous tissue, imbedded in which are found plexiform cylinders which may be readily isolated by teasing or pencilling. In addition to these we meet with spherical, ovoid, or club-shaped figures. Sometimes these branching bodies assume a striking cactus-like outline. They seem to have pushed aside the interstitial tissue, creeping in between its interlacing bundles. All these bodies have a hyaline appearance, and contain numerous polymorphous corpuscles, with large conspicuous nuclei. In many instances such masses correspond to firmer lymphatics, since the peculiar endothelium of these vessels can be readily recognized.

According to Koester, the hyaline spheres and cylinders are the product of a secondary hyaline metamorphoses, which the cell-trabeculæ of a cancroid of the lymph-vessels undergo. This endothelium proliferates and plugs up the lamina of the vessels, which explains why the tumor at first sight bears such a close resemblance to certain tubulated epithe-

homata. That it is not an epithelioma is proved by the sarcomatous tissue surrounding the hyaline masses, and by the minute structure of the cells composing them.

The specimen was referred to the Committee on Microscopy.

INTRA-OCULAR AND EXTRA-OCULAR ORBITAL SARCOMA.

Dr. C. S. Bull presented a specimen of tumorous growth removed from the orbit in order to report progress in the treatment of a case already presented to the Society. He gave the dates of the different previous operations respectively as follows, and concluded with an account of the removal of the last specimen:

July 7, 1879.—First operation. Enucleation of eyeball and excision of a piece of the optic nerve.

October 30.—Second operation. Removal of a very large orbital tumor with fungoid, bleeding surface, and removal of all the orbital tissue.

December 27.—Third operation. Excision of upper lid (outer two-thirds). Removal of diseased periosteum, and of diseased bone from frontal and malar bones by gouge and scraper.

Growth made its reappearance in orbit on nasal side and in inner third of upper lid on March 8, 1880.

March 17, 1880.—Fourth operation. Inner canthus divided horizontally as far as median line of nose. The remains of upper and lower lids dissected up from growth and thrown back—then by means of scissors, hooks, and the finger, the orbit was cleaned of the growth slowly and as effectually as possible. It was very soft and exceedingly vascular, and was found to proceed from the bone of the roof, from the ethmoid, from the antrum, and from the apex of the orbit. The roof and inner wall of the orbit had apparent exostoses developed from them, some of them quite long and projecting into the orbit like stalagmitic growths. They were quite hard, but could be broken off. They were especially noticeable at the junction of the roof with the inner wall of the orbit. The os planum of the ethmoid was perforated, the bone very much diseased, and the tip of the finger could be passed into the superior nasal meatus, and a depression in the floor of the orbit apparently led into the maxillary sinus. After the orbit had been cleansed as far as possible, it was slowly and carefully washed out with a carbolic acid solution (1-20). The fluid entered the nose and apparently the frontal sinus also, from the pain complained of. Caustics were avoided on account of the deep ravages of the disease.

April 3.—Growth has returned at the line of incision over the nose and in the neighboring bone, and also at the external angle of the orbit.

She has had several severe hemorrhages from the orbit, one quite alarming. No head-symptoms except a constant, dull headache. Patient's condition is not good—had frequent sweats—pulse thready, though not very rapid.

VOLKMAN'S OPERATION OF RESECTION OF KNEE.

Dr. Briddon presented a child upon whom he had operated for resection of the knee according to Volkman's method. The patient had been an inmate of the Presbyterian Hospital for eighteen months, suffering from osteo-arthritis, which went through various phases of exacerbations. The operation was performed December 27th, with the usual antiseptic precautions. The limb was kept in an extended position by means of a plaster-of-Paris splint; the soft parts healed entirely, the bisected patella united and could be freely moved upon the inter-condylar notch. The shortening was half an inch.

The patient had also developed a condition of caries of the cervical vertebræ, and was wearing an apparatus for the same.

Dr. Gibney remarked that it very frequently happened that after disease of the bone had existed for a considerable period in the lower extremity, a similar trouble occurred in the spine. The association of these two conditions were oftentimes so direct as to appear almost in the relation of cause and effect. He had intended that evening to bring a specimen illustrating that point. It was removed from a boy aged seven years, who sprained his ankle five years ago; caries of the tarsal bones followed, and in the course of three years thereafter, the 8th, 9th, and 10th dorsal vertebræ became involved in the same disease. About a year subsequently he developed caries of the head of the left femur, and finally died, at the age of fourteen years, with tubercular meningitis.

If there was any causative relation between the first disease and the one which caused the death of the patient, the propriety of early treatment of joint diseases was quite apparent.

Dr. Satterthwaite said that the question raised by Dr. Gibney was an interesting one. He had seen similar cases of caries attacking different parts of the body in succession, showing that such a state of things might have been due to an embolic process.

Dr. Carpenter asked which was the more tenable theory, the one of embolism, or the one which maintained that the successive appearance of caries was owing to local manifestations of a constitutional disease?

Dr. Satterthwaite believed that pus could be transported from one part of the body to another, and thus account for the appearance of caries in different localities in succession. He mentioned a case in point in which pus existed in the uterine sinus, which condition was followed in turn by a carious rib, and finally empyema. The theory of embolism seemed to him to be a tenable one in that it explained the conditions on purely mechanical principles.

Dr. Post, in connection with Volkman's operation, remarked that it was far superior to all other methods of resection of the knee.

RUPTURE OF HEART FROM INDIRECT VIOLENCE.

Dr. Finnell presented three specimens. The first was a heart removed from a negro, 19 years of age, who fell from a third-story window, striking upon the sidewalk. The injuries inflicted were: fracture of the fourth, fifth, and sixth ribs of the right side, fracture of left clavicle and right elbow; rupture of liver, and a laceration of the right ventricle of the heart, two inches in length, and extending up to the root of the pulmonary artery. The latter specimen was exhibited. Death was instantaneous. The pericardium was filled with blood. The rupture of the heart was of course caused by indirect violence.

The second specimen was an enormously distended gall-bladder, removed from a woman aged 45 years, who had died of starvation.

The third specimen was a fibro-cystic tumor, removed from the knee of a woman aged 45 years.

EPITHELIOMA OF RECTUM.

Dr. Post presented an epithelial tumor of the rectum, which he removed by surgical operation, from a man 60 years of age. It appeared, from the history of the case, that the growth was only of three months' duration; occupied less than half the cir-

cumference of the rectum, and extended from just above the margin of the anus to a point reached by the end of the finger. The patient had not suffered from any symptoms of obstruction. A semi-elliptical incision was made on each side of the anus, and the growth with two-thirds of the rectum removed. During the operation there was a time when the patient's pulse became imperceptible at the wrist, and also a period when the same condition obtained after the operation. Stimulants were administered on both occasions with the desired effect.

Dr. Knapp presented a specimen of glioma of the eye, illustrating the propagation of the disease through the optic nerve itself, rather than, as was usually the case, through the tissue between the fibre-bundles.

VESICAL CALCULI IN A DOG.

Dr. Heinemann presented over a hundred vesical calculi of triple phosphate, and of a size varying from that of a small pea to that of a small hickory-nut, which were taken post-mortem from the bladder of a spitz dog. The stones almost completely filled the bladder, but there was little or no thickening of the mucous membrane, or hypertrophy of the abdominal walls. The animal had not suffered from any symptoms referable to the bladder.

HIGH TEMPERATURE WITH ACUTE CEREBRAL MENINGITIS.

Dr. Satterthwaite presented a specimen of acute cerebral meningitis accompanied with unusually high temperature. He gave the history as follows:

In November, 1878, I was asked by a surgeon, now deceased, of this city, to take charge, during his temporary illness, of a young married woman who had been under his care at various times. During the summer, while at a seaside watering-place, she had contracted what was said to be cerebro-spinal meningitis, and this diagnosis was confirmed by the opinions of a number of medical gentlemen who saw her. When first called in I found her in a state of great restlessness, with photophobia, pain in her head, and "showers of cold" running up and down her spine. The pain in her head had induced her to take large doses of opium, and she was at that time confirmed in the habit, taking often the equivalent of eighteen grains of solid opium a day. This amount was doubled in periods of excitement. As symptoms of insanity developed at a later period, she was taken to an asylum, remaining there about two months. She left apparently cured, though in a highly nervous and debilitated condition. She passed the spring and early part of the summer in active outdoor exercise, being much on horseback, keeping up the exercise after her return to the city.

In October of last year she again consulted me for symptoms very similar to those previously related. Her business affairs were a source of much trouble, as also certain family relations, and she was very apprehensive of something impending, had fleeting pains not localized, was exceedingly restless, and could with difficulty be quieted. As a substitute for morphia she had taken the bromide of potassium, though in what doses is not known, as she was in the habit of helping herself with a measure, with which she dipped out the drug from a box. The amount was at least thirty grains. As the bromide was not thought by her to have much effect, for it was substituted the ordinary mixture of the bromide and chloral, āā gr. x., given three times a day. It at once had the happy effect of producing quiet, and securing continuous sleep for six to eight hours. The chief symptoms during this attack were nervous rigors, photophobia, frequent and painful micturition (an old difficulty); headache (over the convexity); the tongue was said to feel thick, and taste was partly wanting. The tongue was usually coated. Bowels were moved by enemata daily. No paralysis or convulsions. Under this treatment, careful nursing, and the application of the continuous current to the spine three times a week, the symptoms were relieved, and she appeared to be convalescing. The duration of the attack was about two weeks. On November 10th she ran up and down stairs a number of times, contrary to instructions, and became violently excited about some carpentering work done in the house, and went to bed. The same symptoms recurred. The bromide of potassium was given for some days, once or twice in as large amounts as two drachms a day, but not continuously. There were clonic spasms of the facial muscles, brought on by a number of exciting causes. There was also suffusion of the eyes, photophobia; tonic spasms of flexors of hands and forearms; headache, but no convulsions or paralysis. On November 17th she became comatose; the water was then drawn twice a day, and the bowels were moved by enemata. Pupils at first were dilated, later they were contracted, but thus far responsive. On November 27th she was seen, in consultation, by Dr. A. L. Loomis. Inquiry was made as to the question of bromides, and the amount taken, and a positive diagnosis was not made. During the preceding ten days she had not left her bed, and had taken no sedative. Previous to that it was difficult to say how much of the bromide she had taken, for the reasons already given. When seen again, in consultation, by Dr. Loomis, November 29th, the diagnosis of acute cerebral meningitis was entertained.

At the post-mortem examination, which was attended with some restrictions, only the brain and medulla were removed. The vessels of the pia mater were found gorged with blood, and there had been a transudation of red and white corpuscles into the meshes. There was also about four ounces of bloody serum which escaped when the brain was removed.

The following very high temperature was noted during the last day of life. It was taken by Mr. Morton, student of medicine.

				Temp. (taken three times.)	Resp.
12.30	P.M.,	Nov. 28,	1879	107.5°	36
1.30	"	"	"	108°	40
2.25	"	"	"	108⅛°	—
3.00	A.M.	"	"	—	40
3.40	"	"	"	108¼°	37
4.30	"	"	"	109°	—
5.00	"	"	"	109°	36
5.30	"	"	"	109¼°	37
5.53	"	"	"	109°	38
6.00	"	"	"	108¾°	—
6.20	"	"	"	110°	—
6.26	"	"	"	Died.	

At the end the register in the thermometer was pushed up to the top of the tube, so that it may have reached even a higher point. Mr. Morton has since tested the thermometer with a standard and found it correct.

Dr. Satterthwaite wished to put this case on record because of the high temperature, which was carefully taken, and he had every reason to believe was correct. He observed that, although physicians had told him in conversation that they had seen remarkable cases of high temperature, as in scarlatina, there were but few of such cases to be found on record. There seemed to be no doubt that wonderful

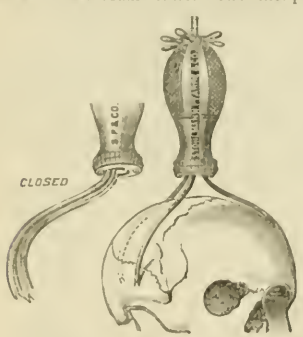
extremes of temperature were occasionally reached. He would simply mention here that quite recently the patient of Mr. Teal, who had a temperature varying between 108° F. and 122° F. during a period of sixty days, came, during a relapse, under the care of Mr. Hind, and the temperature then rose so high as to break the bulb of the instrument.

In this present instance cold sponging and hypodermic injections of quinine in large doses did not prevent the temperature from rising.

Dr. Satterthwaite also presented three new instruments for post mortem use. The first was a

CALVARIUM CLAMP.

The instrument, which is twenty-five centimetres long, is so constructed as to fit into a post mortem case of medium size. It consists essentially of three curved prongs terminating in sharp extremities, which are held and may be easily pressed into the bone where they will remain firmly embedded, as long as is required. These prongs are fitted into a handle which is of metal and has great strength. Upon the upper extremity of the handle is a screw, by the revolution of which the points of the prongs are approximated or separated. The instrument was devised as a means of holding the calvarium firm while it is being removed. After making the usual transverse incision through the scalp, just behind the ears, the *pericranium* should be included in the reflected flaps. This is effected without much difficulty by means of the handle of an ordinary scalpel. One of the prongs should then be forced into the bone in the temporal fossa just below the temporal ridge, in the frontal bone about one-half an inch in advance of the coronal suture. The other prong is



to be placed in a corresponding position on the opposite side. The third prong is to be caught in the rough depressions at the junction of the sagittal and lambdoid sutures, perhaps a little lower down, according to the form of the particular skull. If an assistant steadies the handle, the points of the prongs may be more rapidly and effectively adjusted. Sometimes the bone is unusually hard and then it is well to nick the bone with a chisel before adjusting the instrument. When all these points have been attended to, the calvarium may be removed with great rapidity. There is also no danger to the hand from the accidental slipping of the saw.

MODIFICATION OF BRUNETT'S CHISEL.

This instrument consists of a chisel of great strength, armed with a prong that is designed to run along the spinal canal. From the chisel, about its middle, arises a stout handle for the purpose of steadying it. It is inclined somewhat backward. The instrument terminates posteriorly in a knob, serrated on its head so as to receive the blows of the mallet. The cutting edge of the chisel forming a

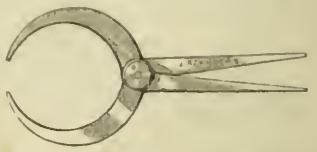
somewhat acute angle with the prong, makes a notch, and is thus retained in its proper relation with the bone. To use it, first remove a few vertebræ from the dorsal region at the greatest convexity, then placing the notch of the chisel against the lamina of the vertebræ, drive the instrument forward with a heavy wooden mallet.

This instrument is particularly adapted for opening the canal in the cervical region, where it is almost impossible to use the saw.

In a recent operation the spinal cord was taken out entire from an athletic male adult in exactly thirty minutes.

COMBINED EXTERNAL AND INTERNAL CALLIPERS.

It has long been desirable to have some simple instrument, both to measure either the diameter of a passage or cavity on the length and breadth of an organ, or in fact any solid body. In estimating the diameter of the cardiac openings, this is particularly valuable. It has been customary to make use of the



term "admitting two fingers, three fingers," which, of course, is not at all precise, depending as it does on the size of the fingers. Some time ago Dr. S. devised an instrument shaped like a wedge and marked off with lines indicating the breadth at different points. This, however, is unwieldy. The instrument here described measures both internal and external diameters, and is really an old tool that has long been used by mechanics. On one side we have curved legs, on the other side, straight ones. They are jointed together by a screw and nut; the latter can be tightened or loosened at will by a key that accompanies the instrument.

MANHATTAN EYE AND EAR HOSPITAL.—Mr. William Astor has given five thousand dollars for the building fund of the Manhattan Eye and Ear Hospital.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 15, 1880.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

DR. F. H. BOSWORTH exhibited a substitute for Belloc's canula, which will be described and illustrated in a future number of this journal.

CONVULSIONS IN CHILDREN.

DR. A. A. SMITH read a paper on the above subject, in which he directed attention to practical points. He thought the statement so frequently met with in literature that convulsions in children, independent of organic disease of the brain, were rarely serious, was very liable to mislead the young practitioner; for, if it was admitted that one in one hundred cases might be dangerous, the statement must be modified. He believed that *any* case of convulsions might be dangerous, and, therefore, the physician should *always* study each case carefully. Probably the age at which children were most liable to have convulsions was between six and twenty-eight months—the period of dentition. They did not occur simply because dentition occurred during that period, but in addition the nervous system of the child was then rapidly developing and was much more impressible than in adult life. Usually the tendency to disturbance of the nervous system manifested itself differently among different members of the same family. For example, if a temperature of 105° F. was developed in a child as the result of simple indigestion, it was very evident that the child possessed a nervous system that was very susceptible to the influence of slight irritation, and such a patient needed watchful care in any form of illness. Hereditary tendency was an important factor in the etiology of convulsions in children, and, in the majority of cases, the predisposition was transmitted by the mother. If, as was maintained by many good observers, diseases of the nervous system were greatly on the increase in the United States, and if it was true that predisposition to convulsions was transmitted from parents to children, the question of convulsions in children was more important than it ever had been. In a few cases he had been able to find a history of convulsions in the childhood of the mother. The weight of opinion was that puerperal convulsions did not leave a permanent tendency to convulsions in the child. Children with rickets were very susceptible to influences that produced convulsions. Overfeeding, undoubtedly, often produced convulsions, and they might be serious. Quite a number of cases were on record in which the child died in a convulsion, and at the autopsy no cause could be found other than a stomach well filled with undigested food. Improper feeding might also cause convulsions in children. The giving to young children a little of everything, as was often done, was calculated to do mischief. The exciting cause in a large proportion of cases of convulsions in children could be found in errors in diet. Malarial poisoning might cause convulsions in children. Dr. Smith then referred to several cases which he saw with Drs. Lente and Murdock, of Cold Spring; all were apparently of the simple form of malaria, and all recovered. It was still a question whether the convulsions in that class of cases were produced by the poison itself, or by the high temperature, or by the sudden hyperæmia of the brain, supposed by some to exist. A convulsion, occurring in the course of an acute disease, especially toward the close, was a grave symptom. A convulsion occurring in the course of whooping-cough was an unusually grave symptom, if unassociated with dentition or some disturbance in the alimentary canal. With reference to syphilis as a cause of convulsions in children, the author of the paper had found recorded cases of unmistakable congenital syphilis, in which convulsions occurred during the first three months of life; and he also referred to a case of that kind which came under his observation while an interne in Bellevue Hospital. Nervous excitability, which showed itself in a tendency to develop convulsions in childhood upon slight provocation, might, in later life, develop into epilepsy. It was fair to presume that, if a child had convulsions, and, later in life, had epilepsy, there already existed the pathological changes which resulted in epilepsy. It would seem almost impossible that functional disturbance of the nervous system could lead to such permanent changes in the central nervous system, as indicated by idiocy or permanent impairment of intellect, unless there existed, previous to the attack of convulsions, some lesion of the brain or spinal cord; and yet, upon theoretical grounds, it would seem just as impossible that such stormy outbursts as seen in convulsions should occur and not leave permanent injury. It would be interesting to know whether or not convulsions in children belonged to civilized life.

Treatment.—Dr. Smith considered the question of treatment under three heads: 1. The management of the attack; 2. Prophylaxis; and 3. The subsequent treatment.

Whatever the cause, whether due to organic disease or to functional disturbance, the convulsion should be arrested and another prevented by the administration of anæsthetics, preferably chloroform. As soon as the cause was found, it should be removed if possible. If the convulsions were due to pain produced by other than causes such as the pricking of a pin, tight abdominal bandage, which could be easily removed, and an overloaded stomach, which could be easily emptied, opium was the most valuable remedy that could be used, and he would employ it if the child was *more than four months old.* The convulsions dependent on the pain of teething should be controlled first by opium, and second the gum lance. The effort to lance the gums before the pain was subdued by opium or a similar agent, probably would cause another convulsion. Convulsions dependent on the pain produced by worms or other foreign bodies in the intestinal canal, or errors in feeding, should be first controlled by opium, and then a cathartic should be given. Convulsions produced by worms were not always attended by pain. The cathartic and opiate might be combined with advantage. If there was reason to believe that the source of irritation was in the rectum or near it, and an enema was indicated, an opiate should be given first, and when its influence was secured sufficiently to control the convulsion, then the injection might be given.

Convulsions due to malarial poison, although not preceded by pain, yielded more promptly to opium than to any other agent; having controlled the paroxysm, put the child fully under the influence of quinine for the purpose of preventing its recurrence. The tolerance of opium was sometimes very great in that class of cases, as well as in all others in which its use was indicated.

With reference to lancing the gums, Dr. Smith believed that if they were swollen and hot they

should be lanced. Further, if it was time for the tooth to appear he believed the gum should be scarified, for the irritation was due, not infrequently, to deep-seated pressure such as could not manifest itself upon the surface. Whatever theory might teach, it seemed to him that from clinical observation it was conclusive that lancing the gums was followed frequently with marked relief.

As in the great majority of cases opium was indicated, the mother might, with safety, be told to give the baby, *over five months old*, paregoric, with explicit directions concerning size of dose; to be repeated every half hour until the convulsions either were controlled or a physician had arrived. If the child was under four months old, Dr. Smith prescribed a teaspoonful every hour of a mixture of bromide and chloral with bicarbonate of soda, of which each dose contained one grain of each remedy. It was conveniently given in warm, sweetened water. Double the quantity might be given every hour or two hours to children from six weeks to four months of age, according to the frequency and violence of the convulsions.

NON-USE OF THE HOT BATH.

Dr. Smith rejected the hot bath in the treatment of convulsions of children; for, almost invariably the child had one or more convulsions while in the bath—the very agitation incident to the giving of it adding to the excitement of an already disturbed nervous system. The object in treatment was to keep the nervous system as free as possible from agitation; hence, he forbade the hot bath, insisted that the child should not be restrained while in a convulsion, that it should be placed on a bed that did not squeak, that the room should be kept perfectly quiet, have plenty of fresh air, be partially darkened, contain only one person at a time, and that opening and shutting of doors should be avoided. Over-active treatment was uncalled for, if not positively dangerous.

Dr. Smith then spoke of the sedative effect of the bromides, and of the value of maintaining it in cases in which the prolonged use of opium was undesirable. He believed that the intense itching, which especially followed scarlet fever and measles, might be the cause of convulsions in young children, and in those cases the bromides acted most favorably. In occasional cases the bromides aggravated the symptoms. Under such circumstances chloral might be used. To control convulsions dependent on high temperature he recommended veratrum viride. Its tendency to produce vomiting might be controlled by combining it with opium. Two drops of the tincture might be given every hour to a child from six to eighteen months old. If it produced vomiting no harm was done, for the pulse and temperature then usually fell and the convulsions ceased. If the remedy failed to control the convulsions, the cold bath was indicated. Coma was quite frequent in that class of cases, and the child was then in imminent danger. The temperature must be reduced, and the cold bath was the most efficient means that could be employed.

The sedative action of calomel, especially in convulsions occurring at the onset of an acute pulmonary affection, was then mentioned with favor.

Under the second head, or *prophylaxis*, Dr. Smith referred to the proper care of the mother during pregnancy, especially with reference to proper exercise, food, amount of sleep, condition of bowels, and all that pertains to diminishing the tendency to nervous disturbances in the child.

Prophylaxis in the child was suggested by a study of the causes of the convulsions. The object to be accomplished under the third head, or treatment subsequent to the attack, was to remove causes and predisposing causes, and keep the child in the best possible physical condition.

The paper will appear in full in the *American Journal of Obstetrics and Diseases of Women and Children*.

Dr. J. Lewis Smith remarked that, at the Bellevue Hospital Outdoor Poor Department, he had carefully observed cases brought there during the last six years, and had been unable to convince himself that there was any connection between the convulsions of young children and epilepsy of later life. The age at which epilepsy was liable to develop was from five to seven years, but he regarded the two as independent conditions.

With reference to treatment Dr. Smith said that he had not carried a gum-lance for five or six years. He had relied upon the bromides, of potassium preferably, in large doses frequently repeated—two to six grains for a child over two months and under one year of age, repeated every ten, fifteen, or twenty minutes, according to the severity of the case—to control the irritation produced by the irruption of the teeth. In convulsions of children he gave hydrate of chloral, and always by rectal injection, and had been astonished to see how quickly the convulsive movements would cease in a child that had been so treated; the first thing noticeable being relaxation of the face, then of the arms and legs, and usually in a few minutes the convulsion had entirely ceased. He rarely found it necessary to remain with the patient more than half an hour, whereas formerly he had not infrequently found it necessary to remain several hours before the convulsions were controlled. With reference to hot water, he could not agree with the author of the paper in condemning its use in the treatment of convulsions. He believed it to be a beneficial agent, and certainly when a child was threatened with convulsions, had twitchings, etc., he would put it into a hot-bath, as he had often seen exceedingly good results follow. Twenty-five years ago musk and assafœtida were used a great deal; but now that the bromides and chloral were so commonly employed, convulsions in infants and young children were regarded as much less formidable than in those days.

With reference to anæsthetics, he now never gave them in the class of cases under consideration.

Dr. S. T. Hubbard remarked that he had under observation several cases of epilepsy, and in some of them the convulsions dated from infancy; in one case the convulsions began when the child was one year old. He was inclined to believe that in some cases there was a direct connection between the convulsions of infancy and epilepsy developed later in life.

As to the opium treatment, referred to by the author of the paper, he was afraid to use opium in the treatment of disease occurring in children. He remembered the directions given him by Dr. Beck—namely, never to give opium to a child under four or five years of age. He had used the bromides and chloral in the treatment of convulsions of children, and with good success.

He had frequently used chloroform and had not feared the dangerous results of which Dr. J. Lewis Smith had spoken. He agreed with the author of the paper that anæsthetics were beneficial in arresting the convulsions.

With reference to the hot bath, he had discon-

tinued its use, in the ordinary sense of the term, but had used hot water with good effect in the following manner: Strip the child, then wrap it in flannel that had been wrung out of hot water, and over that place a dry flannel blanket. The idea was to increase the action of the skin without producing shock, and all the good effects of the hot water were obtained as well as they could be by means of the bath. When called to a case his first inquiry usually was, "What has the child been eating?" The usual answer was, "Nothing of account." But, on close inquiry, insisting that the articles of which the child had partaken should be mentioned, he not infrequently found sufficient to account for the occurrence of the convulsions. He was inclined to the opinion that in a large proportion of cases, perhaps nine out of ten, convulsions in young children were due to errors in diet.

Dr. J. L. Campbell, on invitation, remarked that he was heartily in sympathy with the author of the paper in the opinion that the hot bath was not only not beneficial, but he believed it was positively injurious, inasmuch as it prevented the *sine qua non* in the treatment of convulsions—namely, keeping the nervous system perfectly quiet. The author of the paper had referred to malaria as a cause of convulsions, and he had no doubt that malaria did frequently produce convulsions in children. The author had spoken of the convulsion, in such cases, as taking the place of the chill; he, however, was inclined to believe that it was the result, the chill causing sudden hyperæmia of the nervous centres.

Dr. M. Blumenthal thought that, in the great majority of cases of convulsions in children, it would be found there was some disturbance of the vascular or nervous, and that the nerve-centres were in the condition either of anæmia or congestion. He favored lancing the gums, and related the following case as bearing upon that point: He was called to see a child severely sick with pneumonia, and it had also had convulsions, which he thought depended upon some other cause than the pulmonary disease. He examined the child's gums, found them swollen, filled with blood, and suggested that they be lanced. The attending physician lanced the gums and the convulsions ceased at once, after having continued for twenty-four hours.

Dr. Richards also favored the use of the gum-lance.

THE NEW YORK SURGICAL SOCIETY.

Stated Meeting, February 10, 1880.

Dr. H. B. Sands, President, in the Chair.

OPENING THE SAC IN POPLITEAL ANEURISM.

Dr. J. C. Hutchison read a paper in which he reported a case of popliteal aneurism successfully treated by laying open the sac.

Only one artery was found connected with the sac, except that which entered it directly, and at the operation was found closed below. It was believed that vessel was the internal circumflex rather than the profunda. Hemorrhage from the artery was controlled during the operation by introducing a gum-elastic bougie into its open mouth. The sac had about the usual thickness, the tumor had grown slowly, and the pulsation was powerful. The elastic bandage was applied from the toes up to the tumor, and compression was made upon the abdominal aorta during the operation, and still the hemorrhage was quite profuse. The patient had been operated upon by distal ligation four years and a half previously, but unsuccessfully. The aneurism had also been treated unsuccessfully by the use of injections.

Dr. T. M. Markoe remarked that an aneurism such as described might be expected to have as powerful pulsation as the original tumor. He referred to a similar case in which he ligated the carotid upon the distal side, and subsequently injected the sac with persulphate of iron. Shortly after the injection, the patient fell into a fainting fit and died at the end of about one and a half hours. The aneurism received two injections, and two large hard coagula of ochrey hue were found in the sac when opened.

The President remarked that Dr. Hutchison's case was interesting as showing the great uncertainty of effecting coagulation by injections, because an aneurism more favorably situated for cure by the use of coagulating injections could hardly be found than one which had communication with no artery except the one by which it was fed. Another singular thing to be noticed in this connection was that when coagulating injections fail in causing the consolidation of an aneurism, and yet do not produce any evil results, it is usually taken for granted that the coagulæ which are produced fail to lead to a cure, because they are washed away in the current of blood and taken to some point beyond the sac; but in this case, if coagula were produced, as they seem to have been, by the injections, and subsequently disappeared, they could only have done so by a process of softening or solution gradually becoming mingled with the blood as it entered and escaped from the aneurismal sac.

Dr. Robt. F. Weir remarked that his experience upon the subject had been acquired entirely while in military service. He had opened the sac, in the treatment of aneurism, in only two cases, and those were *recent* traumatic aneurisms, therefore, perhaps, did not strictly belong to the class of cases under consideration.

Case I.—On the 9th of July, 1864, a man was wounded by a bullet which passed completely through his left and lodged in his right thigh. On the 3d of August a large pulsating tumor was recognized, and it was determined to open it. The hemorrhage was controlled by pressure in the groin.

The artery involved was found to be the profunda. The sac was laid open to the extent of five inches, and its contents, nearly a pint, evacuated, and the vessel secured above and below.

Case II.—On the 17th of September, 1862, a man was wounded in the right side of the neck by buckshot. On the 29th secondary hemorrhage occurred. Soon after, by invitation of one of the surgeons, he saw the case when an aneurismal tumor existed, and extended from the jaw to the clavicle.

Persulphate of iron had been applied to check the hemorrhage, and a large mass of material was adherent to the side of the neck. It was removed, but no bleeding occurred. An opening was made, and Dr. Weir was fortunate enough, in introducing the finger, to strike the opening in the carotid artery at once, but he was not able, after laying open the sac freely, for some time to find the vessel above and below, but finally succeeded and secured it with ligatures. The man had the next day another secondary hemorrhage, and died at the end of twenty-four hours. Autopsy showed that the hemorrhage came from the superior thyroid artery.

In one of the following cases Syme's operation was intended, but was fortunately avoided; in the other, the hemorrhage was due to a ruptured aneurismal sac.

Case III.—On the 17th of September, 1872, a man received a gunshot wound just below Poupart's ligament, and came under Dr. Weir's observation about the first of November, when he had a large aneurism extending from below Poupart's ligament up into the iliac fossa, so high as apparently to prevent an attempt to ligate the common iliac artery. It was deemed advisable to do Syme's operation, and the following day was assigned for its performance. During the night however, the tumor rapidly increased in size, and on the following morning it was found that the external iliac could be recognized, it had been crowded up upon the inner surface of the tumor. A straight incision, directly upwards from Poupart's ligament, enabled him to reach the vessel readily and it was secured. The patient recovered.

Case IV.—A man received a gunshot fracture of the inferior maxilla, and serious hemorrhage followed, the blood flowing through the wound from, as it was afterwards learned, an opening in the artery just at the bifurcation of the carotid. The injury was received on the 9th of July. Secondary hemorrhage occurred on the 20th, when the common carotid was ligated. On the 2d of August secondary hemorrhage again occurred, and the artery was again ligated below the site of previous ligation, as the bleeding came from the proximal side, and where a small aneurismal sac was found which had ruptured and given rise to the hemorrhage.

The patient died at the end of twenty-four hours from exhaustion.

Dr. Euskine Mason referred to a case of traumatic aneurism of the carotid occurring in a boy eight years of age, who had been wounded by a shot from a small gun. The common carotid had been ligated. The patient had lost a large quantity of blood. The operation being unsuccessful, and the patient's life being in great danger, Dr. Mason, when the case came under his observation, opened the tract of the wound with the view to secure the vessel above and below, but one gush of blood terminated the case. He also referred to a case of traumatic aneurism of the anterior branch of the temporal artery, about the size of a hickory nut, which was laid open, the artery secured above and below, and the patient did well.

The President remarked that the cases referred to by Dr. Weir and Dr. Mason were traumatic aneurisms, while Dr. Hutchison's case was one of spontaneous aneurism. He thought Dr. H.'s case was interesting as showing, as had been before shown, that the arteries in the immediate neighborhood of an aneurism of spontaneous origin may be healthy and bear the application of a ligature, thus supporting, to some extent, the view taken by Mr. Syme, that the proper method of treating aneurisms of *spontaneous* origin is to lay open the sac and ligate the vessels which feed them, a doctrine which Dr. Sands thought was not considered sound, although it was favored by the results of such cases as the one related by Dr. Hutchison.

DERMOID CYST IN THE REGION OF THE COCCYX AND INVOLVING A PORTION OF THE LEFT BUTTOCK.

Dr. E. Mason reported a case as follows: Three weeks ago he saw a lady twenty-seven years of age, who was supposed to have necrosis of the coccyx. About twelve years ago, without known cause, an abscess appeared upon the left buttock, at the junction of the sacrum with the coccyx, was opened, discharged about a gill of matter, and continued to discharge more or less for ten days or two weeks. The opening then closed, and the wound apparently well for a month, when another abscess made its appearance, opened and discharged, and had continued to discharge almost steadily for twelve years. Several small abscesses had formed in the same region, at different times, and had discharged and healed. On examination he found an opening which gave exit to pus from the left buttock at about the junction of the coccyx with the sacrum, and through it a probe could be passed to the median line, and from there to the lower portion of the sacrum and the first bone of the coccyx. There were two other openings, from one of which he discovered hair protruding, and drew out a small quantity, and from the other he extracted two hairs, between two and three inches in length. The sinus was laid open freely and the sac dissected out, which had two prolongations under the left buttock, about two inches apart. The sac contained a ball of hair. The wound was left to granulate and the patient was doing well.

FRACTURE OF THE INVOLUCRUM OF A FRACTURE.

Dr. Mason also related a case having the following history: In July last a man was admitted to Roosevelt Hospital with a compound comminuted fracture of the leg. The case progressed favorably. About two weeks ago all the openings had closed except one through which a probe could be passed, and a piece of dead bone detected. A small incision was made; a piece of necrosed bone about two inches in length removed. The tibia was surrounded, apparently, by a strong involucrum. The patient was able to go about the wards perfectly well, and a few days afterwards took a pass and went out for the day. On the following day the House Surgeon noticed a false point of motion at the seat of fracture. The man denied having received any injury, but three days subsequently he was suffering from an acute attack of gonorrhœa. The special point of interest was fracture of the involucrum of fractnre, which he had not before seen. The Society then adjourned.

Correspondence.

ABUSE OF MEDICAL CHARITIES.

To the Editor of The Medical Record.

Dear Sir:—While it is not my purpose to reply fully to the communication of Dr. F. R. Sturgis in your issue of April 27th, I cannot but protest against his statement that "the surgeon either in public or private practice is not bound to make any inquiry as to previous physicians." While I believe that we have a perfect right to treat all office patients who seek our advice without regard to their previous advisers, I am certain that it is our duty, when called upon to visit a strange patient at the house, to satisfy ourselves that no other physician is in attendance. The reason for this distinction between office patients and others is obvious; for in the one case every physician considers himself dismissed the moment a patient ceases to visit him, while on the other he is still the attending physician until notified to cease his visits, or until he does so voluntarily. But the main points of my first communication were, *first*, that the attending physicians and surgeons at public institutions, as well as those in

private practice, should not criticise the previous treatment of patients seeking their advice; and *second*, that patients able to pay a medical attendant should not be treated at public institutions. Those points I hold to be incontrovertible, and to their observance we could, I am sure, look forward with confidence to the total abolition of the much discussed and flagrant "dispensary abuses as they now exist." And now, if I may further trespass upon your space, permit me a few words upon the other matter alluded to in Dr. Sturgis's communication. I refer to the omission of names from my first letter. My reasons for doing so were, it seems to me, quite valid. In the first place I did not wish *one* to suffer for many, for although the instance I mentioned was a flagrant one, yet offences of a similiar nature have occurred in other institutions under other hands, and it was the assumption of censorship which I wished to attack, and the treatment of well-to-do patients at public institutions which I wished to expose, and not the holding up to view of the mistake of one physician, which led me to enter upon the discussion of the subject. There is one point, however, which I am willing to admit is perhaps unjust in thus witholding names, and it is this, it does not give the physicians implicated an opportunity to explain any possible mistakes. It is with a view to remove this one hardship, Mr. Editor, that I shall to-day inform the gentleman to whom I alluded that it is his name which I omitted and give him an opportunity to reply and defend his action as publicly as it has been attacked.

I remain very truly yours,

S. S. JONES.

NEW YORK, April 28, 1880.]

BOVINE DISEASE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Ever since the introduction of bovine or animal vaccination in the United States, the only source of supply has been a continued reproduction from the original furnished by an epidemic of the bovine disease among cattle in Beaugency, France.

The reason for this is because of the extreme rarity of such outbreaks, and the failure of its detection when so occurring.

As my memory serves me, I recollect of but one authenticated case of the bovine disease in this country, and that was reported by the late Dr. Loines as having occurred in Cayuga County in the year 1869.

From this he gathered the material for renewing that stock of vaccine which, propagated by "arm to arm" vaccination, constituted the virus which he so successfully cultivated for many years.

By an accidental circumstance I have been recently enabled to see and study an outbreak of the disease among a herd of milk cows on a farm located in the southern part of this State.

The occasion of its discovery, and the tests and results of its application to the arms of infants, are, I believe, of sufficient interest to deserve a more careful description than this short note will allow, and, with your permission, I will be glad, in a future letter, to add what intelligence my investigations may glean to the already existing literature of vaccinia.

Yours truly,

S. S. BOGERT, M.D.

EASTERN DISPENSARY, NEW YORK, April 24, 1880.

INCOMPLETE OUTWARD DISLOCATION OF THE ELBOW.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—An article in the MEDICAL RECORD of April 10, 1880, brings to mind a case of my own.

On Sunday, May 13, 1877, Ira W——, aged about 65, of intemperate habits, while in liquor, on driving rapidly around a corner in a heavy wood-wagon, was overturned, but remembers no particulars. On my arrival an hour later, the right arm was flexed fifteen to twenty degrees, pronation was very marked, the internal condyle very prominent, the olecranon somewhat so, while it, with the whole forearm, seemed carried to the right or outward.

On palpation, all the articular surface of the humerus could be detected under the finger, but the articulating surface of the ulna lay upon the outer condyle. I examined very carefully and repeatedly, hesitating, at first, to diagnose so rare a form of dislocation.

Taking advantage of the intoxicated state of the patient, an attempt was made to replace the parts without ether—it was not successful; and upon giving ether some considerable difficulty was experienced in putting the radius in position and retaining it there; reduction was finally successful, and in a week, contrary to orders, of course, the old man was driving his team again, and recovered remarkably, much to my surprise. He now cannot completely extend the arm, and complains of weakness in it, but has no other difficulty with it whatever.

S. R. TOWNE, M.D.

ENFIELD, ILL.

THE TREATMENT OF EMPYEMA BY SIMPLE INCISION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In reading an article published in No. 491 of the RECORD, I see that a gentleman in Chateaugay, N. Y., Dr. A. M. Phelps, advocates the use of some apparatus of his own devising for the cure of empyema. As I published four cases some time ago in the RECORD, all cured by simple incision and drainage, let me add two more. One was a girl of ten years of age, who was brought to the office with a temperature of 104½°, and a pulse of 120. She was operated upon in the office. We first gave her a good drink of brandy, and then made an incision in the axilla a little superior and anterior to the lower angle of the scapula. I next inserted a drainage-tube eight inches into the pleural cavity, leaving some four inches outside. I packed oakum over the tube after fastening it in place. The tube was fenestrated. Now, what I want to point out is this, that, even if the air does rush in and out when the oakum is removed, it does not do so when it is in place; and I hold that, in my experience, a valvular tube and two counter-incisions are not necessary to insure a cure, and that without deformity of the chest-wall on the affected side. The little girl was operated upon three months ago, the tube is nearly all forced out by the pleural surfaces uniting, and on measuring the chest I find that there is only half an inch of difference between the two sides. I hope to correct this by suitable exercise. My other case was that of a gentleman who was cured before I read Dr. Phelps's article, and he is not now in New York; but he had no perceptible deformity, nor am I afraid of any bad result in the future. To conclude then, I think anything which renders this operation more complicated deters the

profession from performing it, and loss of life results. I am sure that the results are as perfect as any one could have, and the apparatus are required save calomel, a drainage tube, and a sharp pointed bistoury. I think an opening large enough to admit the forefinger all that is required. I do not write this for the purpose of controversy, nor will I explain why I think the calomel acts as a suitable valve, but leave all this to the decision of any one who chances to read this letter.

MARTIN BURKE, M.D.

137 LEXINGTON AVENUE.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from April 25 to May 1, 1880.

MOORE, JOHN, Major and Surgeon. The leave of absence granted him July 24, 1879, from A. G. O., extended two months. S. O. 90, A. G. O., April 23, 1880.

HEGER, A., Major and Surgeon, assigned to duty as Post Surgeon at Fort Clark, Tex. S. O. 78. Dept. of Texas, April 24, 1880.

GODDARD, C. E., Major and Surgeon, when relieved by Asst. Surgeon Waters, to comply with S. O. 74, C. S., A. G. O., in his case. S. O. 78, C. S., Dept. of Texas.

WATERS, W. E., Capt. and Asst. Surgeon, when relieved by Surgeon Heger, to report to Comdg. officer Ft McKavett, Tex., for duty as Post Surgeon, relieving Surgeon C. E. Goddard. S. O. 78, C. S., Dept. of Texas.

SWAN'S ILLUSTRATIONS OF THE COMPARATIVE ANATOMY OF THE NERVOUS SYSTEM.—Prof. B. G. Wilder, of Ithaca, N. Y., desires to learn where a copy of this work can be consulted.

THE DANGER OF CHLOROFORM.—Dr. C. W. Robbins, of Milwaukee, Wis., writes: "I wish to call attention to the very dangerous method of administering chloroform advocated by your Camden, S. C., correspondent (see RECORD, April 17, 1880). The majority of the profession are opposed to the giving of chloroform in any manner, but to give it as advised by S. B. is certainly a method that cannot be too severely condemned.

"Would it not be well if some action could be taken by the Am. Medical Association looking to the entire abolishment of chloroform as an anæsthetic?

"Something like the following might be acted upon:

"1. *Resolved*, That it has become an established fact that chloroform is an unsafe anæsthetic, being ten times as dangerous as ether.

"2. *Resolved*, That this Association do hereby condemn the use of chloroform as an anæsthetic.

"A somewhat curious statement is made by Dr Peaslee in his report before the N. Y. Pathological Society (see RECORD, same date as above). He says (Case III.) the aorta was slightly dilated, being as large as the eye of a goose. Now I don't know what kind of geese you have in New York but I do know that a well bred Western goose would be ashamed to lay an egg that did not measure at least 2½ inches transverse diameter, by 3½ inches from pole to pole. If the specimen shown by the doctor was of these dimensions, the aorta must have been enormously dilated."

THE CARTWRIGHT LECTURES.—Prof. Roberts Bartholow has accepted the invitation of the Councillors of the Alumni Association of the Coll of Phys and Surgs. to deliver the first course of lectures, on the Cartwright foundation, during the session of 1880-81. This course of lectures was founded by the late Benjamin Cartwright, of Newark, N. J. His bequest of $10,000 to the Alumni Association of the College of Physicians and Surgeons was divided into sums of $5,000 — one for the purpose of founding a prize, to be known as the "Cartwright prize," for the best essay, containing original work, on some subject connected with the art of medicine or surgery, to be open only to the competition of the Alumni of the College of Phys. and Surgs. The other to establish an annual course of Lectures, to be known as the "Cartwright Lectures," and to be under the control of the Alumni Association.

These provisions of Mr. Cartwright's bequest will both be fulfilled during the coming session. It has been decided to alternate the "Cartwright Prize" with the prize of the Association, so that there may be an annual prize of $500 offered. The conditions of the "Cartwright prize" of $500 are already announced.

AMERICAN MEDICAL ASSOCIATION.—Dr. Walter R. Gillette, Secretary of Committee of Arrangements of the American Medical Association, writes: "Will you please publish in the next issue of your journal a request that the secretaries of the different sections of the American Medical Association send the abstracts and titles of the papers received by them from members of the profession proposing to present them at the coming meeting of the Association at once to Prof. T. Gaillard Thomas, 294 Fifth Av., New York, Chairman of the Committee of Arrangements? The object of this notification being sent through the journals to the secretaries is that gentlemen who have not yet sent in their papers may do so without delay."

A MINISTER OF PUBLIC HEALTH.—The *Lancet* devotes a leader to urging the new Government to appoint a Minister of Public Health. The President of the Local Government Board, it is argued, ought to be made a cabinet officer, and the sanitary work of the department under his charge be more centralized and efficiently carried out.

THE AMERICAN JOURNAL OF MICROSCOPY is a very excellent periodical. It is hardly fair, however, for it to take our editorials and use them, slightly modified, as its own "current notes." Such practice may impart interest to the "notes," but it is not considered honest journalism.

An Epidemic of Pneumonia exists in Chicago. It is of average severity.

Dr. Wm. B. Carpenter, of London, is expected to visit this country some time during the coming summer.

A French Hospital in New York.—The French citizens of this city propose to hold a festival in June, the proceeds to go toward the erection of a French Hospital.

Nerve-stretching for Sciatica.—As the success in the treatment of sciatica by nerve-stretching has not yet been great, a case reported to the *Lancet* by Mr. Manle Richardson may be of interest. The patient was a blacksmith, aged forty-five, who had suffered from sciatica for nine months. Blisters, the actual cautery, and galvanism had done no good. He finally consented to have the sciatic nerve stretched. This was done antiseptically. The nerve being exposed, hooked out by the fingers and pulled on until a degree of relaxation was obtained, the limbs being kept extended at the time. A good deal of suppuration followed, but there had been no return of the paroxysms at the date of the report, three weeks after the operation.

Spasmodic Croup—Convulsions — Spinal Hemiplegia.—Dr. Henry Jacob, of Altoona, Pa., sends us the following case: The doctor was summoned to a child, aged two years, suffering from spasmodic croup. An emetic relieved it, and having prescribed an anodyne he left the case. The next night he was called again, and found that the child had had the croup again, and was then in general convulsions. A hot bath relieved the symptoms, and having prescribed potas. bromide to be given every three hours, he took his leave. He was again summoned toward morning, however, and found that the child had had another convulsion. This had been controlled, but the left leg was completely paralyzed. After waiting two days, ergot and iodide of potash were given three times daily; at the end of three days the paralysis had disappeared.

Medical Society of New Jersey.—The Annual Meeting of the Medical Society of New Jersey will be held in the lecture-room of physics in the School of Science Building, Princeton, on Tuesday and Wednesday, May 25 and 26, 1880, commencing at 7.30 P.M., on Tuesday.

Oxalate of Cerium.—Dr. F. A. Castle, of this city, writes: "Your reporter of the recent meeting of the New York Therapeutical Society (see Medical Record, p. 493) is in error in saying that I found Wyeth's preparation of cerium oxalate useless in one of the cases referred to. I did not mention whose preparation it was that failed, nor do I know; and I would be very loth to make so unfavorable a comparison of any manufacturer's wares without better evidence than could be furnished by one trial."

(We are also advised by John Wyeth & Brother that they have never made, either in large or small quantities, oxalate of cerium, and have no elixir combination with that chemical as one of its constituents.—Ed.)

Physical Examination of Persons Wishing to be Married.—The Société de Médicine Publique et d'Hygiène Professionelle have been discussing the proposition of Dr. Bourgeois that the State should take measures to prevent the marriage of individuals suffering from hereditary diseases. By such action it is claimed that phthisis, epilepsy, insanity and other diseases, would soon be exterminated.

Dr. Bourgeois would have every candidate for wedlock submit to a physical examination and would allow marriage only to those who obtained a medical license. A difference of twenty-five years should be a bar to marriage between two parties, provided one of them was over sixty. A committee appointed to consider the above project did not report favorably.

The National Board of Health held its annual meeting at Washington during the present week. The conference of health-board officers and those interested in the collection of vital statistics took place at the same time.

International Sanitary Conference.—The joint resolution authorizing the President to call an International sanitary conference has passed the Senate.

The Bill to Regulate the Practice of Medicine in Massachusetts has failed to pass.

The Bill to Establish a State Board of Health in New York has, at date of writing, been ordered to a third reading, and its passage is now ensured.

The Bill Authorizing the Reception and treatment in Bellevue Hospital of persons who do not reside in New York, thus furnishing more clinical material for the colleges, has passed the State Assembly.

A Bill to Secure Registration of births in New York has also passed the Assembly.

An Amendment to the law preventing abortions has passed the State Senate.

Royal College of Surgeons, Ireland.—Dr. Benj D. McDowel has been elected examiner in this college, in place of the late Mr. O'Leary, M.P.

Edison's Polyform.—This is a new patent medicine, discovered, it is said, by Edison, and widely advertised as representing what his great genius can do when applied to therapeutics. It is nothing but an ordinary liniment made up chiefly of chloroform, chloral, camphor, and aconite. Small bottles of this cheap and well-known mixture are sold for $1.50. It is a pitiable fact that Mr. Edison should allow his name to endorse a nostrum which is no better than half a dozen other liniments, and which is sold at an exorbitant price.

Microscopic Examination of the Blood in the Penis of the Living Person.—A novel method of examining the circulation of the blood under the microscope is described and pictured by Dr. F. B. Tiffany, in the *St. Louis Medical and Surgical Journal*. The prepuce is drawn out, put under a clamp which makes it tense, and then held under the stage of the microscope. The results are said to be very satisfactory, the mucous membrane, submucous, and areolar tissues being beautifully seen.

Surgeons and Patent-rights.—Dr. C. R. Parke, of Bloomington, Ill., comes to the front in the *St. Louis Medical and Surgical Journal*, defending the rights of surgeons to patent their own inventions, and saying something in defence of his own metallic splint for fractured femur. He concludes: "To be a *medical gentleman* is all the code we need; copyrights and patent-rights should be placed on the same footing, both sanctioned or both abolished by the American Medical Association."

The Home for Convalescents, on West One Hundred and Twenty-seventh Street, which a number of prominent ladies and gentlemen have been active in establishing, was opened on the 30th ult.

Answer to Correspondent.

The Origin and Description of the Mad Stone.—Dr A. L. Cuckow: "Can you or some of your readers, inform me of the origin and composition of the 'mad-stone,' in the anti-hydrophobic efficacy of which the rural secular press has such firm faith? The superstition concerning its virtues, as I believe, most prevails in the South and Southwest, but I can nowhere find a description of it. I have a vague impression of hearing that it is an intestinal concretion like the bezoar, but cannot verify my recollection."

[We referred the question to Prof. Charles Rice, of this city, who sends us the following interesting reply.—Ed.]

The fable of the "Mad Stone" may be traced back to the earlier period of the middle age—a time when medical men first began to leave the old beaten track of therapeutics laid down by the earlier Greek and Arabian physicians, and to study and observe nature for themselves. Yet their steps on this new ground were not simple, and rational explanations of natural phenomena, or of newly-observed facts, were so difficult for them, that superstition, for a long time afterward, found a fruitful field for development. Not only were new facts discovered which were unintelligible, and were, therefore, often misconstrued, but sometimes there were properties and virtues assigned to newly discovered substances, which were in direct proportion to the rarity of their occurrence, or the singularity of their appearance. Among such rare substances may be counted the peculiar concretions which are sometimes found in some of the inner organs of animals, particularly those concretions which consist of mineral or inorganic matter. There can be no doubt that such concretions must have been known and observed from the earliest times, yet, so far as I am aware, no written record of the observation of any such concretions exists in the ancient classical literature, nor have I met with any account of them in oriental literature before the thirteenth century A.D. The first notice that I am aware of, exists in the work of Ibn Baithâr (died 1248 A.D.),* "On Simples," who gives a detailed, but somewhat confused account of *bâdzahr*, which is our present word *bezoar*, and is, without question, the substance forming the subject of the above query. Ibn Baithâr, as he usually does, gives extracts from the works of his predecessors, and, among others, cites a passage from Aristotle, which, however, must be a mistake, since the contents of the passage are of such a nature that they could not have been known at the time of Aristotle. At the end of the article he quotes Ibn Djâmi', who says that "the *animal* bezoar, or that which is found in the deer's heart, is better than the other kinds." He fails, however, to give a description of the latter, or to mention any vegetable or other bezoars.†

Ibn Baithâr's description already characterizes the bezoar stone as being endowed with wonderful power as an antidote to poison, and ascribes to it the faculty of "attracting the poison of venomous animals."

The word *bezoar*, which has sometimes been written *bezoard*, *bezoart*, *bezoer*, etc., is originally derived from the Persian *pâd-zehr*, meaning "the wind or the breeze of poison," in the sense of "the wafting away of the poison," and therefore "an antidote to poison." The Persian word became *bâd-zhar* in classic Arabic, *bedzoar* in modern Arabic, and *bâdzehr* or *panzehr* in Turkish.

I have stated above, that the term *bezoar*, or rather *bâd-zahar*, in the meaning of "a concretion found in animal organs," did not occur, so far as I am aware of, in any published work written before Ibn Baithâr's time. Yet the word was used long before him by Arabic and Persian authors in its original sense—"antidote to poison." Since Ibn Baithâr himself quotes from works of authors who had preceded him, the word must have acquired its double sense a considerable time before him. After the term had once been misapplied to "bezoar-stones," and the notion of the efficacy of the latter, as antidotes to poison had once spread, the fable—as it happened with many other similar ones—took a firm hold among the ignorant classes, being handed down from one generation to another as a priceless family prescription, sometimes even accompanied by a veritable family bezoar-stone. The claims which were made for these stones, centuries ago, may, even in our days, still be read in modern literature, and it is really surprising with what unshaken confidence even some well educated persons will adhere to a firm belief in their efficacy.‡ These mad-stones are, in our days, principally used as a supposed infallible remedy for the bite of mad dogs, and naturally every application of such a stone to a dog bite, even if the latter would have been of itself harmless, is scored as an additional victory for the stone.

The subject scarcely deserves a more detailed treatment, except, perhaps, at the hands of those who wish to write a history of superstition or of "sympathetic cures." A large amount of literature is at their disposal in the works of the earlier writers on materia medica, such as Garcia ab Orta, Acosta, Bontius, Clusius, Nicolaus, Monardes, and many others.

* *Al-Ghâfiqî min-al-rukâb al-bârjân wa al-ngkâzjath*— = The Collection of the Simples among Mediæval Arts and Accidents. Published in Arabic at Cairo, 1874, in four parts, small folio, 174 pages. The arrangement of its alphabetical, and the article referred to is under the letter *b*. The work was translated by Sontheimer, *Zusammenstellung der einfachen Heil- und Nahrungsmittel*, 2 vols. Stuttgart, 1839–42 (*Cotarnus*, see vol. I. p. 119), but the translation is frequently incorrect. At present an improved French translation is being published by Leclerc, the first part form my desk, xxiii of the work entitled: *Notices et Extraits des Manuscrits de la Bibliothèque Nationale*." Paris, 1877. (*Bezoar*, see on page 198.)

† The *mad-stone*, or bezoar obtained from animals, must not be confounded with the so-called *fossil stones*, or Lapides Judaici, which are described by Hieronymus Tragus (*De Stirpium Historia*, Strasbury, 1532, p. 514, under Artemisia), by J. B. Ionthus in (*Cornarium Historia*, under Artemisia), and later writers. These fossil stones were the hardened and dead remains of the roots of *Artemisia rupestris*, L. These carbonized roots, which were also named "Carbones Artemisiæ," were supposed, if dug up before sunrise or at noon on St. John's day, and worn as an amulet on the chest, to be an infallible remedy for epilepsy.

‡ This form is original Persian *pâd-zahr*, and means "protection from poison," *pâd* being derived from the Sanskrit root *pâ* (*pâtr*, "to protect."

‡ In a correspondent of the *Scientific American* for 1880, Mr. John Smith, is to be believed, it would seem that the Indians also had faith in these stones. He states that he was bitten by a mad dog both his legs twelve years previously, and having gone to a "mad-stone" that is having gone to a person who was known to possess a mad-stone, he has had no trouble since. He says that he himself has a mad-stone, "which will cure a bee sting, when one can hear his breath." He also says that the Indians of the plains informed him that the mad-stone is obtained from the rennet of the deer, and that its size is in proportion to that of the animal.

Original Lectures.

THE ERUPTIVE FEVERS.

LECTURES DELIVERED

By ALONZO CLARK, M.D., LL.D.,

PROFESSOR OF PRINCIPLES AND PRACTICE OF MEDICINE, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

LECTURE III.—SCARLET FEVER.

The next topic that will engage our attention is scarlet fever, and I have a curious fact to disclose to you in regard to its prevalence. I have already told you that we have bills of mortality running back to 1804, regularly kept. The disease of which each person dies is recorded, and the number of cases is easily summed up. From 1804 to 1828 the number of deaths from scarlet fever occurring in this city was very small, the whole number being only 141. Then came a sudden invasion of the disease. In 1829 there were 188 deaths—a number in that year greatly exceeding the whole number of deaths for the twenty-five preceding years. And from that time until now it has held on at a pretty high rate of mortality year by year. For the next year, 1830, the number of deaths from scarlet fever was 246; for the succeeding years, in their order, 258; 221; 179; 418; 174; 202; 579; 257; 158; 391; 416; 223; 224; 63—that was in 1844, which is a small number for that period —115; 142; 93; and so on. And that large mortality has continued to the present time. In 1877 there were 815 deaths from scarlet fever. Well, of course, you expect some increase in the number of deaths from the increase in the population, and in the advancing years and accumulating people it will be necessary to make an average—an equality of deaths proportioned to the number of inhabitants. But even making that reckoning, the scarlet fever mortality has increased a good deal faster than the population of New York has increased.

Scarlet fever has its several periods, as small-pox has. It has its period of incubation; is strictly a contagious disease. The poison dwells in the system a certain length of time before it manifests itself in symptoms. Then, it has its invasion; it has its eruption; its desquamation, and its sequelæ.

In regard to the period of incubation of scarlet fever, it seems to be very variable. I have acquired a considerable number of facts bearing upon that point. The one that I most commonly cite is that of a family in Woodstock, Vermont. When I was lecturing at the Vermont Medical College, I saw several children sick in the family of a man named Cobb. The history was this: There had been no scarlet fever in the town of Woodstock for a great many months, and this man Cobb took his wife and three children on a visit twelve miles from Woodstock in the town of Plymouth. When he reached his friend's house he found scarlet fever in the family, but he allowed his family to remain there two nights, the night of their arrival and the night following. He entered this house on the evening of the 16th of March. He returned home, and one of the children that had made this visit with him was taken sick with scarlet fever on the evening of the 19th—three days after the exposure. Another was taken on the 20th, and then the cases that followed seemed to have been propagated from those that made this visit, and they occurred at about three day's interval. But several children, five in number, were all taken down with the disease. The infant, which was one of the visitors at Plymouth, the last of all. The two sons that remained at home were attacked, one of them on the 23d, and the other on the 26th. They must have taken it from those children that had it developed in them from the contagion received at Plymouth, and in them the period was three days in one and six days in the other, or three days in both, depending upon how the second of the boys who remained at home took his disease. It is reported in Murchison's that it is developed in symptoms in very few hours.

I have another case derived from the same town, that is instructive on the other side of the question. A girl, a daughter of a man in Woodstock, had been in one of the factories of New Hampshire at work, and boarded in a family where scarlet fever broke out. Pretty soon after scarlet fever appeared in this family she returned home, and nine days after she left the house she had scarlet fever, and she communicated it to two of her brothers, who took it, each four days after the other. Four days after the eruption appeared in this young woman, it appeared in one of her brothers; and four days after that in the other of her brothers. Now, we cannot say whether this was an incubation in the last of four or eight days, for we do not know whether he took it from his brother or from his sister. Four days is not an uncommon period of incubation, and then it is reported to run on to fifteen, or even thirty days, but this longer period I think requires new investigation. I doubt whether it will dwell in the system so long a time, and then, there is a chance for other exposures when the time is protracted. It is pretty clear then, that it has a varying incubation. You may say, perhaps for safety, from a few hours to fifteen days.

With reference to the invasion, that is a short period. The period of invasion of small-pox, as I told you, is two full days, and pretty regularly. The period of invasion of scarlet fever, that is the fever before the eruption, sometimes is not over six or seven hours, and it rarely exceeds twenty-four. The invasion is various. In a few children it is attended by convulsions, but in much the greater number it is a febrile action—not necessarily preceded by a chill, or perhaps even commonly. It is attended with a great deal of vomiting. A febrile action attended by vomiting in a child may always be suspected, and all the more if any exposure is known. The vomiting, I cannot say is absolutely constant, but it occurs frequently enough to be a very valuable symptom in diagnosis. The eruption then occurs, say from seven to twenty-four hours, after the invasion, and it appears first upon the forehead and neck, and just the upper part of the chest. It has a progress downward, so that it requires in some instances nearly two days to reach the feet. It is apt to affect the whole body. The different parts of it successfully. I have seen cases of scarlet fever that broke out first upon the limbs, but they are not very common. I have seen them also in which the eruption was general at once, but the rule is as I have stated to you, that it appears first upon the upper part of the body—on the neck, head and face—and advances downward. The peculiar kind of eruption is that you see on this plate, a reddening of the whole surface affected. And yet it begins in patches. The patches spread until one reaches another, and the eruption becomes general. There is with the eruption, not infrequently, a little blister; several together called sudamina; little elevations that will suggest to you the

ules of glass having been broken and some fine particles of it having been left on the skin. The eruption varies, however, so much that you will often be puzzled to know whether you have got scarlet fever to treat or not. In some instances it is the merest blush, you can hardly say there is anything. In other instances it is well marked, as in the figure that I have shown you. And in addition to that, in certain cases where the eruption is full, there will appear a little œdema, a little swelling of the face, a little swelling of the neck, and of the several parts of the body successively invaded by the eruption. The eruption, however, is not the whole of the disease.

Scarlet fever has been divided into scarlatina simplex, scarlatina anginosa, and scarlatina maligna. It is not a very good division, but as it is generally adopted I will not depart from it.

Inflamed fauces make a part of the disease. Perhaps I can make you appreciate the value of this fact by a case. I was called over to Hoboken to see a child sick with scarlet fever, and when I got there I found the eruption clear enough—perfectly red all over the body. It had not observed, however, the order of beginning at the upper part of the body and spreading downward. I looked into the throat; it was as clean and natural as it ever is in a perfectly healthy child. I said to the doctor, "You have not a clear case of scarlet fever here. That cannot be scarlet fever; there is no sore throat." It turned out in a couple of days that the eruption died out. There was not much itching, and yet it was urticaria with as full an eruption as scarlet fever ever has. You observe my diagnosis was based upon absence of sore throat. I could not have distinguished between that eruption and that of scarlet fever, especially as scarlet fever eruption sometimes occurs upon the whole of the body at the same time. There is always some inflammation of the throat in scarlet fever. The tonsils enlarged moderately, or considerably enlarged, as the case may be; the velum palati red and somewhat swollen. It may not be to an extent to give great inconvenience, but it is more certain to occur than an appreciable eruption. Then, as I am now speaking of the lesions, I may as well switch off and say to you that there are no lesions except these and sometimes swelling of the Peyerian glands in the small intestine, with a little tendency to elevation of the solitary glands. The rest is all visible during life, excepting the change in the blood, which is typhoid in its character.

In some instances the affection of the throat comes to be a very grave one. Indeed, you may say a fatal one, and to such cases the name scarlatina anginosa is applied. You will find sloughing of the throat in certain bad cases; the lymphatic glands that are near the surface will become swollen, sometimes suppurate. Sometimes there is hemorrhage into the swollen part. Such are always very bad cases.

Then as to the scarlatina maligna, the term partly applied to the "head" cases, and the head symptoms are not unfrequently preceded by convulsions. The convulsions in scarlet fever I think depend very much upon the condition of the blood in relation to its being purified of the albumen. My impression is, without having investigated the matter so thoroughly as to speak with authority, that the convulsive cases of scarlet fever are cases of albuminuria and uræmia, and yet this uræmia manifests itself in another way, by a comatose condition.

You will occasionally see children in whom the eruption is far from being a bright red, like a boiled lobster, as it is sometimes said, but it will be almost a venous hue, a very dark hue. Then there may be hemorrhagic forms of the eruption, in which the skin will be darkened by ecchymosis. These are always bad cases. The dark eruptions are bad indications, and those with that are apt to go the head symptoms that I referred to. The child will sleep a great deal, will start up suddenly from sleep and scream, as in one form of meningitis; then fall back and be stupid, or perhaps be comatose. Those cases die early after the manifestation of these symptoms, and, as I have said, I think from uræmia. That is called scarlatina maligna.

There is another form of sore throat that is of a good deal of importance. I have seen two children in the same family die of that affection. It is a diphtheria engrafted upon the sore throat of scarlet fever. That condition has been known much longer than the term diphtheria has been used. That there can be a membranous inflammation of the throat I say has been long known, and that membrane forming up on the fauces is inclined to run downward into the air-passages, and produce just the same symptoms as croup. These are the complications that occur in this disease, and the sore throat is manifest as early as the eruption, or earlier. Indeed in scarlet fever and measles the eruption can be noticed upon the roof of the mouth before it appears on the surface of the body.

With reference to the duration of the eruption, it usually lasts upon the whole body one week, six to seven days, with or without the œdema that I have named. And the scarlet fever sore throat takes about the same time; or, if it is a bad sore throat it will continue a good deal longer. A few days after the subsidence of the eruption there will occur a desquamation. It will begin, perhaps, about two days after the eruption has ceased, beginning first upon the part of the body upon which the eruption first manifested itself, and descending, little scaly exfoliations of the old epidermis. The action in the eruption of scarlet fever is sufficiently inflammatory to kill the epidermis, and as it dries up and a new epidermis forms underneath it, it is pushed off. Occasionally the thick epidermis of the fingers, particularly of the palmar surface of the fingers, will exfoliate in one body, and it is said that the whole of the epidermis of the finger may exfoliate, appearing like the finger of a glove. I have never seen that, but I have seen the exfoliation of long ribbons on the palmar surface of the fingers, where the epidermis is thick and strong. In that respect scarlet fever differs from measles, the whole of the exfoliation in measles being of a fine, branny matter. You will always see this exfoliation of the epidermis if the child is not sweating a good deal. If he does sweat you will hardly see it; the sweat will cause the scales to adhere to the sheets of the bed in which he lies, and it may be, therefore, in a sense invisible.

There is, after scarlet fever, a very grave sequence, and that it is a part of the disease, I am led to suppose, because it is pretty uniform in the time of its appearance. About two weeks after the eruption has ceased, the child, running about the room, begins to be a little swollen under the eyes. The face becomes œdematous, the feet become swollen,—indeed, there is a general moderate œdema. The child becomes very pale, but does not lose his vigor. He does not lose his fondness for play at once, but will run about; will run out of doors if you will let him. But after a while he may have a convulsion—a series of them. This œdema may last a very variable time, from a week

to three, four, five months. But the greatest danger is during the first two weeks. I have tried, in certain instances, to confine the child to a temperature of 72° after scarlet fever, until the period of this sequela has passed, and I have not succeeded in protecting it. It does not occur in a majority of cases. It is rather an exceptional occurrence, but as it occurs at two weeks it would seem to have a definite relation to the eruptive disease.

The mortality of scarlet fever is large. Different epidemics differ very much in their severity. We have had epidemics that would run on for a year or two in which there were very few deaths, not more than one in twenty or thirty, and I have heard a clergyman preach who left that morning, when he came to church, three dead children in his house. Some epidemics are fatal to about one-half of those who are attacked, and we never know in the beginning of an epidemic whether it is going to be particularly fatal or not. Some physicians have encouraged their patients to expose their children to scarlet fever in the mild epidemics, to insure, as they say, a mild run of the fever. I do not know whether it is wise or not, because a great many children escape scarlet fever altogether. Hundreds of mothers have scarlet fever when their children have it, never having had it before.

With reference to the management of scarlet fever there is but little to be said. We cannot do much for it. If it be a mild case it will run a gentle course, and you have very little to do. If it be a bad case, it will have its bad features in spite of the best that you can do for it. I have sometimes thought that in the bad cases the best thing to do was just to let the child lie and take a certain amount of champagne, the quantity to be controlled by the pulse, and try nothing else.

In mild cases of scarlet fever, when the eruption appears, the fever diminishes in severity; in severe cases it increases, and the temperature may go up to 106°, 107°, and it is reported to have reached 111°. Of course such are bad cases. When adults have scarlet fever they are very apt to have little or no eruption, but the febrile movement and the sore throat. The disease is a great deal more fatal in children than it is in grown-up persons. Grown-up persons usually bear it pretty well. Now and then you will hear of a person of mature age dying of it, but the greater number of them recover.

The redness of the eruption is produced by the congestion, an active congestion of the capillaries of the skin. You know they rise up in knuckles coming up and going directly down again, and it is these enlarged knuckles of the capillaries that make the separate points of the scarlet fever eruption. As I said to you, it is almost an inflammation, for there is frequently some œdematous effusion, and the cuticle is destroyed by the inflammatory action, so that it exfoliates in the manner that I have described.

There is a point of considerable importance which I omitted to state, and that is the effect of the sore throat upon the hearing. The inflammation of the throat occasionally affects the tubes that communicate with the middle ear, and the inflammation extends to this particular part, the result of which is, frequently, a loss of the tympanum. I once saw a little ring of bone ulcerate away, carrying the tympanum with it—a ring of bone out of the bones of the head, just large enough to hold the attachment of the tympanum, and the tympanum was unbroken. Of course that took some time to be accomplished. But the tympanum is often broken, and the bones of the ear are not unfrequently lost. Dr. Pete, who for so many years had charge of the asylum for the deaf and dumb, wrote me a great many years ago for an explanation of the fact that in 1829 there was a very great increase in the number of deaf brought to that institution. The deafness was caused by scarlet fever, and he wanted to know what made scarlet fever so fatal to the hearing, and it is that that led me to read the statistics yesterday, showing that in 1829 more cases of scarlet fever occurred than from 1804 up to that time; and, of course, with an increased number of cases it would be reasonable to suppose that many of them were severe, and that the effect upon the hearing would be more markedly noticed. This is sometimes a complete deafness, which remains, of course, for life. Occasionally it is an impairment of the hearing of one ear, or of both ears.

I spoke to you of the period that elapses between the inception of the contagion and the development of symptoms. But another interesting point is, how long does the poison last in a person who has had scarlet fever. Very few observations have been made in regard to that. I have but one that is reliable, and that was in the practice of Dr. Cheeseman. He had a patient who had scarlet fever, and that patient had a little sister, I think younger than he. They were both children. The doctor told me that he had separated the two children; he had sent the well one to an aunt who had no young children in the house, and he wanted to know how long he should keep these two children apart—how soon the sister might visit her brother, having had a regular run of scarlet fever. I told him to keep them apart as long as he could, and he did succeed in keeping them separate for six weeks, and then the sister went down to the aunt's. The boy did not go home. The sister went down to the aunt's and took her dinner there, and the two children kissed each other, and in four days afterward the second child was attacked with scarlet fever. There was no other exposure known. If that observation was correct, why then here is a poison lingering in this person—in his clothes, in his hair, in his body, in his breath—we know not where, for a period of six weeks after he was attacked with the disease.

With reference to the treatment of this affection, I made a remark yesterday—and only one, because time did not allow me to make any more—that I often feel as if I may about as well not treat the case; to leave medicine entirely alone, and administer a moderate amount of champagne daily. I cannot tell you in an hour, it seems to me, the number of agents that are used for the sore throat. I have applied calomel; I have applied nitrate of silver; I have had children, when they were old enough, gargle with cold water frequently; and of these the cold water suits me best. But you cannot make use of it in a great many; they are not old enough to gargle. If there is a membranous production in the throat, I am very much attached to the spray of lime-water. Take the lime-water of the apothecary shop and put it into one of these little atomizers, or rather spray-producers; have the child's mouth opened, and throw the spray into the mouth when it is taking an inspiration, and let it go down into the fauces. If you can persuade him to let the mouth remain open with the tongue depressed, shower the fauces with the lime-water. What he will swallow will do no harm. In a case of regular diphtheria that I saw some time ago, this spray was used. The boy was old enough to have some dis-

eruption. It was used triply, and within about six or seven hours the membrane exfoliated and came off whole. The boy was entirely relieved for several hours, and then began to have heavy breathing again. The spray was again used, and another membrane was coughed up, and again came rest and easy breathing and a diminished frequency of pulse; and this was repeated five times, and every time followed by expectoration or discharge of a whole membrane. It was not in fragments. The sixth occurrence of this sort happened in the night, and the parents, though intelligent people, were persuaded that they could not stop the disease, and they allowed the boy to go on and suffocate. I do not know why the sixth formation might not have been discharged as well as the fifth, and if either of the physicians in attendance, Dr Thomas being one, had had his way, he would have had the administration continued as long as the boy had any breath, if the membrane formed anew.

This same lime-water, to be thrown upon the forming membrane, I believe is the most efficacious thing you may have. It does not apparently disintegrate the membrane, but it seems to produce a breaking-up, of its attachments to the living tissue.

We know a little something about the application of cold in scarlet fever. A physician of Connecticut, twenty years ago, came to this college and explained to me his treatment, and he was persuaded that it was more efficacious than any he had ever practised before, and it was to use the wet sheet. Strip the body naked and wring a sheet out of cold water and spread it over the child, and allow the body to be cooled partly by the cold sheet and partly by the evaporation of the fluid that was in it and on his body. It is perhaps five or six years since a very similar recommendation has come from Germany, and the bath is very much used in cases in which the temperature is very much elevated. The bath should be at a temperature of fifteen or twenty degrees below the temperature of the body, and the patient to remain in it until the thermometer indicates a marked fall in the temperature of his body. This does not seem in any instance to cause a recession of the eruption. The profession has been afraid of cold in scarlet fever, lest it should break up the regular course of the eruption; but it does not seem that that has been the result. And here, with reference to the recession of the eruption, as we have but few definite facts with regard to it, I will read to you those that I have quoted from Levy, in his treatment of the young soldiers of France. He says, in the first place, "A recession of the eruption does not occur in more than one in a hundred cases; ninety-nine will run the regular course. But he has collected twenty-one instances of recession, and he says that in fourteen of these twenty-one there was no effect that could be observed. It was merely a recession and an end of the disease.

In one, sudamina appeared the next day—little minute blisters; two had slight diarrhœa; one vomited the next day; in one varicella appeared two days after; in one tubercles followed at some distance of time subsequently. You see then that the recession is not so formidable a thing. The remark was, that we had been afraid of the application of cold, fearing the consequences of a recession of the eruption. But this Connecticut physician told me that he never saw it occur, and the German physicians seem to be trying the cold air upon their febrile eruptive diseases, so that we shall have more light on it before long, probably.

There may be recession and revival of the eruption, as in a case that occurred to Boston a few years ago, reported to me by the late Dr Bartlett. Scarlet fever and measles were both in one family. There were three children. One of these children, that is the third, had scarlet fever; two had had scarlet fever and measles before the third child had scarlet fever. The eruption continued two days and receded, and immediately the eruption of measles took its place, or rather the symptoms of measles, and the eruption in time. The measles ran its course, and on the subsidence of the measle eruption, the scarlet fever eruption came again, and lasted three days, making five days for its duration in all, with an interruption of over a week. These diseases, I may remark here, though it is a little out of place, seem to have great respect for one another. They do not run their course at the same time in the same person, but if the patient have been exposed to the contagion of both, the one that has precedence will run its course, and then the other will take its place.

I saw an instance of this that was quite remarkable. A child had diphtheria, and had been exposed to the poison of both scarlet fever and measles. The symptoms of scarlet fever appeared, and the membranous disease of the throat ceased. The scarlet fever ran its course, and measles appeared and ran its course. The child survived, and then the diphtheria appeared again and killed the child. It waited two weeks and more for these diseases to have their place and run their course, and then was revived; or, it was the result of the measles, which is not very common; or, it may have been a new infection, for that matter. I cannot say; but it did give place to scarlet fever and then to the measles, and then there was a renewal and a fatal result.

There are certain other things connected with this disease that require attention. When the scarlet fever eruption is of a black color, when there is hemorrhage under the cuticle, it is an evidence of a very bad state of the blood, a condition approaching that of scorbutus, and I have always advised just the same things that we would give in scorbutus—quinine and the vegetable acids pretty freely. When you have that immense swelling in the throat, and the swelling of the lymphatic glands outside, and a disposition to suppuration in these glands, and even hemorrhage, I do not know what to advise you to do. I have never done anything that did any good. Such cases I believe are predestined to be fatal.

I have something more hopeful to say regarding the sequela of which I spoke to you—the œdema. I was called into a family where there had been four children. Three of them had had scarlet fever. They went pretty easily through the scarlet fever. They were attacked with œdema and in a few days had convulsions and died, one after another. There was but one child left, and that had scarlet fever, and the father and mother desired the family physician to get assistance. When this œdema occurred I immediately advised that the child be put in a warm bath; that he be kept in a warm room after being taken out of the bath and kept in bed, and that enough clothes be kept upon him to keep him in a constant perspiration—not profuse, but a gentle perspiration day after day. You remember that there are casts and albumen in the urine in this condition. It is a kind of Bright's disease—an acute Bright's disease. The relations of the kidneys and skin are well known to you all. When the skin is chilled the kidneys act more vigorously; when the perspiration is

free upon the surface the kidneys seem to act in a much more gentle way, and this suggested to me, first, the use of those means that will keep up a constant but gentle perspiration upon the surface. This was done for many days and the child recovered. It had no convulsions. I suppose that under the circumstances a portion of the urea is eliminated by the skin; indeed, I know it is, for I have not unfrequently perceived in those who had disease of the kidneys the odor of urine on the surface of the body and in the breath of the patient. At any rate, in practice, this seems to be by much the more successful mode of treatment. The bowels should be kept free, not purged vigorously, but a laxative should be given as often as seems to be necessary, and all the rest consists in an unirritating food, what of drink the patient wants, and this perspiration kept up.

There are many children who will not consent to lie in bed under these circumstances; they do not *feel* sick. If you meet such patients your alternative would be to dress them heavily in flannel, to keep their feet well clothed, and let them run about in the room, the temperature of which is kept steadily at 74° or 75°. In that way you can keep up a perspiration.

In regard to the deafness, one of the sequelæ, I have nothing to say about it. It depends upon disorganization that is the result, secondarily of the inflammation of the throat, and that, I have told you, I have not been able to treat with any very marked benefit. The best of all the means is gargling where the child is old enough, with cold water, or cold carbonic acid water.

Original Communications.

INTESTINAL OBSTRUCTION FROM INTERNAL HERNIA—LAPAROTOMY.

By CHAS. K. BRIDDON, M.D.,

SURGEON TO THE PRESBYTERIAN HOSPITAL, NEW YORK.

The following history is reported by Dr. H. G. Wetmore, house-surgeon:

Wm. Beynton; aged 26; New York; single; plumber; March 27, 1880; father dead, cause unknown; mother living, but in poor health.

Six years ago patient had a complete oblique inguinal hernia on the right side, which has always been reducible, never inflamed or painful. According to patient's story it has not been down for four years. Had scarlet fever; never had peritonitis or an attack like the present one; never had typhoid fever; bowels have always been regular.

Last Wednesday morning (four days ago), had very severe pain in abdomen, about an inch and a half to right of and the same distance below umbilicus, which made him faint and caused him to vomit. In the afternoon had a natural passage from the bowels, with vomiting of contents of stomach. Vomiting continued throughout the night. Next morning a free discharge from the bowels, vomiting after eating. Since Thursday the vomited matter had been tinged with blood and was greenish, not stercoraceous; was stringy and mucous in character. Pain since attack began moderate and intermittent, controlled by morphine given hypodermically. Slight tenderness around umbilicus; tympanitis moderate. No fever, headache, or chill on admission.

March 29th, 2.30 P.M.—Face natural, slightly flushed, not anxious; pulse 120 per minute; temperature normal, tongue slightly coated; complains of pain around the umbilicus tympanitis; no tumor can be felt. Examination by the rectum reveals nothing; slight dulness along the ascending colon; hiccough and vomiting of bile, pupils contracted. Hernial openings all examined. The right external ring was regarded as larger than usual in a case where there had been no descent of hernia in four years. This condition being regarded as significant of "réduction en bloc," the whole inguinal canal was examined and nothing found. Deep pressure in the iliac fossa immediately above Poupart's ligament detected; no tumor; no tenderness over obturator foramen; no pain in course of nerves which passes through it; slight tenderness of abdomen; abdominal muscles relaxed; no peritonitis. Laparotomy was suggested, but it was thought the symptoms were not marked enough to warrant the operation.

7 P.M.—Patient given an enema of two quarts of water and soapsuds, which was returned colored with faces. Temperature normal, pulse 124, has passed ℥ vi. of urine, rejects all nourishment; no stercoraceous vomiting; hiccough continues.

4 A.M.—Patient up on the chair and straining; face cold and covered with perspiration. Complains of pain referred to right of umbilicus. ℞ xv. Mag. sol. morph. sulph. given, which relieved the hiccough. Vomited matter green.

Examination of urine, sp. gr. 1018, acid; no sediment; no albumen, red; no casts, amorphous urates and triple phosphates.

March 28th.—Pulse 98; temperature 99½. Another large enema given this morning with same result as before. Vomited matter darker, not stercoraceous. ℥ xvi. of urine for the twenty-four hours.

8 P.M.—This afternoon vomited only mucous. Retained a little milk; not much pain; no change in abdominal symptoms; hiccough continues. Chloroform administered; patient inverted and an enema of four quarts of warm water with soapsuds and castor oil given. Came back colored brown and containing a few small pieces of hard fæces. Temperature normal, pulse 130. At 11 P.M. the matter vomited was darker, but not stercoraceous.

March 29th.—Hiccough, vomiting and prostration most marked symptoms; temperature normal, pulse 120. Urine for twenty-four hours ℥ xxiv. A consultation called for 2.30 P.M., at which laparotomy was unanimously advised.

Operation, March 29th, 3 P.M.—Under the spray and with all antiseptic precautions, an incision was made in the median line from the umbilicus to the pubes, when the linea alba was reached, such vessels as required it were secured by torsion or gut ligatures; a small opening was then made in the aponeurosis, and it was slit up and downward to the extent of the superficial wound; the peritoneum was incised in the same manner, when a coil of congested small intestine protruded. Two fingers were next introduced deeply in the direction of the right iliac fossa, and in a few moments discovered a small circular aperture into which the point of the index could be insinuated, and also into which could be traced a portion of intestine. After the recognition of these facts by several of the surgical staff, an attempt was made to lift this opening to the surface so as to facilitate the release of the gut, and in attempting to do this something was felt to give way. It was not

intestine, for there was no escape of gas or anything else; in fact, the impression conveyed to the finger was that of the abrupt yielding of an adhesion in the neighborhood of the ring. At all events it was evident that something had given way that confined the gut within the opening, for it now only required very slight traction to draw out a coil of congested and ecchymosed intestine, otherwise in good condition.

The finger could now be passed through the opening with ease and the pouch beyond it could be readily pushed downward in the direction of the inguinal canal, and felt there by the finger of Dr. Mason, who had invaginated the scrotum into the canal.

It was clear now that we had to deal with a hernia retro peritonitis anterior, but still such a condition of parts was not consonant with the fact that we had been repeatedly assured by the patient that his hernia had not been down for a long time, and that frequent and very careful examinations had failed to reveal the true nature of the case; the whole length of the inguinal canal had been thoroughly explored, deep pressure above Poupart's ligament had detected no tumor, in fact the most searching scrutiny in that direction had given only negative results.

The wound was closed with silver wire sutures, with intermediate ones of gut and the whole abdomen was covered with the Lister dressing.

8 P.M.—Patient suffering from shock, but rallying slowly. Vomiting and hiccough have ceased, pulse 120, temperature normal, cold sweat on forehead; gr. i. pulv. opii given every two hours with small enemata of beef-tea and brandy every two hours.

March 30th.—Did not sleep, but had no pain; pulse 100; temperature 100½°. At 8 A.M. passed ℥ ix. of urine; tympanites increasing; slight tenderness on pressure; no vomiting; condition better than before the operation; opium and enemata continued; tongue clear.

8 P.M.—No change during the day; pulse 116; temperature 101½; respirations 28; face anxious. Patient complained of so much pressure from bandages, that dressings were changed under the spray; wound looks well; tenderness more marked; knees slightly drawn up; opium continued in 1 gr. doses every two hours, with nourishment by the mouth.

March 31st.—Temperature 99½; respirations 32; pulse 120; distention of abdomen increased, tenderness more marked; tongue coated brown, slightly cracked; enemata not retained; no movement from bowels since operation; no vomiting; very restless; profuse sweating.

8 P.M.—Takes nourishment well by the mouth; tenderness of abdomen marked; pulse 120; temperature 100½; restless; slightly delirious; tongue brown.

April 1st.—Early this morning patient actively delirious; had torn the dressings off. Morphine given hypodermically; pulse 140; temperature 100¾; respirations 44; abdomen much distended and tympanitic everywhere.

8 P.M.—Pulse 160; temperature 103° in axilla; patient wildly delirious.

9 P.M.—Pulse 160; temperature 101°; respiration 48; passed a small amount of water; delirium continues.

11 P.M.—Pulse 160; respirations 28; temperature 103°; clammy sweat; anxious face; hands cold; headache; abdomen very tympanitic; stimulants and opium continued.

2 A.M.—Noisy, violent delirium continues; ℥ iij. of high-colored urine drawn off.

6 A.M.—Pulse 160 and almost imperceptible; extremities cold; respiration 18.

Died at 8.10 A.M., four days after operation.

Necropsy by Dr Wm H Porter, Curator to the hospital, twelve hours after death. Rigor mortis well pronounced; body well provided with fat; after removal of the sutures from the incision of operation, which extended from umbilicus to os pubis, there was no gaping of the wound.

Pericardium and heart.—The pericardium was normal; there were two small milk patches on the anterior surface of the left ventricle. The pericardial sac contained three ounces of clear straw colored serous fluid, all the heart cavities were nearly empty of blood, though there was a small amount of coagulum in the right auricle. There was slight insufficiency of the bicuspid valve, caused by commencing fatty degeneration, thickening and retraction of the folds of the valve, the other valves were free and normal. Left ventrical slightly hypertrophied; weight of heart thirteen ounces.

Pleura and lungs.—Lungs were a little œdematous; otherwise nothing abnormal was noted. The intestines were free, but enormously distended with gas, the large as well as the small. Just below the splenic flexure, the lumen of the colon was apparently diminished, but the gas and fluid contents could easily be made to pass through the constriction. When the loose connective tissue, binding the colon normally to the posterior wall of the abdomen, was divided, the previous apparent constriction at once disappeared. No other even apparent contraction was noticed until they were laid open; there was no evidence of peritonitis, and the bright, glistening appearance of health was apparent throughout them. There was, however, some very dark spots at two points along the line of the small intestines, but no old fibrinous bands in the peritoneal cavity, and there were no abnormal openings in the mesentery, but it exhibited four or five old stellar cicatrices. All the tributaries of the portal vein were enormously distended with blood, but not over the surface of the intestines, the congestion arising from the mucous instead of the peritoneal surfaces; the inferior vena cava and renal veins were fully distended with blood.

Liver.—The liver was intensely congested, and seemed swollen to its utmost capacity. Weight of liver fifty-six ounces. The liver in this swollen condition may have pressed upon the inferior vena cava, thus causing its distention.

The alimentary tract was removed entire, and the intestines were opened along the margin of their mesenteric attachment. The following condition then presented: the colon contained considerable semi-solid fæcal matter, the small contained only fluid fæcal matter; the mucous surface of the colon was congested, most markedly in the ascending portion; the lumen of the last twelve inches of the ileum was only one half that of the upper portion, the mucous surface of the contracted part was deeply congested and dark in color; Peyer's patches and the solitary follicles were quite prominent, but the zone of congestion terminated abruptly at their margins; the adjoining twelve inches, just above the portion described, was also deeply congested and red in color, contrasting strongly with the darker portions on either side. The abrupt termination of the congestion at the margins of the glands was not so well shown in this portion, the appearance here was that of an acute inflammation. The remainder of the small intestine, from this point to the stomach, was also

deeply congested in its mucous coat. At two places—one seven, the other ten feet from the stomach—the congestion was much more marked, and the color of the intestine, greenish black, as if gangrene was about to set in; the stomach was congested especially at the cardiac and pyloric extremities. The true and false pelvis were carefully examined for abnormal openings, but none were found. The internal abdominal ring on the right side opened into a dilated inguinal canal, lined by a serous membrane, but did not communicate with the scrotum, cicatricial bands having been formed at Poupart's ligament.

Kidneys.—The renal veins were distended with blood, the kidneys enlarged and congested, weighing seven and seven and one-half ounces; capsule slightly adherent; after removal of the capsule the intercapsular surface were finely granular. On microscopical examination, evidence of chronic diffuse nephritis was found; the connective tissue was considerably increased and there was granular and fatty degeneration of the epithelia; the Malpighian bodies were studded with lymphoid corpuscles.

Brain.—Upon removing the calvarium a small quantity of bloody serum escaped; the vessels of the meninges were distended with blood. The pia mater and arachnoid were considerably thickened and gave the membrane an opaque whitish look, as if there was a deposit of lymph over the convexity. On both surfaces of the falx cerebri there were a number of small bony projections, the puncta vasculosa were unusually prominent. The whole brain was deeply congested, and there was a slight amount of bloody serum in the lateral ventricles.

Remarks.—The fact that we had to deal with an intestinal obstruction in this case was manifest from the beginning; that it was moderately acute was also plain, but the usual difficulty was encountered in deciding as to the seat and anatomical cause of the occlusion. Thorough and repeated exploration of the usual sites of hernial protrusions elicited nothing; the more open condition of the right inguinal attracted attention, as it was thought possible that a protrusion might have been reduced with its sac, but examination of its whole length detected nothing, and there was no deep-seated tumor above Poupart's ligament on the corresponding side. In the early stage of the attack, before meteorism masked the condition of things, and when it was possible to make a very complete examination, there was at no time discovered such a tumor as one would expect to meet with in intussusception, and at no time had there been any of the bloody or slimy discharges that always accompany that condition. His age was against the probability of any slowly forming stenosis suddenly closed by the impaction of fæcal or foreign body, and he had not suffered from the alternating constipations and diarrhœas that are met with under such circumstances. The same point was always indicated as the seat of pain, one inch and a half to the right of and below the umbilicus, but in the beginning, deep pressure detected nothing between that point and Poupart's ligament. Exploration of the rectum by the finger found nothing, and the same result followed the introduction of large quantities of water under chloroform narcosis, and in the inverted position this was done with a view to determine the location of the occlusion, as it was an important therapeutic element to know whether it was in the small or large intestine. If in the latter the injection might possibly soften down or remove a fæcal mass, or release a twist in the sigmoid flexure, and it being now known by experiments on the living that such agents may pass the ileocæcal valve when the patient is narcotized and inverted, it being also known that paralysis of the hyper-extended gut by changes in the muscular fibre adjacent to inflammatory processes in the mucosa, or through influences reflected from the peripheral branches of the splanchnic might produce the same effect upon the valve and permit the introduction of water into the small intestine; but by this means all we were able to determine was that the colon was probably free.

That the obstruction was not high up was probable from the fact that anuria did not exist; the amount secreted by the kidneys was diminished, it is true, but it was not by any means entirely suppressed. By some it is understood that anuria only exists when the obstruction is in the beginning of the ileum or jejunum, but it is now well known that the condition is as much influenced by the acuteness of the attack, as by the position of the obstruction. Another symptom that warranted the belief that the trouble was in the small intestine, was the meteorism which in the earlier part of the attack was confined to the meso- and hypogastrium, and on the 29th was markedly prominent at that part where he had always located the pain. These considerations, in the absence of anything definite, warranted the supposition that the obstruction was near the termination of the ileum, and that it was caused by diverticle, band, twisting, or internal hernia.

Recovery from such a condition being so exceptional as scarcely to be worthy of consideration, the propriety of an operation was debated, and it was unanimously agreed that the interests of the patient called for immediate interference. The special operation likely to succeed was next discussed, and three methods presented themselves as likely to meet the wants of the case.

The first—exploration of the right inguinal canal, which was rejected because frequent search had failed to find any tumor in the immediate vicinity of the crural arch.

The second—laparo-ileotomy, or Nelaton's section, made immediately above the right Poupart's ligament, without reference to or search for the obstruction, but simply with the view of securing the first presenting loop, and securing it to the wound in the abdominal walls, condemning the patient to an artificial anus for life.

The third—laparotomy by median section, which was selected as affording more room to search for and act upon the obstruction, whatever its character or condition might be.

It was surprising with what ease the obstruction was found, after a few moments' search, the finger came directly in contact with, and its point could be insinuated into an aperture which appeared to be situate in the centre of the iliac fossa, and the first impression was that it was a hernia iliaco-subfascialis, or into one of the recesses sometimes found in the neighborhood of the cæcum or appendix. It was only when the intestine was released that it was found that the pouch could be pushed downward into the inguinal canal, which it is presumed should be regarded as evidence that it was the variety known as "Hernia Retroperitoneal is" (Klebs).

Typhus Fever, as well as diphtheria, is scourging Russia. In St. Petersburg nearly a hundred deaths per week have been reported from the former disease.

ON THE RELATIONS OF NERVE AND MUSCLE.

By THOMAS W. POOLE, M.D.,

[illegible]

(Continued from page 14.)

The following are additional facts and considerations in support of the thesis that the true function of nerve-force is to restrain muscular contractile power, not to stimulate it.

Objection has already been taken to the assumption necessitated by the theory of the day, that in dyspnœa and asphyxia impure venous blood is to be regarded as superior to normal arterial blood as a pabulum for the generation of nerve-force in the respiratory centre. On the theory advocated in these pages, the more rapid breathing of the first stages of slow asphyxia is no more indicative of increased power than is the rapid pulsations of the heart in conditions of lowered vitality; while as this process deepens, or in the more rapid asphyxia of tracheal occlusion, the respiratory centre becomes so enfeebled that a prolonged interval is necessary between each exertion of its power before it has again acquired sufficient nerve-force to relax the contracting muscles and effect another effort at inspiration; such intervals of repose and recuperation becoming longer and the nervous discharges feebler, and the consequent restraint over the muscles less effectual, in proportion to the increasingly defective arterialization of the blood, till ere long the power of the nervous centres is extinct and respiration ceases with it. Thus the spasms and convulsions which attend fatal asphyxia (Dr Burdon-Sanderson), and which affect not only the muscles of respiration, but the muscles of a wide area of the body, and which intensify as death approaches, are due, as in other cases, to a deprivation and not to an excess of nerve-power. Let the reader say whether such a view of the case is not more in accordance with sound physiology than the one already quoted, in which pure arterial blood is declared to be less effectual than impure venous blood in promoting the functional activity of the nervous centres.

The author referred to in this connection in the previous article (Dr. Fothergill) is not alone in his estimate of the efficacy of venous blood as a "stimulus" in the production of muscular contraction. Dr. Carpenter propounds the same view, and in illustration of it quotes the following experiment of Dr. Brown-Séquard. In a pregnant rabbit "the injection of venous blood into the uterine vessels" immediately "caused the expulsion of two or three fœtuses." ("Phys.," 7th ed., p. 762.)

There is here no proof that venous blood is a stimulant to nerve-action. Such is assumed to be the case merely because it serves to offer an explanation of the effect produced. But any other hypothesis which will equally explain the situation is as much entitled to consideration. Is it not quite as rational to hold that by the substitution of venous for arterial blood, nerve-action in the ganglia and nuclei of the uterine walls was arrested, and the uterine muscle thus deprived of its normal nervous restraint, exerted its inherent power of contraction accordingly, with the effects mentioned, just as a dose of ergot might also be expected to do, and in a similar manner? The restoration of arterial blood put an end to the nerve paralysis, and with this to the uterine contraction. Our explanation has the advantage of being consistent with other facts regarding muscular contraction; while the other view of the case, besides failing in this respect, has the disadvantage that neither venous blood nor ergot of rye can properly be regarded as physiological stimuli to nerve-tissue.

This simplified theory of vascular control enables us to dispense with the complicated and confusing vaso-motor theory of the day, in which "inhibitory," "accelerating," "depressor," "constricting," "dilating," and other systems of nerves, with their hypothetical centres have been invented to meet the exigencies of the theory of the day. What a frightful waste of force is implied in opposing systems of nerves, checking and counter-checking each other, and playing at cross purposes in every part of the organism! Already the axe has been laid to the root of this tree, and it has been frankly admitted that, so far as the so-called "accelerators" and "depressor" are concerned, they exert no direct influence over the heart at all, and only influence it indirectly, like ordinary vaso-motor nerves, through "the peripheral circulation." (See Prof. Kuss's "Lec. on Phys.," p. 167; Dr Burdon Sanderson's "Handbook," etc., p. 286.)

This theory explains how, in the hands of the surgeon, the twisting of an artery arrests hemorrhage. This little operation effectually breaks up and destroys the vaso-motor nerve connections with the muscle without too much injuring the muscular fibres themselves. The nervous restraint over arterial contraction is thus removed, and the contractile power of the arterial muscle occludes its calibre. It has been specially advised to avoid "twisting the vessel till the end is twisted off, for by so doing we do away with the chief safeguard against bleeding." (Dr. Bryant: "Guy's Hospital Med.-Chir. Trans.," 1868, p. 193.) The reason is now obvious why the integrity of the muscular tissue should be spared, while destroying its more delicate nervous connections.

The arrest of hemorrhage by water, not simply warm, but *hot*, admits of a similar explanation. If a frog be placed in water at a temperature of 42° C., or 107½° F., it dies with its muscles in a state of rigidity. If the hot water here acts as a "stimulus" to the nervous system, thereby increasing its functional activity, *why does the frog die?* Is it not preferable to hold that in the arrest of hemorrhage from a bleeding vessel the hot water paralyzes the vaso-motor nerves of the part, and, in the case of the frog, that it paralyzes the motor nerves generally, in both cases causing muscular contraction by withdrawing nervous restraint?

This theory accounts for the cure of congestive and inflammatory states by drugs which paralyze or lower the activity of the vaso-motor nerves. The *dilating* power of these being thus reduced, the contractile power of the arterial muscle predominates, and a reduction of the arterial calibre follows with its accessory results. A wide field is here opened up which, if properly improved, would place our therapeutics upon a greatly improved basis.

Even the *quasi* stimulant action of digitalis in relaxed states of the vascular system, finds its explanation here, consistently with the general paralyzing character of that drug. By reducing nervous dilating power over the heart and the larger arterial trunks, the contractile power of these, no longer unduly restrained, asserts itself more vigorously. A reduction in the calibre of the flabby blood-channels causes an acceleration of the blood-stream (increasing nutritive changes in the heart itself), and if the effect produced does not proceed too far, circulatory

activity is materially improved. Remember that Dr. Stillé denies that digitalis gives "a real increase of power to the heart" ("Nat. Dis.," p. 504), and Dr. Ringer combats the tonic theory of the action of digitalis on this organ. The above explanation is therefore submitted with the greater confidence.

The action of strychnia, when properly understood, will not be found adverse to this theory. Dr. Anstie well points out that it has been too hastily classed as a spinal stimulant, in deference to prevailing notions rather than on any basis of facts; and further, that, notwithstanding the appearances of excitement, the action of strychnia is attended by a loss of common sensibility, and he concludes that whatever thus impairs innervation must be a paralyzing agent (Stim and Narcot). Dr. Harley teaches that it reduces the blood to the character of venous blood, which Dr. Radcliffe claims to be a condition equal to the loss of blood. It is significant that profound motor paralyzers like calabar bean and conium have been discarded as antidotes to strychnia-poisoning, and that for this purpose stimulants, as whiskey, are rapidly coming to the front as the best antidotes. (See *Amer. Jour. of Med. Sciences*, Oct., 1879, p. 587; *Canadian Jour. of Med. Science*, Jan., 1880, p. 15.) Even the most reputable antidote to strychnia-poisoning at present—hydrate of chloral—need not necessarily be regarded as a depressant when thus used, for has not Dr. W. A. Hammond declared that it is a dangerous remedy in "maniacal excitement," and that "its first effect is always to augment cerebral congestion" ("Dis. of Nerv. Syst.," p. 383.) May it not produce a stimulant effect under the exceptional circumstances of strychnia-poisoning, even in large doses, just as "the ordinary *stimulant* effect of small doses of alcohol and opium may be produced in cases of acute exhaustion of the nervous system, by doses of these drugs, which, under other conditions, would be *narcotic* in their action?" (Drs. Anstie, Stim, and Narcot, p. 213.)

It would be interesting to note the varying conditions of the iris and pupil resulting from disease or drug action in the light of this theory. That the iris is an erectile tissue, and that the size of the pupillary opening is dependent upon the fulness or emptiness of the blood-vessels of that tissue is an opinion rapidly winning its way among leading writers and authors. Dr. Anstie and Dr. Radcliffe strongly support it, and Dr. Alfred Stillé, in the National Dispensatory, practically concedes it (p. 1017). The simplified theory of vaso-motor control here advocated, will be found admirably in accord with pupillary changes as produced by the fulness or emptiness of the iridal vessels, with which the vascular condition of the brain usually corresponds.

The theory here advocated tallies with the true nature of electricity as a paralyzing agent, in virtue of which it sets the muscles free to contract. It acts on the arteries like other paralyzers in reducing their calibre—an effect never attending the action of a stimulant, and, in addition, like a true ally of death, it materially hastens the onset of rigor mortis.

It explains the onset of "early rigidity" from a *paralyzing* lesion of the brain, depriving the muscles promptly of their customary nervous restraint. This result cannot be due to any hypothetical "irritation" of the brain, since Dr. Ferrier maintains that even cauterization with a red-hot iron is not a source of irritation to the insusceptible tissue of the cerebral lobes.

It also accounts for the occurrence of "late rigidity" by the slower and secondary *degeneration of tissue* in the spinal cord—a condition which it is impossible to suppose favorable to increased elaboration of nerve-force wherewith to stimulate the muscles, as the theory of the day requires.

The truth of the theory here advocated finds a strong confirmation in the description given by Dr. J. Thompson Dickson, A.M., M.D., in his "Medicine in Relation to the Mind," of the "wasting and atrophy" of the brain, which forms one of "the most common conditions" in cases of insanity and general or progressive paralysis, where this condition is regarded in the light of the following extract, quoted by Dr. Dickson from the *Journal of Mental Science* for July, 1869:

"Drs. Ponicasè and Henri Bennett state: 'In general paralysis the cells of the whole chain of the great sympathetic are covered with brown pigment to a degree much more intense than in other subjects from whatever disease they may have suffered. In the ganglia of the cervical region, and often in the ganglia of the thoracic, there is evidently a substitution of cellular tissue and of adipose cells for the nerve-cells, which are comparatively rare. . . . Everything leads us to think that this is the anatomical starting-point of the affection, and that the alterations of the encephalon are the mere consequences of the disorder which this sclerosis, by a *paralyzing action* of the cervical ganglia, produces in the cerebral circulation" (pp. 280–281).

On the theory now popular, diminished blood-supply to the brain, with "atrophy, shrinking, and degeneration of tissue" as its consequences, could only be produced by undue excitation of the vaso-motor nerves, arising in turn from an excessive production of nerve-force in the sympathetic centres. But here is the anatomical and physiological proof that these centres are the victims of sclerosis, that owing to substitutive changes the proper nerve-cells "are comparatively rare," and that paralysis and not excitation is the term expressive of their functional state. On the theory here advocated, this paralysis, with its accompanying failure of vaso-motor nerve-power, is precisely the condition most favorable for bringing about contraction of the cerebral arteries, and thus starving the brain tissue into a state of atrophy and degeneration, which theory is most deserving acceptance and endorsation.

The arguments against the theory of the day on the relations of nerve and muscle, and in favor of the theory here presented, are by no means exhausted in what has here been written. But the case is submitted to the reader for candid consideration. If in his unbiassed judgment the theory here advocated is not justified, or "not proven," we ask him to remember how difficult it is at the outset to forlify every point, and to recall how very little in medical, or even in physical science outside of mathematics, demonstrations can be regarded as positively proven. If the facts above cited have any value, then the prevalent theory on this subject is not only not proven, but untenable; and if we must have some theory on the subject, as is certainly the case, then that theory is best which most nearly accords with the great majority of the facts, and best serves to elucidate them. Such, I firmly believe, is the theory here presented—the theory of the future, when the mists of prejudice shall have cleared away, and a great truth finds abler advocates.

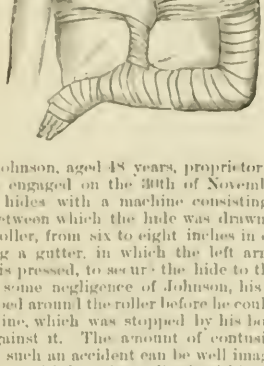
Surgeon-General Cahill, of the British service, has been visiting this city.

A CASE OF A COMPOUND AND COMMINUTED FRACTURE OF THE ARM AND FOREARM

By JAMES S. GREEN, M.D.,

PLAINFIELD, N. J.

This case is reported as remarkable for the number of fractures occurring in same limb: three in the forearm, two of which were compound, and two in the arm, one which was a fracture near the surgical neck of the humerus: the recovery being perfect, following complete envelopment of the limb in a plaster-of-Paris bandage, applied within two hours after the injury, supplemented on the sixth day with Stillman's cable splint to secure the fracture at the neck of the humerus.



John Johnson, aged 48 years, proprietor of a tannery, was engaged on the 30th of November, 1879, splitting hides with a machine consisting of two knives, between which the hide was drawn by a revolving roller, from six to eight inches in diameter, containing a gutter, in which the left arm of the operator is pressed, to secure the hide to the roller. Through some negligence of Johnson, his left arm was wrapped around the roller before he could reverse the machine, which was stopped by his body being drawn against it. The amount of contusion occasioned by such an accident can be well imagined. I saw Johnson with Dr. Alonzo Pettit within two hours of the accident; found him suffering considerably from shock, in great agony, and pretty freely stimulated with alcohol. Upon removing the clothing, we discovered that the left upper extremity was fractured in five places. The ulna, about three inches above the styloid process, had a compound fracture, and also was broken within two inches and a half of the olecranon. The radius suffered a compound fracture at a point nearly opposite a similar one of the ulna. The humerus was broken at the junction of the lower and middle third, and also at the surgical neck. The skin was not broken, except at the points of compound fracture, from which a small quantity of blood was discharged. The hand was warm, and the pulses in the brachial, radial, and ulnar arteries were good. Having placed the legs of two stockings upon the arm and forearm, the whole limb was enveloped in a plaster-of-Paris bandage, from the fingers to the shoulder, the arm and forearm being kept in a straight line, so that the circulation should not be interfered with by the flexion of the elbow. Windows were then cut out of the splint at the points opposite the compound fractures, and the wounds dressed with picked oakum and Peruvian balsam, and the whole supported by a bandage. The patient was then put to bed, and his arm drawn down by his side, as it was found impossible to keep the fracture at the surgical neck in opposition in any other way, while the line of the arm and forearm was straight. A full dose of morphia was given.

Dec. 1st.—The patient passed a comfortable night, after a second dose of morphia. The fingers are warm, sensation is good. The wounds of the skin at the points of compound fracture look well, except that at the edge of the windows small blebs filled with yellow serum have appeared. The fenestra were enlarged until the pressure was relieved.

Dec. 3d.—Johnson has considerable traumatic fever; pulse, 120; temperature, 101. The limb, however, is not painful, and the bulbs have not refilled. Hand is sensitive and warm.

Dec. 4th.—Patient's fever less. Wounds looking well.

Dec. 6th.—The skin of the hand and that to be seen around the wounds of the compound fractures being healthy in appearance, it was determined, in consultation with Dr. Pettit, to flex the elbow and secure the fracture at the surgical neck. A large ovoid piece was cut out of the splint in front of the elbow, extending by its points nearly to the olecranon. The forearm was flexed nearly to a right angle, and the skin being protected by cotton, a plaster bandage was placed around the elbow to secure it. The patient being clothed with a tight-fitting knit shirt, "the cable splint" (devised by Charles F. Stillman, M.D., of Plainfield, N. J., and published in the MEDICAL RECORD of October 20, 1877) was applied. On the second day after the last dressing the patient was able to be about his tannery. No further attention was required, except dressing the wounds of the compound fractures, which were healed perfectly at the second week.

Jan. 10, 1880.—The splints were removed, and all the fractures were found united without deformity. The wrist, elbow, and shoulder-joints in good condition.

March 1st.—Patient has perfect use of his arm, and, with the exception of occasional traumatic rheumatism, is as well as he ever was.

This case demonstrates the great value of the "cable splint" in fractures near the shoulder-joint, and the propriety of *immediate immovable dressings properly applied* in fractures involving joints, or in those where a large amount of swelling and inflammation will naturally occur as the result of injury, if *the circulation* of the *part* is not properly *controlled* by *pressure*. In a future paper I propose more fully to discuss the last statement, and illustrate it by a number of successful cases in which "*swelling*" was not "*wanted for*."

OVARIOTOMY BY A TRAVELLING QUACK.—*The Cincinnati Lancet and Clinic* reports a case of ovariotomy in which no ovarian tumor was found. The patient, aged fifty five, had been suffering from abdominal enlargement for some time. Several physicians pronounced it an ovarian tumor, among them an itinerant doctor who pretended to have come from New York. He advised an operation, and the patient consented. Upon making an incision, the operator discovered that there was no ovarian tumor at all, but that the enlargement was due to deposits of adipose tissue in the abdominal wall. The wound was sewed up, but the patient died in three days.

Reports of Hospitals.

CHARITY HOSPITAL.

Notes of Practice and Peculiarities of Treatment.

Reported by Dr. Walter B. Johnson, House-Surgeon.

CAPILLARY INSUFFICIENCY WITH MITRAL AND AORTIC OBSTRUCTIVE MURMURS.

J. H —, æt. 22, printer. Patient is tall, thin, and anæmic; has at all times a dull, heavy expression. He came to Charity Hospital about two months ago (on service of Thos. H. Allen, M.D.), complaining of swelling of the lower extremities, with pain, redness, and heat.

Family History.—Indefinite. The family are all dead. Cause unknown.

Previous History.—The patient's recollections of his early childhood are indistinct. He suffered at one time with sore mouth, and at another with sore eyes—probably catarrhal conjunctivitis. He has been a steady drinker, principally of whiskey. Would drink some each day, before and after meals, and get drunk about once a week. Has indulged in excess of venery, and frequently exposed himself carelessly, but denies all venereal history, specific and non-specific.

Has used a great deal of tobacco, both chewing and smoking. He does not remember of having been ill at all until he was eighteen years of age. Patient then suffered from malarial fever, which lasted about three weeks, and was probably remittent in character.

During the attack he had intense headaches, the pain being situated in the anterior portion of the cranium, and these continued, at intervals of two or three days, for some time. Six months after that, from exposure to cold and wet, he had an attack of rheumatism, which lasted about seven weeks, and confined him to bed three weeks of that time. This affected only his lower extremities, which were red, swollen, and painful, particularly on motion. He had at this time considerable fever. About a day or so after the rheumatism came on he noticed a rash, which appeared first on the ankles, and spread over his lower and upper extremities (the rash will be described in the history of his present attack).

The rash lasted about one month after he was entirely cured of rheumatism. During the three weeks he was confined to bed the rash disappeared, but immediately showed itself on his getting up. During this attack he suffered from cough, dyspnœa, pectoral pain, and after recovery he noticed that he was troubled by palpitation, dyspnœa, and præcordial pain, especially on exertion. About four months subsequently, the heart trouble became much ameliorated, and remained so until about three months ago, when, with his present attack, it returned with renewed vigor. He has not been troubled by much œdema of the feet, although it has always been present when the eruption first appeared, and also at times after standing for a long time in one position in cold or damp weather. His feet and hands are often cold and blue, and at those times painful.

Present History.—About four months ago—after a drunk and exposure, his clothes being wet through—he had a severe cold, and a few days after this he commenced to suffer from pains in his feet, which were rapidly followed by heat, redness, and swelling of the parts, and the appearance of a peculiar rash.

This eruption is macular in character, unattended by pruritus, the spots varying from the size of a millet-seed to that of a pea. These appear very suddenly, are bright red in color, irregular in shape, and do not disappear on pressure; and they are always brighter in the evening, if patient has been up during the day, also on exertion, or on rising after spending a few days in bed. On disappearing, they leave a copper-colored pigmentation, which remains for some time before absorption takes place.

The rash is confined mostly to his upper and lower extremities—on the lower especially—being very closely aggregated, so as to appear confluent in some places, on superficial examination. He also has a few scattered spots on his body, none on his head and neck.

Shortly after the rash appeared he had an ulcer on his left leg (lower third, outer side), which appeared as a pimple, and spread to about the size of a two-cent piece; also, a small ulcer on upper third, inner side, of the same leg. The former proved to be very indolent, and not amenable to treatment, and was only healed after his general health was improved. He has complained, during the entire attack, of a dry cough, attended by dyspnœa, palpitation, and præcordial pain. The rheumatic symptoms above described, lasted, with more or less severity, for about three months, and on his recovery the rash was still present. He had been treated with:

Tr. digital.	ʒ i.
Tr. aconit.	♏ xij.
Syrup	℥ i.
Aquæ	ad. ℥ ij.

M. et sig. ʒ i., t. i. d., increased to ʒ iij. doses.

Under this treatment, and a rheumatic mixture, the patient being in bed, the rash disappeared in about three weeks, when its brightness had gone, and only the pigmentation remained. The rheumatism being cured, he was allowed to get up and walk around the ward, and in three hours the rash had reappeared in its brightest hue.

Patient was permitted to remain, and was put on ♏ xxx. doses of the muriated tr. iron, and ʒ ss. doses of ol. morrhuæ. His strength increased daily. His bowels, which had been costive, became regular, and he recovered his appetite.

Present Condition.—Patient's general health is much improved. His rheumatism troubles him only slightly on damp days. Appetite is good, bowels regular. His heart symptoms are also much relieved. The rash now consists of pigment stains, and a few scattered spots, which become bright red by evening, and then gradually disappear. Patient is going to work, and will probably not be seen again.

Physical Examination.—Lungs negative.

Heart Inspection.—Slightly diffused impulse.

Palpation.—Apex-beat displaced downward and to the right about one and a half inches. A slight purring tremor is felt.

Percussion.—Area of heart, dulness increased, except on the left side.

Auscultation.—A loud, blowing murmur is heard with most distinctness at apex, and is presystolic; also a murmur with the second sound of the heart with most distinctness at the base, and transmitted up carotids and heard over vertebral column.

The eruption above described was thought to be due to insufficient capillary integrity, which had some connection with the heart lesion.

Progress of Medical Science.

Danger of Salicylic Acid in Rheumatism.—Dr Mackenzie makes the following statements: 1. In acute rheumatism the heart is apt to be inflamed. In a mild form this is much more common than is usually supposed. Myocarditis may exist independently of inflammation of the membranes. In all forms it produces softening and weakness of the muscular substance. 2. Salicylic acid, no matter whether given alone or in combination with soda, exercises a depressing action on the heart. This action is by no means general, and is probably due to some idiosyncrasy of the affected individuals. 3. If this depressing action be produced in one in whom the heart is physically sound, no great harm will be done. With the omission of the drug the depression will soon pass off. But if it be produced in one who is already the subject of rheumatic myocarditis (an ailment which is not easily recognized during life), and in whom therefore there exist softening and enfeeblement of the ventricular walls (for the left ventricle is the chief seat of such inflammation), the depression is likely to be alarming, and may be fatal.

To form an adequate estimate of the nature and extent of the dangers attendant on the administration of salicylic acid in acute rheumatism, we must recognize—first, the tendency of the rheumatic poison to produce inflammatory softening and weakness of the muscles of the heart; and, secondly, the tendency of salicylic acid to depress that organ. It is in the combination of these two that lies the danger of the drug. It is in the absence of the tendency to produce such depression that lies the superiority of salicin over salicylic acid.—*The Lancet*, Feb. 28, 1880.

Case of Adeno-carcinoma Nasi et Cerebri.—At a post-mortem, Prof. Axel Key found besides hyperæmia of the cranium and dura mater, together with hyperostoses on the interior surface of the skull, the entire upper lamella of the ethmoid bone perforated and in great part destroyed by a tumor which extended on the left side into the nasal cavity. The tumor had also implicated the dura and extended into the cerebral substance, forming a nodule larger than a walnut in the anterior portion of the left frontal lobe. On transverse section no demarcation was perceived between the dura mater, pia mater, and cerebral tumor. The latter consisted of an external, firm, grayish gelatinous layer, within which was a reddish gray, semi-solid tissue with closely approximated injected vessels. Caseous foci and abscesses were disseminated through this tissue. The cerebral substance was softened around the tumor.

The correctness of the diagnosis of cerebral syphilis, made in the clinic, seemed to be shown by the pachymeningitis externa with hypertrophy of the internal table found at the abduction; and the tumor might possibly have been a gummous new formation which originated in the nose, and which later extended to the cerebral membranes and the brain. The microscopical examination showed, however, that an entirely different condition existed. Throughout the cerebral tumor there were found the prettiest glandular tubes with cylindrical epithelia and open lumina, together with numerous transitions to the carcinomatous types with cell-filled alveoli and solid cell-knobs. The new formation in the nose showed only a cancerous structure. It was therefore almost certain that this new formation, which is so rare as far as the nose is concerned, had its origin in the nasal mucous membrane, that it commenced there as an adenoma, which afterward became a carcinoma and as an adeno-carcinoma broke through into the cerebral cavity.—*Hygiea & Norsk. Med. Arkiv*, Bd. II., No. 16.

Red Perspirations of the Axilla.—At a meeting of the Swedish Medical Society, Prof. Axel Key reported the case of a colleague who had for some time noticed that the hairs in his axilla adhered together, and that this was occasioned by a sticky substance covering the hairs. The perspiration from the axilla stained the shirt red, but occasioned no other inconvenience.

On close examination, Key found the hairs roughened and sticking together, and many of them were covered with a yellowish coating resembling honey. The latter was situated on the free ends of the hairs and formed partly isolated or confluent intumescences, partly rosary, chain-like globules, or a coherent mass surrounding the hair. There were no changes in the skin. The microscopic examination showed that this condition depended on a peculiar fungous vegetation which by transmitted light had an amber yellow color. At its commencement the vegetation appeared as small, thin, glistening lamellæ, of a pale yellow hue, which soon formed small globular elevations of homogeneous appearance in the main, but with numerous embedded small glittering spores. The flakes seemed to be in part on the surface of the hair, in part and predominently the vegetation pressed in between the outer layers of the epidermic plates of the hair, giving the latter a roughened appearance. Again and again the vegetation could be followed as far as the medulla of the hair. No mycelium was discovered. No mention of a similar case could be found in special literature. Buhl, alone, describes, in *Zeitschr. f. rat. Medicin*, Ser. 3, Bd. 16, S. 357, 1863, a new hair fungus which appears to resemble that described above, and which he calls zoogloea capillorum. Hence, it would seem, that this fungous formation is extremely rare.—*Hygiea & Norduskt Medicinskt Arkiv.*, vol. ii., No. 16.

A Cataractous Family.—O. M. Giersing reports the statistics of a peasant family in which cataract was hereditary to an extreme degree. Of twenty-six individuals in five descents there were only six who had not yet had cataract, and of these six two were still small children. The cataracts appeared under many different forms, and some were congenital. In six of the cases the cataracts were removed by operation, and in four of these good sight was obtained.—*Ugeskrift for Læger & Nord. Med. Arkiv.*, Bd. II., No. 16.

Bromide of Potassium as a Local Anæsthetic for the Urinary and Sexual Apparatus.—It has long been known that bromide of potash, locally applied, diminishes the sensibility of the throat and larynx. Dr. J. Kijanizyn (*St. Peters. med. Wochenschr.*, No. 51, 1879) has also found this remedy useful for its local effects on the urinary and sexual apparatus. He injects a solution of the salt into the urethra, when the latter is the seat of painful, acute, or chronic inflammation, in strictures, and in cases of frequent pollutions. He presents cases showing the good results of the remedy.

In urethritis, the pain, redness, and tumefaction of the mucous membrane decreased rapidly, the dis-

charge diminished, and soon disappeared completely with the aid of mild astringents. In a case of stricture, with chronic urethritis and painful micturition, where the urethra was extremely sensitive, and the severe pain prevented the introduction of bougies, in spite of the use of cannabis indica and belladonna salve, a bougie was introduced with scarcely any pain, after the use of bromide of potassium injections for seven days.

Kijanizyu uses 8 grammes of bromide of potassium dissolved in 180 grammes of water. The injection of four grammes is to be made two or three times a day, and the fluid should be retained in the urethra several minutes. From his observations, he draws the conclusion that these injections are of undoubted use in all cases where the indication is to diminish sensibility in the urethra and neck of the bladder; likewise in the treatment of strictures with bougies, in inflammations of the urethra and their complications; in chordee, dysuria, neuroses, etc., and for pollutions depending on peripherical causes. He also recommends the local use of the salt, as indicated in catarrh of the bladder, and of its neck, in increased sensibility of the latter, and for cystic calculi and the like. He considers the effect to be due to the diminished irritation and lessening of the quantity of blood in the inflamed tissue.—*Ugeskrift for Lager*, No. 5, 1880.

Chyluria and Filaria Sanguinis.—Dr. E. Pontoppidon reports (*Hospitals-tidende*, R. 2, Bd. 6) that he has, in the course of a year and a half, seen a score of these cases. The disease was first noticed, as is well known, in 1868 by Wucherer in Bahia. It occurred in both sexes, and at all ages, though not in infants. The duration varied between months and years. Generally no symptom was presented, except that the urine had the appearance of milk, though not constantly; a few hours later the urine might be completely clear; generally, it was most clear in the morning. In one case only, there was retention of short duration; this was caused by fibrinous coagula in the urethra. On extraction with ether, the urine was usually found to contain half to one per cent. (once 1. 3) of fat. Filaria were found in the blood as well as in the urinary deposits.—*Nordiskt Medicinskt Arkiv.*, Bd. 11, No. 26.

Through Drainage in the Treatment of Open Wounds.—Dr. Thomas M. Markoe presents an extended and elaborate article upon this subject in the April number of the *American Journal of Medical Sciences*. He first discusses the Lister treatment of wounds, taking ground directly against Lister's theory, and in part against his practice. Mr. Lister asserts that all the evils, local and general, that result from wounds are caused by the presence of bacteria, which set up inflammatory or destructive action in the wound, and entering the system lead to fever and other constitutional disturbances. Dr. Markoe shows that, while this view has never been practically proved, there are certainly other influences which modify the course of the local affection, as well as the general condition of the patient. Among these are extensive laceration of the parts, overheating or chilling the same, and irritation by foreign substances, all which may so impair the vitality as to make reparative and perhaps even inflammatory action impossible. Furthermore, as regards the constitutional condition, it is certain that such complications as tetanus, convulsions, and neuralgias cannot be caused by bacteric infection.

Having shown that the Lister theory is insufficient, Dr. Markoe proceeds to argue that the practical methods employed by that surgeon may secure their acknowledged good results in another way than by simply destroying bacteria and preventing putrefaction. On this point the belief is asserted that carbolic acid has a special action in allaying inflammation and promoting repair. What this special action is cannot be explained, but it is known that carbolic acid depresses the vital activity of bioplasm.

Referring to the details of Lister's dressing, the writer is of opinion that many of them are unnecessary, and sometimes even actually injurious. They are also cumbersome and expensive. The thick and heavy wrappings will at times retain the secretions, heat the part, and lead to bad results.

On the whole, Dr. Markoe avers the belief that the theory of Lister is insufficient and unproven; and that the good practical results are due to the specific action of carbolic acid, and the surgical cleanliness which the treatment demands.

The mode of treating wounds, which the writer had been employing for ten months in Roosevelt and New York Hospitals, is then described. It consists in passing rubber drainage-tubes into the wound, making counter-openings, when necessary to secure free drainage, and covering the whole with a few layers of carbolized gauze. Carbolized water is then injected through the tubes at first during every two or three hours; after this less frequently. Fifty-two cases are cited illustrating the good results of this treatment. In almost every instance there was but little traumatic fever, the wound was not painful and reparative action soon set in. The treatment seems to be of especial value in compound fractures. Here counter-openings are generally made and plaster-of-Paris bandages with fenestra then applied.

The Typhus Epidemic of 1878 and 1879 in Breslau.—In his report on this outbreak, Dr. Buchwald states that the first case was discovered in February, 1878, and that the epidemic at first seemed destined to assume large proportions. The prison was one of the chief centres of the disease. The number of typhus patients treated at the two principal hospitals of the city was 455, of whom 59, or about 13 per cent., died. The number of cases reported to the police was over 600, but in many of them the diagnoses were probably incorrect. The plague spared no age, but of the children between one and ten years of age attacked, none died, while the disease proved almost invariably fatal to persons over sixty years of age. It was proved, positively, that the epidemic was not autochthonous in Breslau, but that it was brought into the city by travellers. Isolated cases of the disease occurred in every street of the city and its suburbs, but the great propagating centres of it were the lodging-houses patronized by the homeless. These unfortunates were the chief transmitters of the contagium. In some cases the mode of infection could be traced without difficulty. The paper pays a high compliment to the sanitary authorities of the city, for the thorough manner in which they performed the task assigned to them. With regard to the treatment, Dr. Buchwald stated that the salicylate of soda had proved exceedingly valuable; in addition to it, supporting measures and the freest possible ventilation were found most useful.—*Allg. Med. Cent. Zeit.*, No. 4, 1880.

Dr. Wm. Farr has received the order of C.B., the smallest and least useful of orders, so says the *Lancet*.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, May 15, 1880.

SINS WHICH NO CODE CAN REACH.

The adoption of a new code of ethics by the Massachusetts Medical State Society furnishes the occasion for much editorial comment throughout the country. We have been educated to believe that a code of ethics is so essential to our prosperity as a profession, that the opportunity seems to be a good one for congratulation, in that another brilliant page of our history has been written. The man medical, studied from a purely moral point of view, appears to be a dangerous individual when at large and in the ordinary exercise of his calling. From what we can learn he is even more to be feared by the professional brother who calls him in consultation than by the patient who is the occasion of such extra attention. In other word, it seems to be quite necessary that we shall watch each other and be ready with a rule of discipline that shall cover every possible unprofessional act. The trouble is, however, in meeting all the little emergencies. The Massachusetts code is an improvement on that of the American Medical Association, because it is shorter and gives a wider latitude to the interpretation of the spirit of those relations which should exist between honorable professional gentlemen. But like all similar rules they fall so far short of perfection that none but the stupid blunderer is likely to be entangled in their provisions. In any code professedly made for the moral government of any organization there are loop-holes large enough to allow any artful dodger to go in and out before all men with perfect safety against formal discipline. When it is possible to reach such transgressors the profession can rest secure that it has a perfect system of government, and that there is a reasonable protection for the practitioner who attends to his business and believes that every one is as honest as himself.

We would be reflecting upon the high character of the profession as a whole, if we did not assert that the honest men and true are not in the large majority, but there is nevertheless a goodly number who even occupy the chief seats in the synagogue, and who use the code as a phylactery upon a very loosely fitting garment. The former men really need no code to tell them what is right, how to act to their professional brethren, while the latter use it as a plausible covering for the meanest and most underhanded trickery, and are, technically speaking, beyond the reach of ethical accountability. The truly honorable professional physician unconsciously governs his acts according to that higher law which is based upon the golden rule. Practically speaking, a code is as useless to him as would be a set of rules on ordinary politeness for a gentleman. There are many men who have gone on in the good old honest way, in entire ignorance of the code, or at least of its special provisions, and who have done right to their brethren because they could not help it, while there are others who know the code by heart, but who are always ready to quote it as an excuse for acts which every honest man would repudiate. Such are the practitioners, the type of which has been described in the recent letters from Pine Ridge on the Hudson. Even the Boston code cannot reach the one who is always ready "to damn with faint praise" his trusting brother. No set of rules can prevent the so-called successful man from showing his disposition to help a younger brother, especially if the community is told that such help is very necessary. When the old doctor shows a willingness to teach the young and inexperienced practitioner in the presence of the patient, there is a generosity about the proceeding which usually appeals to a sympathizing public. If the younger man loses any business by this means, the public, although they are sorry for his ill luck, generally think that it is a fortunate circumstance for the patients. At least there is nothing in the code that prevents such a conclusion. The young man who has no respect for experience, for age, nor for position is apt to believe that the code, as a whole, only benefits those who dare to transgress its provisions. But there is in reality no law which can punish a practitioner for saying that he has never heard of a worthy brother in his neighborhood; for being surprised that Dr. A. knows anything of chest troubles, that Dr. B. is a gynecologist, that Dr. C. has much experience in the treatment of children's diseases, or that Dr. D. is anything more than an ordinary man. Although this may only show ignorance of well known facts in the profession, yet the public generally takes a different view, not always favorable to the unfortunate unknown. When the consulting physician believes, at a critical juncture in the disease, that it is necessary to substitute chalk mixture for bismuth, or to use any other potent remedy instead of the one being employed, it is of course done for the good of the patient, and in strict accordance with such provisions of the code as tend

to encourage consultations. Any attending practitioner can at once appreciate the danger of losing the family unless due regard is paid to the suggestions of such a consultant. And so it must be so long as the general profession are governed by the mere letter of the law. The accounts given by Drs. Seabury Jones and A. L. Carroll of professional men who are ready and willing by this and similar means to destroy the good name of an associate, find their parallel in the experience of almost every practitioner. It is not that the men who are consulted cannot have a different medical opinion concerning a case, but that they express it either openly or covertly in such a manner as to injure the previous attendant. The shrugging shoulder, the upturned eye, the bland smile, the mild surprise, the ominous and seemingly polite silence show a respect for the code ; at the same time they have a significant effect on the anxious friends of the patient. If the medical attendant is discharged as incompetent, it is of course owing to the ignorance and prejudice of the patient's advisers, rather than to any overt act of the new professional candidate. But when the practitioner tries to explain to himself why these things should be, neither the old nor the new code help him a particle. He is more than ever convinced that there are no laws yet enacted that can make a man honest against his will, no loom, however perfect its workmanship, that can convert the auricle of a pig into a purse of silk.

THE PATHOLOGY OF GRANULAR KIDNEY.

At a recent meeting of the London Pathological Society, Drs. Saundby and Greenfield exhibited a series of microscopical specimens illustrative of this common renal lesion. The views of different authors on the pathology of granular kidney were cited, and an interesting discussion followed. We think the subject is well worthy the attention of American physicians also, and, without attempting a comprehensive analysis of various opinions, we will briefly indicate the present status of our knowledge concerning this form of nephritis.

Most German pathologists agree in regarding the primary lesion as confined to the connective-tissue stroma of the kidney. Accordingly they speak of a *nephritis interstitialis*, and granular kidney represents the second stage of a diffuse chronic hyperplasia of the stroma elements. Hence, all morbid changes in the tubules are secondary, and even the vascular thickening is confined to the adventitia, or connective-tissue coat of the blood-vessels. Active participation of intra-tubular epithelia in the inflammatory process is excluded. Many English pathologists, on the other hand, assert that a chronic desquamative inflammation of the renal epithelium takes place, and that this leads to atrophy of the organ. The kidney is eventually composed of the wasted remains of the uriniferous tubules and hypertrophied blood-vessels. This view of the nature of the lesion is clearly inadequate to account for the presence of well-formed connective tissue in such abundance as it is commonly found. Gull and Sutton affirmed that an interlobular deposit of a hyalin-fibroid material in the kidney takes place. This, they supposed, was followed by atrophy of the intra-tubular epithelia. The vascular thickening was the result of a similar deposit in the inner portion of the external coat. Dr. Saundby attempts to reconcile these opposing views with, as we think, poor success. We have yet to see proliferation of renal epithelia leading to the filling up of the tubules with free nuclei. Moreover, the conversion of such nuclei into spindle cells appears to us extremely doubtful. True, Dr. Hamilton, of Edinburgh, has recently described the mode of development of fibrous tissue from hepatic epithelia, and Dr. Creighton affirmed the transformation of mammary epithelium into connective tissue ; and Dr. Noeggerath, of this city, has also pointed out the possible development of epithelium from non-epithelial tissue. But these isolated observations do not suffice to overthrow Remak's embryological law of the non-convertibility of epithelial into connective-tissue elements, and *vice versa*.

Without wishing to belittle the good work done by the English pathologists, we must freely admit our partiality to the views of the German school on this subject. Still, there is room for more extended investigation, as the discrepant accounts of the lesions of granular kidney abundantly prove. It is to be hoped that our American pathologists will assist in the work of conducting these important and interesting researches to a successful issue ; for it is only through a clear comprehension of its pathological anatomy that we can ever hope to arrive at a right understanding of this disease.

A CRISIS IN NURSING.

For some time past our English brethren have been much exercised over certain disagreements at Guy's Hospital. A new matron was appointed there last winter, and she at once undertook to reorganize the nursing system, introducing new nurses and arranging matters generally after the fashion of the modern training-school. We gave at the time some of the details of this revolution, and referred to the strong opposition which it excited among the medical staff. As the facts appeared to us at the time, a great part of the complaints made was quite uncalled for, and, on the whole, there seemed to be as much conservatism and unreasonableness among the doctors as there was arrogance and radicalism with the executive of the hospital. Letters were written to the various medical journals, claiming that the old nurses were quite as good as those who had been educated and had received a careful training. The

change from black dress to gray appeared to be an outrage, and the transferring of nurses from one ward to another, and the increased authority of the matron, were equally objectionable.

The conflict has steadily continued up to the present time, neither party yielding, but the doctors having much more to say through the medium of the medical journals. In a recent number of *The Nineteenth Century*, however, one of the pupils of the matron appears for the other side in an article entitled "The Present Crisis at Guy's Hospital." Taking this as her text, the authoress proceeds to discuss systems of nursing in general, and draws up a very severe indictment both against the old-fashioned hospital nurse, the hospital doctors who employed her, and the medical students whom she assisted. The whole spirit of her description is exaggerated, and often does great injustice to the persons she discusses. But there is enough of truth in it to confirm us in our original view that the nursing at Guy's Hospital was far from what it should be, and that those attempting reform were not altogether in the wrong, although perhaps carrying out their plans with too much absoluteness and too little deference to the opinions of the medical staff.

The writer in *The Nineteenth Century* asserts that the nurse of the old school was, as a rule, a person of unsatisfactory moral character and very bibulous habits; she was drawn from the class to which the domestic charwoman belongs, and began often as a scrubber or ward-maid. She was overworked, underpaid, and irregularly fed. She often neglected her orders, and, when a night-nurse, was especially apt to be found sleeping at her post, perhaps with a whiskey-bottle in her arms. These nurses, to be sure, did at times show a measure of intelligence, and even became quite skilful in the discharge of their particular duties. The doctors, we are told, tolerated this class of women, and now resent their withdrawal, because such nurses countenanced certain experimenting upon the patients, and allowed, without protest, the intrusion of medical students into the wards. These medical students, "who are proverbially uncouth," seemed to consider that they had a sacred right to enter the wards where and when they pleased, to go behind the screens, to order about the nurses, and to create confusion and "messes" for those unfortunates to clean up. In fact, the patients of Guy's Hospital, at least, seem to have been gotten there for the doctors, not the doctors for the patients. It is further intimated that the relations between nurses and house-doctors was not always of the most proper kind.

Such are some of the evils charged against the old system. That there are touches of truth in the charges will be admitted by those who remember how some of our large city hospitals were conducted not many years ago. In regard to the present controversy, there is right and wrong on both sides. It will, we believe, be the unanimous judgment of America, pervaded as it is with the spirit of reform, that training schools for nurses are most desirable institutions, and that trained nurses are infinitely superior to those of old-fashioned style. There has never been anything but encouragement to these schools from the medical profession in this country, and it seems impossible for us to believe that the charge that English physicians oppose them is grossly unjust. With us the relations of the training-schools with the medical staffs of hospitals have been uniformly amicable. The matron of the school is allowed entire authority over the nurses as regards their assignment to wards, their hours of work, study, exercise, dress, and general mode of life. The doctor, on the other hand, has absolute control over them as regards their direct relations to the sick. Obedience to his orders in this direction is strictly and persistently inculcated. If a nurse is unsatisfactory, the doctor has but to report it, and she will be at once removed. Thus, while the matron has proper authority on her side, the physician is supreme on his.

It has not been very difficult to establish a satisfactory system like the above in many American hospitals, and it is not easy to conceive how so much trouble has arisen at Guy's. We must conclude that there is in the affair quite as much of British slowness and obstinacy as of philanthropic desire for reform or manly defence of inalienable rights.

THE CARTWRIGHT LECTURES.

The establishment of the Cartwright lectureship will be gratifying to the profession of the city, as it must be useful to the profession in general. New York has now obtained a reputation as the medical centre of the country. Its twenty hospitals, with more than that number of dispensaries; its four medical colleges, and fifteen hundred medical students, represent opportunities for medical study and evidences of medical activity that are absolutely unrivalled.

It is desirable that our city should sustain and increase its present reputation, and the establishment of lectureships upon medical science will do much to help this. The Cartwright course ought not long to remain the only one. Indeed, it would be somewhat humiliating to feel that a private citizen of another State, and he not a physician, remained the sole founder of our independent medical lectureships. The Academy of Medicine is rapidly growing in membership and prosperity. The profession will look to that Society to follow the example of the Alumni Association of the College of Physicians and Surgeons.

THE PHARMACOPŒIAL CONVENTION.

The Pharmacopœial Convention held in Washington was in every way a success. It was thoroughly rep-

resentative in character, was perfectly harmonious in its deliberations, and the results of its labors will be hailed with satisfaction by all interested in the progress of pharmacy and therapeutics. The appointments upon the different committees were eminently judicious, and there is every reason to believe that the necessary work will be thoroughly and promptly done.

Reviews and Notices of Books.

A Text-Book of Physiology. By M. Foster, M.A., M.D., F.R.S., Prælector in Physiology, and Fellow of Trinity College, Cambridge. With illustrations. Third Edition, Revised. New York: Macmillan & Co. 1880.

The established reputation of this author, and the demand for a third edition of the present work so quickly after the publication of the revised and illustrated second edition, places the text beyond the reasonable reach of the general reviewer. It is a book that leads the reader into the higher walks of physiological study, and its proper place is, really, in the hands of the advanced student in this most pleasing department of scientific observation and research. The most important changes in the third edition are to be found in the section on Muscle and Nerve, which has been rearranged with the hope of rendering a difficult subject easy to be understood. He who begins the study of this section, however, will soon become convinced that the average student will not have an easy task to master or even reach a clear conception of the problems involved in it, although there can be no question that the author has presented us with the simplest and the most intelligent statement yet given. The technique of the author is of the highest order, and he does not in the least compromise it to suit the variable capacity of his readers. All must go up to his standard, or they will get confused in their study. The tendency of the book, therefore, is to enlarge the views of the student in physiology; and this tendency is manifested not only from a purely physiological point of view, but by occasionally leading the reader up to the door which opens into the citadel of consciousness and intelligence, and, for a moment, standing and querying with him as to what is within.

The theory of "motor" centres and "localization of function" is discussed in a concise and pleasing style, and, without committing himself by dogmatic statement, the author carefully analyzes the latest observations of the best observers.

The graphic method, which has raised experimentation to almost the dignity of exact science, pervades the book, and enhances its intrinsic value. Mathematical accuracy, applied to physiological experiments, has already lifted the science to a plane of exactness hitherto unattained, and may yet yield results which shall be revolutionary. The volume contains about 800 pages, is printed in good-sized type, and is well worthy of a place in the library of every medical man who wishes to march in the vanguard of his profession.

Pharmacology and Therapeutics; or, Medicine Past and Present. The Goulstonian Lectures delivered before the Royal College of Physicians in 1877. By T. Lauder Brunton, M.D., F.R.C.P., F.R.S. London: Macmillan & Co. 1880.

This, the latest work from the pen of the well-known author, is so good, that we cannot help regretting it is no better—better and more comprehensive. For it must be admitted, that a small octavo volume, with 196 pages of reading matter in very large print, can scarcely suffice to give the reader a fair idea of either "pharmacology and therapeutics," or "medicine past and present." There is too much title and too little vindication for it. In his preface, the author states that the lectures have been divided into chapters, and some slight additions made to them. With more copious additions, the character of the work might have been greatly improved. The reader is first presented with a short historical résumé of the various methods by which the study of medicine has been pursued in the past. This portion of the book, comprising 94 of the 196 pages of subject matter, clearly proves the author's careful study of such excellent works on the history of therapeutics as Petersen's "Hauptmomente," etc., Curt and Sprengel's comprehensive treatise, and Wunderlich's manual. The remaining chapters form short but pithy essays on somewhat heterogeneous subjects. They treat successively of pharmacological methods, pathology, therapeutics, respiration, digestion, and the action of ferments or enzymes in forming tissues. These chapters are rather arbitrarily selected from the broad domain of scientific medicine, to illustrate the author's peculiar views regarding the subjects treated of. Chapters six and seven contain valuable information concerning the action of cascara bark. The author concludes, from his experimental investigations, that cascara is more powerful and better than digitalis. He thinks it quite possible that "it may succeed in those cases of advanced mitral disease where digitalis fails." At the same time, we are cautioned that the drug may disturb the digestion and cause an unpleasant surprise if carelessly given.

The chapters on respiration and digestion are physiological essays, with occasional allusions to pharmacology and therapeutics. But though by no means peculiarly appropriate to a work purporting to treat of "medicine past and present," they form interesting reading matter, and contain some practical suggestions addressed to the practitioner. In his concluding chapter, Dr. Brunton very aptly observes, that "facts all seem to point to ferments or enzymes as the agents by which the tissues are built up and pulled down in that constant change which continues during life, and the action of drugs upon these enzymes is becoming one of the most interesting questions in pharmacology." The book contains good, though brief descriptions of the mode of action of some few drugs, together with an adequate rationale of the indications for their employment in disease. The historical analytical portion of the work is a creditable compilation, from trustworthy sources.

A Practical Treatise on Nervous Exhaustion (Neurasthenia). By George M. Beard, A.M., M.D., Fellow of the New York Academy of Medicine; of the New York Academy of Science; Member of the American Neurological Association; of the American Medical Association; of the New York Neurological Society, etc., etc. New York: William Wood & Co., 27 Great Jones Street. 1880.

This book contains 193 pages, which are devoted to the description and treatment of a functional ner-

vous disorder that heretofore has not had full recognition by the medical profession. It is doubtless true that, if one hundred physicians were asked consecutively, if they knew what nervous exhaustion is, they would all answer in the affirmative; and, it is equally true that not more than five per cent. of that number can give an intelligent description of the condition, that is, such a description as would impress either the student or the practitioner that they were familiar with its differential diagnosis. To aid in making a differential diagnosis of the affection is one of the objects of the present book. The author has presented his views in five chapters, which embrace a thorough description of the symptoms of neurasthenia, a harmonizing of the complex developments and manifestations of the malady, and indications with reference to its pathology, rationale, prognosis, sequences, treatment, and hygiene. It is a presentation of the author's researches since he gave his first contribution upon the subject to the profession in a paper read in 1868. Skeptical, indeed, have his hearers been, and still skeptical does the larger portion of his audience remain, when they attempt to seize and bring into scientific grouping the functional phenomena of the nervous system, and why? Simply because a confusion of ideas, and the tendency of the partially trained mind everywhere, drives the general practitioner and many specialists either into the unscientific denial of the existence of such symptoms, or to the rejection of what cannot be confirmed by the ears or eyes. Dr. Jewell, of Chicago, the accomplished editor of the *Journal on Nervous Diseases*, touches the keynote in this department of investigation, when he says that, "inference is almost habitually placed at a disadvantage as compared with direct sense, observation, and practical demonstration. But this arises out of wrong conceptions as to its nature and value, as well as an overestimate of the dependence which we may legitimately place on the 'evidences of the senses.'" In other words, the great tendency, conservative, therefore commendable in certain departments, is to ignore what cannot be demonstrated by the aid of such modern appliances as the microscope, the spectroscope, etc., well calculated to supplement the defects of the senses. At the same time, all intelligent observers admit that there are human nervous phenomena which are real, and yet which have not been, and perhaps never will be, explained by any material change within the reach of finite research.

Dr. Beard has gathered a group of symptoms that he believes characterize a condition which he calls *neurasthenia*. In the second chapter of his book these symptoms are given with great precision. Their name is legion. Many of them are sufficiently eminent to be almost worthy of the designation of separate affections. But the reviewer believes that the author has done wisely in retaining them in the group of symptoms, when they appear as the leading features in certain cases, while, in other cases of the parent malady, they may not be present.

The third chapter contains an account of the nature and diagnosis of nervous exhaustion, or neurasthenia. This is, perhaps, the most important chapter in the book. It is here that the reader finds the peculiar features of neurasthenia pointed out, and brought in contrast with those usually recognized as belonging to hypochondriasis and hysteria, the affection with which, of all others, it is probably most likely to be confounded. Hysteria, hypochondriasis, and malaria, form a scapegoat tripod whose legs are sufficiently long to stand astride of a gigantic mass of ignorance, and by the addition of syphilis, a quartet is formed that can sing a most acceptable requiem over any obscure visitation of disease and death. All intelligent practitioners have failed to see the reasoning hypochondriac, or hysteria associated with a well balanced mental organization in other than very exceptional cases. The neurasthenic patient, on the other hand, is cognizant, usually painfully cognizant of the fact that he is bound hand and foot by impressions which his reason teaches him are fallacious, and yet he is held in abject slavery by them. In many cases, happily, reason overcomes the tendency to do the bidding of this would be master, and in the mental conflict overcomes and gives the patient an apparent, only an apparent, victory, and he goes out, or goes across a bridge, or visits a friend, although constantly goaded by his cerebral tormenter. That certainly is neither hypochondriasis nor hysteria.

The fourth chapter contains the author's views regarding prognosis and sequences of neurasthenia, and the fifth contains the treatment and hygiene of the disease.

The book is written in the author's usual lucid style, and exhibits the results of original research in a most interesting department of medicine. No one can successfully deny that new light has been shed upon a class of cases with which every practitioner meets, and which have heretofore been uniformly regarded as "rather obscure." The ultimate result will be—it may be in the far distance—that the author's views will be substantially accepted. They may be modified, they may be elaborated; doubtless they will be, but "that there are aspects of nervous and mental disease in which the patient is fully aware of a certain tendency to mental aberration and to false perception, or to acts of impulsive eccentricity, and yet corrects the tendency by a deliberate process of reasoning," we believe will sooner or later come to be generally admitted.

The medical world owes to Dr. Beard its warmest admiration for the really good work which he has done in this special investigation made in the neutral space between clear physiological and pathological conditions. Every well-trained microscopist knows that one of the difficult things to do in certain cases is to determine where physiological granulation of the renal epithelium ceases, and pathological granulation begins; and yet, the patient who carried such kidneys was a sick man. So it is with regard to the symptoms and phenomena referable to the human nervous system, and any honest labor which will force the portals a little ajar, and give us even a peep into the mysterious chamber, should be received with commendation.

The book presents the well known care and neatness with which its publishers do their work.

STUDENT'S PRIMER ON THE URINE. By J. TRAVIS WHITTAKER, M.D., Glasgow. Small 8vo, pp. 75. Philadelphia: Presley Blakiston. 1880.

THIS little book, designed more especially for the use of hospital physicians and clinical students, in its limited way, is certainly an excellent one. It contains all that is needful and indispensable for ordinary purposes of urine examinations, and, what is better still, it contains nothing but this. The author is also an artist, and deserves credit for the admirable clearness and neatness of most of his copper etchings. Some of the latter are, however, rather deficient in the details of execution. Plate XVI. for example, showing fragments of hair, feathers, various animal

and vegetable fibres, fails to give an adequate idea of the characteristic appearance of these structures, which so frequently puzzle beginners. Of course, this small volume cannot presume to replace the larger standard works on this important subject, but as a student's primer we hasten to welcome its appearance, according it the commendation which it seems to deserve.

ANIMAL VACCINATION. A Preliminary Report on an Investigation of the Results of Vaccination from the Calf. By ERNEST HART, Esq. With a report of the proceedings of the conference. London: Office of British Medical Association. 1880.

THIS Report was first published in *The British Medical Journal*, and has already been noticed to some extent in these columns. It represents the results of a very conscientious and exhaustive investigation on the part of Mr. Hart, who, as Chairman of the Parliamentary Bills Committee of the British Medical Association, did most of the work. The whole report, with its accompanying discussion, however, shows that the profession in England are entirely behind us in America as regards the subject of animal vaccination. We have learned its usefulness and superiority, mastered its difficulties and adopted it practically in this and many other large cities. The present report gives a great deal of interesting information as regards the mode and prevalence of vaccination in various parts of the world, and its conclusions, favoring animal vaccination, are correct as far as they go, and in accordance with our views and practices. More practical points, however, can be gained from reading the circular on vaccination of the New York Health Board than from a laborious study of the report before us. It seems probable that the English Government will introduce animal vaccination, and it will soon learn by actual experience, as we have done, its value, its difficulties, and its limitations.

TRANSACTIONS OF THE WISCONSIN STATE MEDICAL SOCIETY, Milwaukee, June, 1879.

THE superior typographical appearance of this volume prepossesses the reader in its favor, and an examination of its contents does not disappoint one. The papers and discussions are all of much interest, and some show a great deal of study. This is notably the case with the address of the President, Dr. Nicholas Senn, upon Medical Legislation. Dr. Senn treats the subject historically as well as critically, and his work is full of interesting facts. There is a very fully illustrated article, by Dr. J. S. Meachem, upon New and Improved Instruments. A Report upon Diphtheria by Dr. Marston brings out many facts of local and general interest. Dr. J. K. Bartlett gives a full report upon Obstetrics and Gynæcology. The utility of forceps and of chloroform in labor are, to a considerable extent, indorsed. In a paper on the Pathology of Scrofulides and Syphilides, Dr. R. H. Williamson draws the pathological and clinical distinctions between these two affections, with great clearness. There is a very practical article upon New Remedies by Dr. Henry P. Wenzel. Several articles upon Ovariotomy are contributed. The Society elected Dr. J. G. Meachem President, and Dr. J. T. Reeve, of Appleton, Secretary and Treasurer for the ensuing year.

TRANSACTIONS OF THE TENTH ANNUAL SESSION OF THE MEDICAL SOCIETY OF VIRGINIA, at Alexandria, Oct. 21, 22, and 23, 1879.

THE President, Dr. L. S. Joynes, in his opening address, states that the membership of the Society is now 400, which is about one-fourth of the whole number of physicians. He laments this fact in view of the great benefits that medical societies confer when properly supported. Dr. Joynes makes an eloquent defence of the country practitioner, and of the medical profession in general.

The Society has adopted the excellent plan of introducing reports on the progress of medicine in its various branches. These reports make up a large part of the present volume, and add greatly to its value.

Among other papers are that of Dr. H. P. C. Wilson, on Paquelin's thermocautery and the antithermic shield, and that of Dr. J. Marion Sims on the diagnosis of abscess of the liver by symptoms of cerebral hyperemia.

The annual address to the public and profession, by Dr. Oscar Wiley, is a thoughtful and earnest effort.

The officers for 1879–80 are: President, Dr. Henry Latham; Recording Secretary, Dr. Landon B. Edwards, of Richmond; Corresponding Secretary, Dr. Christopher Thompkins, of Richmond; Assistant Recording Secretary, Dr. Charles S. Brittan; Treasurer, Dr. Landon B. Edwards.

PROCEEDINGS OF THE LOUISIANA STATE MEDICAL ASSOCIATION, April 9, 10, and 11, 1879.

THE bulk of the matter contained in this volume is, quite naturally, devoted to the questions of hygiene and yellow fever. The address of Dr. Chaillé upon state medicine is a particularly able piece of work, and ranks far above any similar effort that we have seen for a long time.

A very long and exhaustive article upon the comparative pathology of malarial and yellow fevers is contributed by Dr. Joseph Jones. Other articles, as that of Dr. L. T. Salomon, upon leprosy, have already been quoted or discussed in this journal.

The officers elected for the ensuing year were: For President, Dr. J. W. Dupree; seven vice-presidents, a Recording Secretary, Dr. Thomas Layton; a Corresponding Secretary, Dr. S. S. Herrick; Treasurer and Librarian, Dr. Geo. K. Pratt. The Society now numbers 106 members.

SEVENTH ANNUAL REPORT OF THE NEW HAVEN BOARD OF HEALTH. 1879.

THE annual mortality in New Haven from zymotic diseases has been gradually reduced from 394 in 1876 to 163 in 1879. New Haven is now claimed to have the lowest death-rate of any seaport town in the world of its size. These facts are sufficient to show the city board of health is an efficient one.

ON A CASE OF MOLLUSCUM VERRUCOSUM. By JAMES NEVENS HYDE, A.M., M.D. Reprinted from *The Edinburgh Medical Journal*.

DR. HYDE presents the history of this rare and curious form of skin-disease. The diagnosis of its true character involved the settlement of some very nice pathological questions, and led the author into a very exhaustive investigation.

SOME OBSERVATIONS CONCERNING THE VALUE OF THE AUDIPHONE. By H. KNAPP, M.D. Reprinted from the *Archives of Otology*.

DR. KNAPP gives the details of a number of cases in which he has tried the audiphone, and compared it with a dipper shaped ear-trumpet of his own inven-

tion. His conclusions are, that the Rhodes audiphone produced no increase in the acuteness of hearing in 20 per cent., a slight increase in 20 per cent., a moderate increase in 60 per cent. The dipper shaped ear trumpet produced increase of hearing in all cases, slight in 8 per cent., moderate in 45 per cent., great in 48 per cent. The audiphone has some value, therefore, but less than the ear trumpet.

Report of the Resident Physician of the Bingham Hall Hospital for the Insane. 1879.

This report shows a small but evidently well conducted hospital. No statistics are given, however, which enable one to give the results of treatment. The resident physician, Dr. D. B. Burrell, estimates that about one-fifth have reasonable prospects of recovery.

Eleventh Annual Report of the Willard Asylum for the Insane. 1879.

The Willard Asylum is the largest institution for the insane in the country. It contains at present 1,800 chronic pauper insane. Under Dr. Chapin it has always been excellently managed, and the present report shows that he is continuing his good work. During the year fifty-four patients were discharged improved and five cured. The general condition of the other patients has been good, as shown by the mortality rate, which is less than four per cent. The patients are employed to as great an extent as possible, and their work upon the farm and indoors earns for the Asylum twenty-five cents per day for each person, reducing the per capita cost to $2.40 per week. The trustees recommend the erection of one more group of buildings to accommodate the demand for more room. Such new buildings would increase the capacity to 2,000, a number which the trustees believe could be well cared for, and at a cost slightly less than the present per capita rate.

Twentieth Annual Report of the New York Dispensary, 1879.

The number of cases treated in this dispensary during 1879 was 26,944; in 1878 it was 38,051; and in 1877, 43,623. The decrease has been caused, it is believed, by the introduction of the small fee system and by the more rigid exclusion of unworthy applicants for relief. To this might be added the multiplication of other dispensaries and the increased business prosperity. The receipts from patients' fees amount to $4,352.27. And of all the applicants only 3½ per cent. of the males and 6½ per cent. of the females were unable to pay. A new feature in the dispensary work is the employment of a district nurse to help carry out the orders of the physicians. Much good has been done in this way.

Bromide of Ethyl, Its Physiological Action. By Isaac Ott, A.M., M.D. Reprint from *Detroit Lancet*.

This pamphlet embraces the results of some quite extended original investigations by Dr. Ott. They form a valuable contribution to our knowledge of the physiological action of the new anæsthetic. The writer's experiments were made upon frogs and rabbits. His conclusions are:

1st. That bromide of ethyl increases the pulse by direct stimulation of the heart itself.

2d. That it increases the blood-pressure, either by stimulation of the spinal or peripheral vaso-motor system.

3d. That it decreases respiration by central action.

An Improved Method of Treating Depressed Fractures of the Nasal Bones. By Lewis D. Mason, M.D.

In this reprint from the *Annals of the Anat. and Surg. Med. Society*, Dr. Mason recommends the passage of an ordinary surgical needle of medium size, transversely, through the nose, so that it shall afford not only a posterior support to the nasal bones, but will act as a thread, holding together the sides of the nasal arch. Several cases illustrate this method, which is an original and apparently very useful one.

Notes on the Anatomical Relations of Uterine Structures, etc. By T. H. Buckler, M.D.

"A muscular muscle, arranged around the lower third and the neck of the uterus like an elastic garter, particularly liable to irritation and subsequent contraction, having direct power to impede the venous flow, and yet too weak to control the arterial circulation, becomes, by arresting the return blood and backing it on the womb, the factor of engorgements in the neck and body of the uterus, and, as a consequence, is the cause of procidentia, retroversion, retroflexion and anteversion, according to the part of the womb which is weighted by the hæmatic engorgement."

If the reader can follow the foregoing sentence in its wonderful prolixity, he will understand the basis of Dr. Buckler's new views on uterine pathology. It remains for gynæcologists to decide upon the value of the same.

Clinical Lectures on the Diseases of Women. By J. Matthews Duncan, M.D., etc. Philadelphia: Henry C. Lea. 1880.

In this series of lectures, which were originally delivered to the students of St. Bartholomew's Hospital, Dr. Duncan has by no means gone over the whole gynæcological field, nor has he attempted to treat his chosen subjects exhaustively or in accordance with strict scientific method. He has, however, taken up a number of the most important and practical topics, and he writes about each in an interesting and instructive manner. Such titles as Missed Abortion, Ovaritis, Chronic Catarrh of the Cervix Uteri, Painful Sitting, Aching Kidney, show that he aims more to throw light upon the everyday work of the general practitioner than to make any special contribution to gynæcology.

In discussing the subject of Missed Abortion, Dr. Duncan refers to the causal relation which disease of the heart has to it, and regrets that more definite knowledge of this relation has not been obtained. Speaking of chronic cervicitis, he expresses the belief that its frequency is somewhat overrated, and that it has rivals in this respect in chronic ovaritis, and chronic inflammation of the uterus and ovaries. The treatment which he recommends is the application of zinc-alum in stick form. One application is often sufficient. In the chapter on irritable bladder the importance of distinguishing the difference between irritation and catarrh is insisted on. The author especially commends the use of the vesical sound as a help in settling the question. By it the tenderness, elasticity and size of the bladder are determined, and the diagnosis greatly facilitated. The lecture on Hepatic Disease in Gynecology and Obstetrics is a very suggestive one, but space is lacking for any further quotations. The reader cannot help getting many useful hints from the book.

THE MICROSCOPE AND MICROSCOPIC TECHNOLOGY; a Text-book for Physicians and Students, by HEINRICH FREY, Professor of Medicine in the University of Zurich. Translated and edited by GEORGE R. CUTTER, M.D. Illustrated. Second Edition. New York: William Wood & Co. 8vo, pp. 650. 1880.

IN preparing a second edition of Professor Frey's work, the American editor states that it has been thoroughly revised, that a large amount of new matter has been added; the type improved, and the size of the page increased.

The reputation which this work of Professor Frey's has already obtained makes an extended notice of it now unnecessary. It is one of the standard text-books on microscopic technology, and is universally recognized as such. The present edition will be welcomed for its additions and improved typographical appearance.

TRANSACTIONS OF THE MEDICAL ASSOCIATION OF THE STATE OF MISSOURI, Twenty-second Annual Session, May 20 and 21, 1879.

THE contributions to this volume of the State Transactions have for the most part been published already. They need no review now, therefore, and the fact that they have been twice printed is a sufficient commendation.

Of the other articles, the Report of the Committee on Medical Education is a very thin piece of work. The members of the committee evidently went no further than to peruse the announcements of the four State medical colleges. The deans of these institutions reported them all to be at a very high pitch of excellence, and that seemed to satisfy the committee. The Society passed a resolution recommending a greater degree of proficiency in the Arts and Sciences for those intending to become physicians. Thus the matter of medical education was dropped.

The address of the President upon the dangers of popular scientific education is one of considerable merit. It will be noticed, however, that he wanders from the subject proper to the question of homœopathy and its relations to scientific medicine. And he there takes the opportunity of misrepresenting the RECORD and of showing considerable obtuseness and ignorance of the question to which he has strayed. The President would have us make no terms whatever with anything that has borne the name of homœopath. The RECORD has taken the position that, theoretically, there is no reason why a medical man who professes and practises no exclusive dogma should not be received as a regular physician, though he may employ peculiar remedies as part of his therapeutic armory. This position was indorsed by the Committee of the County Medical Society. It is found, however, that practically there are some difficulties in the way of fraternizing with the so-called liberal homœopaths. Nevertheless, the position is perfectly unassailable, and is the only logical one that can be taken. The subject of homœopathy, however, seems to unbalance the usual fine equipoise of the distinguished President of the State Society, and drive him out of logic into a fine frenzy of indignant ejaculation. We regret that his otherwise excellent address should be marred by such an exhibition of narrowness and immaturity.

The officers elected for the ensuing year are, Dr. G. M. B. Maughs, of St. Louis, President; four Vice-Presidents; Drs. A. J. Steele, and W. E. Fischel, of St. Louis, Recording Secretaries; Dr. E. C. Evans of Sedalia, Corresponding Secretary; Dr. A. B. Sloan of Kansas City, Treasurer.

THE CAUSES AND RESULTS OF PULMONARY HEMORRHAGES, by REGINALD E. THOMPSON, M.D., CANTAB. London: Smith, Elder & Co. 1879.

THE author of this little volume has evidently studied his subject with great care, and he presents here the result of considerable original investigation. His work on the whole, however, rather fortifies what is already pretty generally taught, than introduces what is novel. He takes much the same ground on the subject of pulmonary hemorrhage as did Graves, many years ago, that it may produce a tendency to consumption, but is not necessarily a cause of it. In his pathological views the author follows Virchow rather than Bennett. Statistics which he has collected in regard to the ultimate causes of pulmonary hemorrhage show it to be more common in men, and to occur oftener in summer and in foggy, damp weather.

A person specially studying this subject would find much to interest him. To the average reader, however, it will prove rather unsatisfactory.

Reports of Societies.

NATIONAL PHARMACOPŒIAL CONVENTION.

Sixth Decennial Convention, held in the City of Washington, May 5, 6 and 7, 1880.

(Special report for THE MEDICAL RECORD.)

WEDNESDAY, MAY 5TH.—FIRST DAY.—FIRST SESSION.

THE Sixth Decennial Convention for the revision of the United States Pharmacopœia, met in the National Medical College, May 5, 1880, and was called to order at 12 M., by DR. JAMES E. MORGAN, of Washington, D. C.

On motion made by Dr. Robert E. Rogers, of Philadelphia, Dr. Morgan, the only surviving officer of the Convention for 1870, was elected temporary chairman, and DR. D. W. PRENTISS, of Washington, D. C., temporary secretary.

Dr Morgan returned his thanks to the Convention for the honor conferred upon him, and expressed the belief that the proceedings would be successful and harmonious.

COMMITTEE ON CREDENTIALS.

On motion by Dr. R. E. Rogers, the chairman was empowered to appoint a committee of three on credentials, and the following gentlemen were appointed:

Drs. W. S. W. Ruschenberger and A. B. Taylor, of Philadelphia, and Mr. W. S. Thompson, of Washington, D. C.

The Convention then took a recess of fifteen minutes, at the end of which time it was again called to order, and the committee on credentials reported that they had received credentials of delegates from the following organizations:

The Massachusetts College of Pharmacy, the Philadelphia College of Pharmacy, the Louisville College of Pharmacy, the Maryland College of Pharmacy, the Medical Society of the District of Columbia, the National Medical College, Columbian University, the Medical Department of the University of

Georgetown, D. C., the National College of Pharmacy, Washington, D. C., the Medical Department of the University of Pennsylvania, the Massachusetts Medical Society, the Bellevue Hospital Medical College, New York City, the College of Pharmacy of the City of New York, the College of Physicians and Surgeons, Medical Department of Columbia College, the Dartmouth Medical College, Hanover, N. H., the Connecticut Medical Society, the Rush Medical College, Chicago, Ill., the Philadelphia County Medical Society, the State University of Iowa, Medical Department, the Iowa State Medical Society, the St. Louis College of Pharmacy, the University of Michigan School of Pharmacy, the College of Physicians, Philadelphia, Pa., the Medical Department of the United States Army, the University of the City of New York, Medical Department, the Medical Department of Medicine and Surgery of the University of Michigan, the Chicago College of Pharmacy, the Cincinnati College of Pharmacy, the Woman's Medical College, Philadelphia, the Medical College of Indiana, the Medical Society of the State of New York, the College of Medicine of the Syracuse University, the Medical Department of the United States Navy, the United States Marine Hospital Service, the Miami Medical College, Cincinnati, O., the Pennsylvania College of Pharmacy, the Missouri Medical College, St. Louis, the College of Physicians and Surgeons of the City of New York, the Medical Department of Howard University, Washington, D. C., the University of Albany, N. Y., Medical College, the Jefferson Medical College, Philadelphia, the New York Academy of Medicine, the Medical and Chirurgical Faculty of Maryland, Baltimore, the University of Maryland, the Woman's Medical College, New York, the North Carolina State Medical Association.

The delegates from the above organizations were admitted with the exceptions noted below, which received separate action.

On motion of Dr. S. C. Busey, of Washington, D. C., the delegates from the Medical Departments of the Army and the Navy and from the Marine Hospital Service [not being incorporated organizations] were invited to seats in the Convention, and to exercise all the rights and privileges of the other delegates.

On motion by Dr. Busey, the delegates from the Medical Society of the District of Columbia, technically not a State organization, were admitted to the Convention.

Dr. Robert E. Rogers, of Philadelphia, moved that the delegates from the Philadelphia County Medical Society be admitted to the Convention. The motion gave rise to considerable discussion, but was carried by a vote of 35 to 22.

COMMITTEE ON NOMINATIONS.

On motion by Mr. Dolber, of Boston, a Committee on Nominations was appointed consisting of one member from each body entitled to representation in the Convention, and each delegation present was empowered to name the respective members of this Committee. The following was the Committee so formed:

S. A. D. Shepard, A. B. Taylor, C. Lewis Diehl, Jos. Roberts, Dr. Antisell, W. W. Johnston, S. C. Busey, R. B. Ferguson, H. C. Wood, E. S. Wood, F. A. Castle, Charles Rice, E. Curtis, H. M. Field, H. H. Smith, Wm. H. Crawford, H. B. Parsons, I. M. Hays, D. L. Huntington, H. G. Piffard, G. M. Hambright, A. Fennel, Clara Marshall, J. D. Rushmore, G. R. Metcalfe, B. F. Gibbs, Oscar Oldberg, J. F. Judge, M. Roche, O. A. Wall, J. C. Peters, G. S. Palmer, Robert E. Rogers, Laurence Johnson, W. J. C. Du Harnel, G. H. Fox, Thomas F. Wood.

The Convention then took a recess until 3 P.M.

FIRST DAY—SECOND SESSION.

The Committee on Nominations being ready to report, the Convention was called to order at 3.30 P.M. by Dr. Morgan, and the following report was made:

For President, Dr. Robert Amory, of Brookline, Mass.; for First Vice-President, Dr. S. C. Busey, of Washington, D. C.; for Second Vice-President, Prof. P. W. Bedford, of New York; for Secretary, Dr. F. A. Castle, of New York; for Assistant Secretary, Prof. C. H. A. Kleinschmidt, of Washington, D. C.

On motion by Dr. Rogers, of Philadelphia, the report was accepted and adopted.

Dr. Amory, President elect, then took the chair, and thanked the Convention for the unexpected honor it had conferred upon him.

Prof. Maisch, of Philadelphia, moved that Dr. E. R. Squibb be admitted to the floor of the Convention, with the rights and privileges of a delegate. The motion was heartily seconded by Dr. Rogers, of Philadelphia, and was unanimously adopted, the Convention taking a rising vote.

Dr. Squibb made an appropriate response.

On motion by Dr. Busey, the thanks of the Convention were extended to Dr. Morgan for his justice and impartiality as temporary Chairman, and to Dr. Prentiss for his faithfulness as temporary secretary.

On motion by Dr. Parvin, the minutes of the last Convention were read by title.

Prof. A. B. Taylor, Secretary of the last Convention, then made his report in writing, which was received and adopted.

PRESENTATION OF REPORTS.

Reports were received from the following organizations:

Philadelphia College of Physicians, Philadelphia College of Pharmacy, Maryland College of Pharmacy, Louisville College of Pharmacy, American Pharmaceutical Association, Pennsylvania Pharmaceutical Association, Philadelphia County Medical Society, National Medical College, and the National College of Pharmacy.

On motion by Dr. C. L. Diehl, the President of the Pennsylvania Pharmaceutical Association, Mr. C. B. Heinitsh was invited to a seat in the Convention, with the rights and privileges of a delegate.

Prof. Maisch introduced the following resolutions, which were adopted:

Resolved, That the Committee on Nominations be instructed to nominate a committee of revision and publication consisting of ——— members.

Resolved, That the Committee on Nominations be instructed to report a plan for revising and publishing the Pharmacopœia, and to make provision for the revision of the United States Pharmacopœia in the future.

On motion by Dr. A. B. Taylor, the Convention directed that the Committee consist of *twenty-five* members.

The Convention then adjourned to meet on Thursday, May 6th, at 12 M.

The Convention was called to order at 12 M., May 6th, and adjourned to 2 P.M. It was called to order at 2 P.M., and adjourned to 10 P.M.

THURSDAY, MAY 6TH—SECOND DAY—EVENING AND MORNING SESSION.

The Convention was called to order at 10 P.M., by the President.

Dr. James L. Cabell, of the University of Virginia, was elected as delegate to the Convention.

REPORT OF THE COMMITTEE ON NOMINATIONS.

The report of the Committee on Nominations being in order, it was first read, and then the items were considered seriatim.

The following gentlemen were nominated and elected as the *Committee of Revision and Publication of the Pharmacopœia of the United States.*

The President, Robert Amory, of Brookline, Mass.; the Secretary, F. A. Castle, of New York; D. L. Huntington, U. S. A.; B. F. Gibbs, U. S. N.; O. Oldberg, U. S. Marine Hospital Service; P. W. Bedford, of New York; C. Lewis Diehl, of Louisville, Ky.; Louis Dohme, of Baltimore, Md.; Thomas Doliber, of Boston; Laurence Johnson, of New York; J. F. Judge, of Cincinnati, O.; John M. Maisch, of Philadelphia; G. F. H. Markoe, of Boston; H. B. Parsons, of Washington, D. C.; H. G. Piffard, of New York; J. P. Remington, of Philadelphia; Chas. Rice, of New York; W. S. W. Ruschenberger, of Philadelphia; E. R. Squibb, of Brooklyn; A. B. Taylor, of Philadelphia; W. S. Thompson, of Washington, D. C.; O. A. Wall, of St. Louis, Mo.; E. S. Wood, of Cambridge, Mass.; T. F. Wood, of North Carolina; and T. G. Wormley, of Philadelphia.

The committee was empowered to fill its own vacancies, and also to employ skilled experts.

The items of the report read and adopted were those found in the report on the Revision of the United States Pharmacopœia, preliminary to the Convention of 1880, prepared and compiled by Charles Rice, Chairman of the Committee of the American Pharmaceutical Association, on the revision of the United States Pharmacopœia, with some amendments. They related to language, alphabetical arrangement, synonyms, cross references, description of crude drugs, description of chemicals, chemical formulæ, processes for chemicals, expressions of quantity, numerical relations of quantities, fluid extracts, temperature, definition of physical properties, specific gravity, definite expressions of weight, weight of finished product, and tables to be appended to the Pharmacopœia.

The following were added: That all doses be omitted from the Pharmacopœia, a table of saturations, and the committee was empowered to add such other tables as might seem advisable.

A resolution that *parts by weight* be adopted in the formulæ of the Pharmacopœia was adopted.

INSTRUCTION RELATING TO PUBLICATION.

The Committee of Revision and Publication was instructed to award the publication of the Pharmacopœia of the United States to the publishing house offering the best terms; the committee to hold the copyright, the price of the work to be limited, and the book to be sold through the ordinary trade channels. The action under this resolution shall be bound by a majority vote of the whole committee. The committee was also authorized and directed to publish a supplement to the Pharmacopœia at the end of five years, or oftener, if necessary.

The report, as a whole, was then adopted by the Convention.

Several resolutions were then passed, extending the thanks of the Convention to those by whom it had been entertained, to the press, and to the officers of the Convention.

The roll was then called and seventy-four delegates responded.

DR. J. MINIS HAYS, of Philadelphia, moved that the names of the delegates from the College of Physicians and Surgeons, in the city of New York, be stricken from the roll. Unanimously tabled.

DR. HAYS also questioned the legality of the seats of the delegates from the New York Academy of Medicine.

DR. BUSEY, of Washington, then moved that the delegates from the New York Academy of Medicine *are* entitled to seats in this Convention. Unanimously carried.

The Convention, at 1.45 A.M., May 7th, adjourned.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, April 26, 1880.

DR. A. E. M. PURDY, PRESIDENT, IN THE CHAIR.

THE SOCIETY was called to order at eight P.M. by the President, and the minutes of the previous Stated Meeting were read by the Secretary, DR. F. A. CASTLE.

The report of the Comitia Minora, based upon a careful consideration of the merits of the case, and a legal opinion given by Judge Fancher, recommending Mrs. Carrie L. Black for membership, subject to the approval of the Society, was, on motion made by DR. ELLSWORTH ELIOT, laid upon the table.

The Society then took a recess for ten minutes.

During the recess, the organization known in its charter granted in 1807, as the

COLLEGE OF PHYSICIANS AND SURGEONS,

was called to order, and Dr. A. E. M. Purdy was elected Chairman, and Dr. F. A. Castle Secretary.

The Society, entitled to send delegates to the National Pharmacopœial Convention, to be held in May, 1880, proceeded to the election of three delegates to represent it in the next convention, and Drs. John C. Peters, Laurence Johnson, and Leroy M. Yale were chosen. The Society then adjourned.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK

was again called to order by the President, and in the absence of its author, DR. ALLAN MCLANE HAMILTON, the Secretary proceeded with the reading of a paper

ON THE USE OF NITROUS OXIDE GAS IN CERTAIN DISEASES OF THE NERVOUS SYSTEM.

After a review of the literature of the subject, in which the credit was given to Dr. J. L. Blake for first directing attention to the agent in this country, the author passed to the consideration of the use of the agent in certain conditions in the insane, particularly the depression of melancholia. In these cases, according to his experience, it had improved the circulation, increased the warmth of the extremities, increased the brilliancy of the eye, and given at least marked temporary benefit. He then referred to its use in the treatment of severe sick headache, various neuralgias, sciatica, insomnia in consequence of overwork, hypochondriasis, functional heart trouble, chlorosis, tobacco and opium nervousness, and in most cases it had proved beneficial. For the sleeplessness dependent upon excitement, or congestion, and with cardiac hypertrophy, it was not beneficial. Indications of excitement or organic cardiac disease contraindicated its use. He had not used it in epilepsy, although he had no doubt that it would be serviceable. In only two cases had he seen any unpleasant effects, and he used it according to Dr. Blake's method, which was described by

Dr. Blake, who regarded the agent as a diluted gaseous diffusible, stimulant tonic. The manner in which it operated seemed to be as a diffusible stimulant, with no tendency to subsequent depression or reaction, when given so as *not to produce any evidence of anæsthesia*, and that was what was to be understood by his method. It was possible to administer it in small doses, so as to produce a gentle tonic influence. Dr. Blake then exhibited a portable apparatus for administering the gas, which placed the agent completely under the control of the physician. He thought, however, it would not be used in the office of physicians in general on account of the expense. The first evidence of intoxication was the blush of the face, and as soon as that appeared, more atmospheric air should be admitted. He had used it in insane melancholia with good results, and in a variety of other affections.

Dr. A. E. Macdonald remarked that certainly, so far as its temporary benefit was concerned, he could speak favorably of the agent. He had not used it sufficiently long to enable him to judge of the results that could be obtained with reference to final recovery. Its use was indicated in cases of depression with tendency to melancholia, especially with an epileptoid condition. In cases of excitement or frenzy, he thought its use was contraindicated. He then referred to two cases of melancholia in which the patients refused to take food for three and six weeks respectively, and after taking one or two gallons of the gas, they went to the table of their own accord and took a good supper. For slight surgical operations among the insane, it answered a good purpose, especially and above all in uterine cases.

Dr. Beard referred to the fact that physiological experiments had given the general conclusion that the effect produced by the gas was temporary, although of a decided character. He thought that, as a rule, the results would be more temporary than permanent. He also believed that it was agreed to by most that remedies given by inhalation, save those administered for local effects, disappointed us with reference to final results. But everything which assisted temporarily was to be heartily welcomed. The single symptoms, insomnia and depression, were so prevalent that if we could have something to remove them readily, it might tide the patient over the point, perhaps, of committing suicide, and in that way the agent might be very beneficial.

Dr. Goodwillie referred to the purity of the gas as now generated, and also remarked that if the border-line between stimulation and anæsthesia was crossed, the good effect of the gas was lost. The point of anæsthesia should not be reached if the stimulant effect was to be retained. The circulation in the lobe of the ear, together with the respiration and general aspect of the face, were what he relied upon in determining when the person was approaching anæsthesia.

ON THE USE OF CERIUM OXALATE FOR THE RELIEF OF COUGH

was the title of a paper then read by Dr. Honart Cheesman. The paper had already been presented to the Therapeutical Society, and was noticed in connection with the proceedings of that Society. (See Record, p. 492.)

The Society passed a resolution instructing the Comitia Minora to defray the travelling expenses of the delegates to the Pharmacopœial Convention, to be held in Washington, D. C., in May, 1880, and then adjourned.

Correspondence.

THE ALLEGED CURE OF CATARACT BY ELECTRICITY.

To the Editors of The Medical Record.

Sirs:—In Virchow's Archives for March, 1880, page 474, in an article by Dr. Wm. H. Neftel, New York, is found the following statement: "Mrs. M——, a lady 62 years of age, of pretty good health, except that she suffers from sciatica and rheumatic pains, had complained for a year of gradual impairment of vision. At first she could not see distant objects plainly, then reading became impossible, and finally she was unable to see plainly larger objects. She consulted at different times two of the best ophthalmologists in New York, Drs. Agnew and Webster, who made the diagnosis of cataract of both eyes, but advised that the operation be deferred until the cataract became ripe. On July 26th I commenced the galvanic treatment in the following manner." The doctor then goes on to tell how, and how often, he applied the galvanism. "After each sitting the patient declared that she could see more plainly. After one week she declared herself able to read coarse print pretty well, and after two weeks she could read quite small type. After twenty-five applications the treatment was discontinued. The patient declared that not only had she recovered her earlier seeing power, but also needed weaker spectacles than before. Additionally, she received, at various times, some ten applications. After ending the galvanic treatment, the patient again presented herself to Dr. Agnew for examination, who now could find nothing abnormal either in the structure or in the functions of the eyes; at least he could discover no trace of opacity of the lens or its capsule. These conditions remain unchanged up to the present time."

The following are our notes of the case of Mrs. M.:

"July 24, 1878.—Mrs. M., æt. 62, eight years ago had some inflammation in her eyes, and 'everything had a rainbow,' and nothing would allay the inflammation but hot water. Since that they get tired easily. Vision, $\frac{2}{3}$ each eye, without a glass. With her own glasses, for the distance $+\frac{1}{4}$, right eye sees $\frac{1}{2}$ and left eye $\frac{2}{3}$. With $+\frac{1}{2}$, each eye has vision $\frac{1}{1}$. Mrs. M. states that she did not use glasses until 52 years of age. Her reading glasses are $+\frac{1}{2}$; she reads better with $+\frac{1}{4}$. Ophthalmoscopic examination shows incipient cataract, more advanced in left eye. Ordered $+\frac{1}{4}$ for the distance and $+\frac{1}{2}$ for reading, and advised bathing the eyes with warm water and salt (℥i. to Oj.).

"Oct. 22, 1878.—Mrs. M. again called upon us, after having had her course of treatment by Dr. Neftel. The note made by us at that date is, 'no apparent change since last visit' (July 24, 1878).

On the 15th of April, 1880, Dr. Webster made a careful examination of the eyes of Mrs. M., without dilating the pupils, and found that there were large masses of opacity in the lower periphery of the left lens, and a prominent streak of opacity extending upward and outward nearly to the centre of the lens. He found that minute opacities existed in the periphery of the right lens. He found that Mrs. M. could read Jaeger No. 1 at about fourteen inches through her spectacles, and as easily with the left eye as with the right one.

It will be observed, then, that Mrs. M. had incipient cataract when she first came to see us on the 4th of July, 1878; that she had incipient cataract on the 15th of April, 1880. In the interval between those two dates she had received galvanic treatment from Dr. Neftel. The vision of Mrs. M. was $\frac{2}{10}$ before her alleged cure, $\frac{2}{10}$ after her alleged cure, and sufficient to enable her to read Jaeger No. 1 at fourteen inches on the 15th of April, 1880. The crystalline lenses, so far as our notes and recollection serve, are now just as they were before Dr. Neftel treated the case with galvanism. The case is simply one of those common ones of stationary or very slowly increasing opacity of the lenses, and we must calmly wait for new light if we are to change our belief that galvanism will not remove opacities of the crystalline lenses. The publicity given to this matter makes it necessary to state the facts.

THE SUPERVISION OF INSANE ASYLUMS.

To the Editor of The Medical Record.

Sir:—The opponents of the bill to provide an effective supervision of insane asylums in this State, now pending in the Legislature, have made no little use of the statement that in England, where a Lunacy Commission has existed for nearly fifty years, public opinion and the highest authorities have declared in favor of its abolition, and a return to the independent management by local boards, as in this country. Some personal knowledge of the subject, and an examination of the authorities referred to enable me to say that there is really no foundation whatever for this statement.

In his evidence before a Committee of Parliament, in 1877, Lord Shaftesbury, for more than thirty years Chairman of the English Commissioners in Lunacy, objected *to any addition* to the present number of these Commissioners, and favored an increase of visitation by local boards.

Another witness (Hon. F. Scott) spoke of "the confusion of authorities," caused by the number of boards charged with the supervision of the insane. There are now six of these boards, namely: the County Committee of Visitors (corresponding to our boards of managers), the Court of Quarter Sessions, the Board of Guardians, the Home Office, the local Government Board, and the Lunacy Commissioners, besides the three Lord Chancellor's Visitors, whose duties are confined to chancery patients.

It is proposed by Dr. Bucknill, in an address published in the *British Medical Journal* of Feb. 7th to combine three of these supervising boards in two, thus doing away with a single board only; which certainly seems a not too radical or unreasonable change. But this is all, and there would still be, if Dr. B.'s plan were adopted, "two new and enlarged authorities placed over all subordinate authorities having control over the care and maintenance" of insane. The giving up of governmental supervision of the insane, it will be observed, is not even hinted at, and no one acquainted with English opinion upon the subject could for a moment suppose such a change possible.

It is well known to the medical profession that there is at present no authoritative supervision whatever of insane asylums in this country. Their administration is conducted by a board of local managers through their agent the medical superintendent. These managers, the present Commissioner in Lunacy declares, have "franchises given them for the purpose of acting in official capacities, and there is no proper ground upon which the Legislature can intervene," except by general laws "when there is no existing remedy, either under the common or statute law of the State, for alleged wrongs." The chief function of the Lunacy Commissioner is held by himself to be simply that of a special judge for the trial of such of these "alleged wrongs" as may be brought before him according to the proper forms of law.

This may be a correct theory of the constitutional law of the State, and if so the Legislature should be convinced of its powerlessness to provide for any other than a formal supervision of the insane. But to declare that public opinion and high authorities in England have finally come to believe that no governmental supervision is necessary, is a misrepresentation of facts which deserves to be exposed and rebuked.

Utica, N. Y.

TREATMENT OF ASPHYXIA OF THE NEW-BORN—AMYL NITRITE.

To The Editor of The Medical Record.

Sir:—Dr. W. E. Forest's communication in the Record of the 10th inst., describing his method of resuscitation of asphyxiated infants, prompts me to report a case where, after trial of the usual methods, including Dr. Forest's, resort to amyl had the desired effect. The case is as follows: Mrs. McC——, æt. about 25, mother of three children, two of which are twins, was taken in labor about noon, March 29, 1880. Was called about 4 P.M., and found patient having moderately good pains, in the second stage, breech presenting in the second position, and a long loop of the cord prolapsed and lying between the patient's thighs. The cord was pulsating vigorously, the os perfectly dilated, with the breech engaging.

Due preparation was made for the reception of an asphyxiated infant, warm flannels, hot and cold water, whiskey, etc., were provided—forceps placed within easy reach to extract the head, if necessary. An unsuccessful attempt was made to return the cord to the cavity of the uterus. I could not possibly get my hand past the breech. A foot was then seized and brought down, and the other reached with some difficulty. Some fifteen minutes or more passed before delivery was accomplished, the child being large. The greatest delay occurred in extracting the breech and shoulders, requiring strong traction. With firm pressure on the uterus by a stout nurse, and the determined efforts of the patient, no unusual delay occurred to the delivery of the head. Pulsation of the cord ceased long before the breech was extracted. As may be expected, the child appeared altogether lifeless, its color was very pale, lips colorless, cord bloodless, flaccid limbs, complete muscular relaxation, and no appreciable cardiac action. The cord was cut and tied, and the infant placed in a very warm bath, where it was rubbed and spanked unavailingly; dipped in cold water and returned to the hot alternately for some minutes, when it was taken from the bath, wrapped in hot flannels, and artificial respiration commenced by Sylvester's method, in connection with rubbing it briskly with a little whiskey on the hands, spanking, etc. Direct insufflation of the lungs, by placing my mouth to the mouth of the child, closing its nostrils, and forcing air into its

lungs was also tried some minutes. It was noted by the clock to the room that twenty-five minutes had passed since delivery, and not a gasp had yet been made. There was a trifle more color on the lips to encourage me to proceed, that was all—no pulsation of the heart could be seen or felt.

I then thought of Dr Forest's method, given in the RECORD for December 20, 1878, and trial was made of it for perhaps ten minutes, and finally direct insufflation combined with it, with no better result. It was again taken from the bath, rubbed and spanked some more, its lungs again inflated methodically, and after some minutes of this, its heart could be felt and soon beating, not very fast nor strong, but, do what I could, the infant would make no effort to breathe. It then occurred to me that as the nitrite of amyl is so valuable in chloroform narcosis, possibly it might be useful in the asphyxiated infant. Happening to have some in my pocket, I put two or three drops on my handkerchief and placed it over the child's face, continuing at the same time Sylvester's method. After about a minute had passed, I lifted the handkerchief; the neck, chin, lips, and eyelids had become of a distinct *cyanotic* color, the heart was beating vigorously, and I had not long to wait for the welcome gasp, followed by another, another, and in perhaps five minutes' time respiration could be considered established, to the supreme satisfaction of the patient and husband, and, it is needless to add, myself. The cyanotic hue soon passed away, and in its stead appeared the normal bright red color of the skin.

Again glancing at the clock, I was surprised that nearly fifty minutes had passed. Up to date the infant is thriving and well. I shall not forget to take a little amyl with me to obstetrical cases hereafter, for to that agent I attribute the rescue of this infant, and will not hesitate long in using it again in profound asphyxia.

Respectfully,

C. H. HUMPHREYS, M.D.

BRANDT, O.

THE DETERMINATION OF SEX IN UTERO.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Having recently noticed several articles upon the above subject, I have concluded to make known a singular rational sign by which I have been able to predict, with a degree of success, the sex of the child. In the issue of December 7, 1878, of the MEDICAL RECORD, Dr. Upjohn gives us a theory by which, as he says, he can ascertain to a certainty the sex of the child. This seems to be put in pretty strong language. But this is his statement: "In every case where I can obtain sufficient and accurate data, I am able to predict the sex previous to delivery," and then gives the law by which he does so. "Conception resulting from intercourse *subsequent* to the menstrual flow will result in female offspring; while conception from intercourse in the *latter half* of the menstrual period, or *previous* to the menstrual flow, will result in male offspring."

Dr. Sweet, in the *Medical Brief*, gives three cases, as follows: "Mrs. C —— was recently confined of her second child, the first one being about five years old. In the first instance, her husband, who was a fisherman, came home one night, during an absence of many weeks, just after a menstrual period. She became pregnant that night, and the result was a boy. The next time she had intercourse a few days after her period, and the next day went away for an absence of several weeks. The result of this was a girl.

"Miss I —— was seduced by a young man a few days after her period. She never had any connection with him afterward. The result of this pregnancy was a boy."

In the last two cases cited the time of conception is exactly the same, but the sex is different; and in the first and last cases the result is contrary to the "theory" of Dr Upjohn. I have no disposition to criticise the remarks of either, but will proceed to give my theory and the manner in which I have made my observations. My attention, before I began the study of medicine, was called to the irrational theory that I am about to advance. Obstetricians are all aware of the fact that the areola and nipple change color when in the pregnant state. The difference in the change is the index to the sex. When I first began the practice, I closely observed the areola and nipple to see if I could discern any difference. I found almost invariably that when the sex is male the color of the areola was much darker than when the sex was female. I have a record of thirty-eight births in which I have noted as follows:

19 males: areola very dark (in) color.

1 male: areola very light color.

11 females: areola *not* very dark color.

3 females: areola rather darker than the average female in color.

3 females: areola very light color.

1 female: areola very dark color.

My plan, in order to observe, is to put the child immediately to the breast, not that I expect it to get nourishment in all cases, but to induce contraction and make my observation. It has been my habit to question the woman, and upon her word predict the sex. I have, as the table shows, been deceived but seldom. Five times out of the thirty-eight the rational sign would have been almost a failure. Yet this is better than we are able to do by judging from the time of intercourse previous or subsequent to the menstrual flow. I have never seen or heard this theory advanced before. It may have been done, but not to my knowledge.

S. D. CARLILE, M.D.

PALMYRA, ILL.

BROMIDE OF ETHYL.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—I desire to narrate my brief experience in the use of bromide of ethyl, as the anæsthetic in question is attracting so much attention of late.

To-day, I had occasion to perform Chopart's amputation of the foot, upon a patient who had lost the use of that member by reason of an old and irreducible dislocation of the tarsal bones. James Scanlan, æt. 41 years, applied for amputation of his foot, as he thought the operation would afford him better facility for walking. There was great distortion of the tarsal bones—the effect of an old fall; and accordingly, assisted by Drs. Wilcox and Johnson of this city, I proceeded to operate.

The bromide of ethyl was given by myself at the start. One drachm was poured on a towel and held closely to the face. A speedy and pleasant intoxication followed in about one minute. I then added another drachm, when a transient state of muscular excitement followed, which lasted about a minute and which required some restraint. The pulse and respiration were now very frequent, but it was attributed to the muscular spasm just alluded to. Within

three minutes from the beginning of the anæsthesia he patient was thoroughly asleep. I now requested Dr. Wilcox, my house-surgeon, to superintend the further administration of the ethyl, while I proceeded to perform the operation.

Scarcely had I made my incision when Dr. Johnson remarked, "I can feel no pulse at all." I glanced at my patient and saw his face blanched. Almost simultaneously his breathing stopped short. There was now no time for theorizing. The patient was virtually dead. I ordered him to be suspended in the air, head downward; and in this position Dr. Johnson attempted artificial respiration. No response was elicited, however, when I sent for my nitrite of amyl. This was applied in half a drachm dose to the nose, when soon a few feeble impulses were perceptible at the wrist; the face flushed, movements occurred, and we laid him back upon the bed. Within a minute more he was asking us questions.

The ethyl was continued, but not "crowded," but the patient never fell into a thorough sleep after this, and the amputation, etc., were performed in a state of semi-anæsthesia. The patient felt no pain, however, in all the procedure, except at the ligation of the arteries, and on stitching my flaps together. He insisted that the foot had not been amputated, until the stump itself had been shown to him, when he expressed surprise. The operation lasted forty-five minutes, and only during ten of these was anæsthesia complete.

Wyeth's preparation of methylic ether was used. Vomiting early set in and lasted about five hours, but was ultimately controlled by ½ grain of morphine under the skin. Pulse soon after rose to 125 per minute, and the temperature to 101°.

Now, I do not pretend to say that these unfavorable symptoms were entirely due to bromide of ethyl; but I must state that about three months prior to date, this patient underwent urethral dilatation "under chloroform," and stood the operation well. He was somewhat debilitated to-day, however, and was fasting when the operation was performed.

From the foregoing brief experience with methylic ether, I am forced to the following conclusions already:

1st. Dangerous symptoms may manifest themselves during the inhalation of bromide of ethyl.

2d. Cardiac debility and alarming cerebral anæmia can follow the use of the anæsthetic in question.

3d. Unless the ether is "crowded," a state only of semi-anæsthesia must be expected, and

4th. If the agent is "crowded," like all other anæsthetics, dangerous symptoms may instantly appear.

On the other hand, I will add that,

1st. Methylic ether, like nitrous oxide, produces rapid and pleasant insensibility, and

2d. Restoration to consciousness is sooner accomplished from its influence than from either chloroform or ether.

In conclusion, I believe methylic ether to be, when cautiously administered, as convenient if not as safe an anæsthetic in minor operations of surgery, as we have at our command.

Respectfully,

C. H. Wilkinson, M.D.,
Surgeon-in-Charge, St. Mary's Hospital.

Galveston, Texas, April 30, 1880.

To the Editor of the Medical Record.

Sir:—Having noted the favorable mention of, and the definite account and directions given by Dr. Levis in the Record of March 27th, in reference to the bromide of ethyl as an anæsthetic, I determined to give it a trial.

Accordingly, having invited my friends Drs. Folsom and Calderwood, on the 24th ult., we proceeded to remove an encysted tumor from over the mastoid process. The patient was a lady of very nervous temperament, in good health, aged fifty-four. In five minutes after commencing the administration of the ethyl she was thoroughly anæsthetized. In six minutes the operation was commenced. In fifteen minutes the operation was completed. The anæsthetic was removed one minute before the tumor was removed. In sixteen minutes the patient was talking rationally, and had perfect control of all her muscles. In seventeen minutes we informed the patient that we must take some stitches, and that it would give her some pain. This we did, and it gave her *no* pain. The remainder of the day the patient was about her house as usual, feeling no bad effect from the anæsthetic. The pulse came from seventy-two up to eighty-four in the five minutes and there remained. The preparation used was Wyeth's. The quantity was one ounce, but as it was given upon a napkin only, and no measures taken to prevent its evaporation, I am sure the patient did not get even one-half the quantity, as it is very volatile.

Should the bromide of ethyl prove as safe as ether it must be a far preferable anæsthetic, especially for minor and short operations, and particularly for extracting teeth, as there is very little excitement and *no* vomiting.

Since the possibility and perhaps probability that the fatal result in the case in Dr. Sims's hands was due to the ethyl, it must as yet be considered *sub judice*, and must be given with fear and care, especially in operations of any considerable length.

G. B. Bullard, M.D.

St. Johnsbury, Vt.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from May 2 to May 8, 1880.

Wood, M. W., 1st Lieut. and Asst. Surgeon. Granted leave of absence for six months, and at expiration thereof to comply with par. 1, S. O. 74, C. S., A. G. O. S. O. 97, A. G. O., May 3, 1880.

Gray, W. W., 1st Lieut. and Asst. Surgeon. Assigned to temporary duty at Fort Point, Cal. S. O. 55, Div. Pacif. and Dept. Cal., April 27, 1880.

McCreery, George, 1st Lieut. and Asst. Surgeon. Assigned to duty at Fort Apache, A. T., as Post Surgeon, relieving Asst. Surgeon Walter Reed, U. S. A. S. O. 48, Dept. of Arizona, April 16, 1880.

Schué, E. D., 1st Lieut. and Asst. Surgeon. Assigned to duty as Post Surgeon at Fort Grant, A. T., S. O. 48, C. S., Dept. of Arizona.

Cochran, J. J., 1st Lieut. and Asst. Surgeon. Assigned to duty at Ft. Lewis, Col. S. O. 94, Dept. of the Missouri, April 28, 1880.

Medical Students' Union Clubs.—A large meeting of medical students was held in London recently, to consider the advisability of forming a Medical Union Club. The meeting was addressed by Mr. Holden, president of the Royal College of Surgeons. A resolution was passed, that the meeting considered it desirable to establish a Medical Union Club.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT.—Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending May 8, 1880.

May 8, 1880.	0	11	41	9	76	33	0	0

DEATH OF WILLIAM SHARPEY, THE ANATOMIST.—William Sharpey, M.D., F.R.S., died on April 11th, at the age of seventy-eight years. Dr Sharpey studied medicine at Edinburgh, London, and Paris. He graduated from the Edinburgh school in 1823, and, after a short period of country practice, which he found distasteful, he went abroad again. There he studied at a number of schools in Germany, Italy, and France. Returning to England, he was appointed lecturer on anatomy in the Edinburgh school in 1830. In 1836 he was made professor of anatomy in the University of London. This position he filled until 1874, when advancing years compelled him to resign. From 1861 to 1874, Dr. Sharpey was one of the crown representatives on the General Medical Council.

Dr. Sharpey's principal work was as a teacher and a student of anatomy and physiology. His power to impart the knowledge he had acquired was unrivalled, and his reputation as a professor shed lustre over the school to which he was so long attached. His writings were not numerous, but his contributions to Quain's Anatomy give proof of his powers of exposition, as well as of the extent and exactness of his anatomical knowledge. Other original matter was contributed by him to Todd & Bowman's Encyclopædia. Dr. Sharpey's best work was as a teacher; but he will always take a high rank as an original investigator in the sciences of anatomy and physiology.

CHIAN BALSAM cures cancer. This is the latest.

MEETINGS OF MEDICAL SOCIETIES IN JUNE.—The following State Medical Societies hold their annual meetings in June: West Virginia Medical Society, at Parkersburg, June 2d; Massachusetts Medical Society, at Boston, June 9th; Minnesota Medical Society, at Albert Lea, June 15th; New Hampshire Medical Society, at Concord, June 15th; Ohio Medical Society, at Cleveland, June 15th.

THE AMERICAN NEUROLOGICAL SOCIETY will meet in New York, June 15th.

A BRANCH ASSOCIATION of the British Medical Association is to be established in Canada. The British Medical Association has now branches in all parts of the British Isles, in India and in Australia. It is the largest and most powerful medical organization in the world.

MEDICAL GRADUATES IN CANADA.—Twenty-nine gentlemen have received the degree of M.D., C.M., from the McGill Medical College, Montreal. The Royal College of Physicians and Surgeons has recently graduated thirteen.

AN INCREASE IN THE FEES of the Medical Colleges of the province of Ontario and Quebec is now under consideration. The fees hereafter paid have been ridiculously small, ranging from $5 to $12 a ticket for a single course of lectures.

CHOLERA IN HINDOSTAN.—Deaths, 94; population, 1,142,147.

ETHER is said to have discovered a new anæsthetic.

THE BINGHAMTON INSANE ASYLUM is now being investigated by a committee of the State Senate, on account of alleged abuses and mismanagement.

APPARATUS FOR LOWERING THE TEMPERATURE OF THE BODY.—At a recent meeting of the Académie de Medecine of Paris, M. Dumontpallier described an apparatus for lowering the temperature of the body. It consists essentially of a coil of rubber tubing, which is placed about the trunk, and through which water is run until the temperature in rectum and axilla indicate that a sufficient extraction of heat has been accomplished.

In connection with this apparatus, the *Lancet* reminds its readers that a similar one has been for some time employed by Liebermeister, and will be found figured in the article on "Abdominal Typhus," in the first part of "Eulenberg's Cyclopædia," now in course of issue. The opportunity is not lost of drawing a moral as to the ignorance among Frenchmen of all that is done outside of their own country.

OVARIOTOMY IN ITALY.—According to recently published statistics, out of the first 100 operations of ovariotomy performed in Italy, the recoveries were 37, the deaths 63. Thirty four surgeons did the sanguinary work. The mortality is explained by the fact that the operations were done by so many different men, none of them having any special experience.

PROFESSOR VIRCHOW has been elected, by an overwhelming majority, to represent Berlin in the German Parliament.

THE HOT-AIR CURE FOR CANCER is now rivalling that by Chian Balsam. Dr. G. A. Keyworth, by means of a foot-bellows, drives air through chloride of lime and hot iron tubes, and then throws it against the surface of the cancer. It relieves the pain and the parts are said to dry up considerably.

Original Lectures.

THE ERUPTIVE FEVERS.

LECTURES DELIVERED

By ALONZO CLARK, M.D., LL.D.,

PROFESSOR OF PRINCIPLES AND PRACTICE OF MEDICINE, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

LECTURE III.—SCARLET FEVER—*continued.*

A word now in regard to belladonna. The homœopathic physicians, almost as soon as they became a distinct class, announced that belladonna was the specific for scarlet fever, upon the ground that belladonna given in certain measure would produce an eruption analogous to that which appears in scarlet fever. It was the proper medicine, inasmuch as *similia similibus curantur*, and I believe they hold to it to this day. I have given belladonna a good deal as a remedy. It has a certain degree of soothing effect, but it has no advantages over Dover's powder or an opiate. With reference to its prophylactic effects, there was a good deal in my earlier professional days said about that, and a good many experiments were tried. A colored physician here had charge of the Colored Orphan Asylum, and there was an outbreak there of scarlet fever, and he adopted the plan of giving to every one of the inmates of the institution what he hoped would prove a prophylactic portion of tincture of belladonna. In writing to me, he said that he thought there was a less number of cases than there would have been if the belladonna had not been given; but he did not feel so very sure about that, because all that could be separated from the sick were isolated, not allowed to breathe the same air, and, of course, not allowed to see them.

The principal of a very large school for boys, a good many years ago, at Pittsfield, Massachusetts, had scarlet fever break out in his school, and he gave, under the direction of his physician, to every one of the pupils that were not affected by it, belladonna, either in extract or in tincture. And he did another thing that was a good deal more protective—he separated all the well ones from the sick, kept them in different buildings—and the disease was stopped pretty promptly; and, in talking with him about it, I told him I thought he had not made the experiment fairly. If belladonna is protective against scarlet fever, these boys might have run among the sick just as well as be isolated—shut off from them—but the isolation had been tried a hundred times before, and we knew that that was protective. If no poison had access to the system, the children would not have scarlet fever, and my own impression is that this is about all the prophylaxis there is about it: that if children are not exposed to the poison they will not get the disease. I do not believe belladonna has the power to protect one who is exposed to the poison.

LECTURE IV.—MEASLES.

I CALL your attention now to another of the eruptive diseases—measles. A disease so mild in many cases that the family do not call a physician; and yet so severe in many as to make a pretty large mortality in a city like New York. You will be surprised, perhaps, to hear, if you know anything about the course of measles as it most commonly presents itself, that the mortality here is two, three, or four hundred a year, varying very much; down below a hundred many years, and up to two or three hundred, or more, some years. The explanation of this lies partly in the fact that measles is a more prevalent disease than scarlet fever. If you look into the medical register, or any medical journal that reports the number of contagious cases that occur in the city week after week, you will see almost invariably that measles is two or three times ahead of scarlet fever in the number of cases.

It is, then, sometimes a very grave disease; at other times a very mild disease. I will describe it to you in the same manner that I did scarlet fever, by marking the several stages.

It is only to be had by contagion. It does not arise *de novo*, even from decomposing oat-straw! A western physician made this a source of measles for the young members of the army in the late war; but there is no good ground for the opinion that I can see. Measles is obtained from measles, and from nothing else.

The period of incubation is not definitely fixed. Indeed, it *is* fixed, and we have ascertained that it is *irregular;* that it is uncertain. As for example, Dr. Buell, who lived in New York a good many years ago and moved to San Francisco, recited to a medical society his experience with reference to a house down town, in College Place. College Place was then a place of residence; it is now a place of stores. At a boarding-house there a lady with two or three children was so unfortunate as to have measles break out among them. As soon as it made its appearance, the boarding-house mistress, conscious that it would injure her business by causing other boarders to leave, required this one to go out of the house. The room was left unoccupied for a week, when another family came in to occupy it with children also. In seven days from the time they entered that room measles broke out in the family. The landlady drove this family away and another took its place, and in seven days after the third family came in measles broke out among their children, so that for two particular instances seven days was the period of incubation. But there are other instances that can be quite as well marked in which it goes on to eight, nine, ten, or even to fourteen days. The period is given very variously by the different persons who have written about the disease. As for example, Holme makes it from seven to fourteen days; Williams, from six to sixteen days; Rilliet and Barthez, five to thirty, and even fifty days; and they are very good authority. Their statements are received as statements made on careful observation.

I should doubt very much whether it has an incubation of fifty days; at the same time I cannot limit possibilities in the matter.

When, then, it makes its appearance in different persons, at a variable period after exposure it has its stage of invasion, and this is pretty long for an eruptive disease; the longest of them all, three to four days. It is rarely ushered in with a chill, though cases are recorded in which a chill did occur as the first symptom. There is commonly, before anything very marked is observed, an indefinite feeling of not being well; *malaise*, as the French call it. And then comes a little febrile action, which increases day by day, and with that febrile action a redness of the eyes, and a little watery condition of them. The tears are secreted, and then there is the extension of the inflammation that was at first confined to the membrane of the eyes. On the outer membrane of the

eyes it extends into the nose and into the fauces, and so down gradually into the breathing tubes. You have, in a word, a catarrh, and the catarrh, when it is fairly formed, is attended by a peculiar cough in most of these children. The French have called it the "rire" cough, a harsh, coarse cough. The eyes run a good deal, the nose is a little hasty in that same business. There is some headache, the temperature is elevated moderately, and this condition continues for a period of from three to four days. The invasion of small-pox is two days, the invasion of scarlet fever from six or seven hours to twenty-four, the invasion of measles three to four days. The child is not very sick during this period of invasion, as a rule, though, as I told you, there is considerable fever, the temperature rising to 102°, or it may be to 103°.

Then comes the eruption. The eruption appears upon the upper part of the body first, and gradually descends to the lower part, just as scarlet fever does in the majority of cases, and yet there are exceptions. Measles may break out all over the body, or it may break out upon the back first, but the general rule is that it appears upon the neck and face first, and gradually descends. It takes it about two days to reach the feet in the greater number of instances.

The character of the eruption you may get an idea of from this portrait, and notice particularly the condition of the eyes. They are red, and so are the fauces and the bronchial tubes and the nasal passages—all reddened by this catarrhal inflammation. This eruption is sometimes called crescentic. I believe this is a fair representation of it, and you will hardly find a crescent in any of these spots of eruption. It is better described as being irregular in shape, varying somewhat in size, but rarely larger than a bean—sometimes in some degree linear and curved, but always varying. Every particular case of measles will give you a multiple form of eruption; it does not occupy, as the scarlet fever eruption does, all the skin. There will be healthy skin along between the several spots; red eyes, and a peculiar eruption of a dingy color, not bright red. The eruption lasts in any one spot about four days, and the whole eruption about six or seven days, it disappearing on the feet after four or five days of continuance, as it does upon the upper part of the body in the same period. You observe there is no difficulty in distinguishing the eruption of scarlet fever from the eruption of measles. They are both produced by numerous slightly elevated little points, the loops of the capillaries of the skin, but the irregular patches of measles and the darker hue of the eruption are sufficient to distinguish it from the continuous eruption of scarlet fever.

In a mild case, as in scarlet fever, the fever gradually diminishes after the eruption appears, but in a bad case the fever continues and the temperature rises. The bad cases are made by certain complications. As for example, there is the hemorrhagic form of measles, in the old time called black measles. The patches take on a dark, ecchymotic color—not so marked as ecchymosis, but still approaching it. In this case, as in the hemorrhagic cases of scarlet fever, the danger becomes very great, and the chances of recovery of course are diminished. In certain other instances there is a tendency to gangrene, particularly about the mouth; and in the female, the vagina, and sometimes about the anus. And this gangrene comes to be a very grave matter. It is exceptional, fortunately.

Then, again, you have a form of measles that resembles, in its general symptoms, that form of scarlet fever I described to you under the name of scarlatina maligna. The child appears to be overwhelmed by the poison that produces the disease. The nervous system seems to give way. He becomes delirious and comatose, perhaps awakening occasionally from his coma, making a shriek, a hydrocephalic cry, though there is no hydrocephalus.

You observe then, that measles, though in a greater number of cases a very mild disease, can take on very grave symptoms.

When the period of desquamation occurs, there is a noticeable difference between the desquamative scales of scarlet fever and measles. They are branny in measles, and branny for the most part in scarlet fever, but the scales are larger in scarlet fever than in measles, as a rule. Sometimes in measles you have it in great quantities. I have scooped it up in teaspoonfuls from the sheet on which the patient lay. There is nothing of the glove-form of exfoliation in measles.

There is, as a sequela of measles, a very considerable amount of coma, as it is sometimes called—a bad catarrh; running at the nose; the eyes retain their redness frequently for a considerable time; the cough holds over, and may continue for some months. And persons have been known to pass into phthisis, tuberculous disease of the lungs, out of measles.

As to the treatment of measles, the mild cases hardly require any. The catnip-tea that the mother gives us as about as good as anything. And when you come to the severe complications you are baffled very much, because you can hardly find anything that will have much influence over it. If it is the hemorrhagic form, why, then, iron and the vegetable acids, together with the supporting effects of quinine and food, will probably do more for you than anything else, if you can save the case at all. If it is attended by gangrene, there is nothing that has as good a reputation as quinine, and you of course support the power of the patient by alcoholics as far as your judgment will require. In the malignant form I do not believe you will find any medicine do much good. If ergot has the control that it has the reputation of having over the capillary circulation, it may be possible that it may have some effect upon this form of disease. It has not been tried, so far as I know, and I do not know that it would be useful. Cold to the head, cold to the body as the temperature becomes more and more elevated, is certainly admissible and desirable, to reduce the temperature to a safe point at any rate; and in measles the temperature rises in the bad cases sometimes to 106° or 107°.

There are a few things more to be said regarding measles. I neglected to say to you that another name for it is morbilli. Among the symptoms is rather a curious one; an odor like that which comes from the nest of mice—a mouse-odor. In any case of pretty full eruption you will be likely to find it.

Among the sequelæ will be found, not unfrequently, indeed pretty commonly, a certain amount of nasal catarrh, and this may continue for some weeks after, and associated with that, very commonly, is a pulmonary catarrh. One of the features of the disease, and with its early development, is this catarrhal affection of the mucous membrane of the eyes, nose, and breathing-tubes, and this holds over in a considerable number of cases, and not unfrequently gives some anxiety, and the anxiety is in a few cases well founded, for this disease and typhoid fever are followed more frequently by phthisis than any of the other acute affections that I know—by a tubercular

phthisis. Still the vast majority of persons who have measles recover from it wholly.

This ophthalmia is sometimes the occasion of some trickery. I was, a great many years ago, in company with a gentleman from the south. His eyes were red and inflamed to a certain extent, and I saw at once that it was a peculiar relic of the measles. After dinner the entertainer's son asked me what that young gentlemen had better do for his eyes. He had been to an advertiser, and the advertiser had informed him that it would cost him $500 to be cured, and the friend asked me whether it was worth while to pay it. When I learned who it was that he had applied to, I told him certainly not, but to go to Dr. Delafield, the father of my colleague (who was then giving considerable attention to the eyes), and let him put him under the regular treatment. He had sent word to his father to forward to him the $500 as a fee that he had to pay to cure his eyes. Instead of it, however, at my advice, he went to Dr. Delafield. Dr. Delafield applied around the eyes some veratrum ointment, and in five, six, or ten days, he was all right, and the fee was $19. This advertiser had tricked him in this way. When he urged that $500 was a large sum to pay, the advertiser replied: "The medicine is so expensive. You get the medicine and I will treat you for very much less." He gave him, therefore, a prescription for an ounce of veratrum, which at that time cost about $500. He called on one druggist with the prescription. The druggist said: "I have not that amount, but I can procure it for you." "Well, what will it cost?" "Four hundred and seventy-five dollars."

He went to another, and what would it cost? He had not that quantity, but he could get it for him. What would it cost? Four hundred and eighty dollars. And, after trying three or four times, he went back to the advertiser and said he could not do any better, and the advertiser was getting ready to use a few grains of this ounce that he had prescribed.

Occasionally wry-neck follows measles. The muscles of the neck get stiff and contracted, and turn the head. That is rather a wearisome thing when it occurs. It occurs exceptionally, and frequently requires a good deal of patience on the part of the physician, and I cannot tell you of any particular prescription, or any method of treatment that is of special aid.

Anasarca not unfrequently follows scarlet fever. It is a very much less frequent sequela of measles, and yet it does from time to time occur, and acts in the same way, with the same symptoms, the same developments with reference to the tendency to convulsions, the tendency to the production of inflammatory action, particularly about the heart and pericardium, and will require the same treatment. But its unfrequent occurrence will give you a little satisfaction. That is, as you are coming to the end of a case you will not consider that, as a matter of course, this œdema or anasarca is to occur.

The Cinchona Cure for Intemperance, by Dr. Chas. W. Earle. The claims of cinchona rubra as a specific for the cure of drunkenness was loudly heralded in Chicago a short time ago. Dr. Earle finally made a careful examination of the subject, and concluded that the cinchona treatment made more drunkards in the past year than any one liquor saloon.

Original Communications.

THE CAUSE AND TREATMENT OF GENU VALGUM.

By CHARLES T. POORE, M.D.,

SURGEON TO SAINT MARY'S FREE HOSPITAL FOR CHILDREN, AND TO CHARITY HOSPITAL, NEW YORK.

Part I.

The treatment of the deformities at the knee-joint, known as genu valgum and genu varum, has, until the last few years, been unsatisfactory, their causes have not been clearly recognized, and cases have been reported as belonging to this class which evidently should not have been so placed. Patients with these deformities have been reported cured under one mode of treatment which has entirely failed when applied to others seemingly not more aggravated. Much of this uncertainty is due to a misapprehension as to their real cause, and placing cases of different pathological conditions under one head. The following paper is a contribution to the study of this subject, and is based on a careful examination of thirty-six cases seen within the past year. The subject naturally divides itself into two parts, namely, the cause and treatment of genu valgum.

Genu valgum may be defined as a deformity in which the long axis of the tibia, when the leg is fully extended on the femur, inclines outward from the median line, and forms, with the long axis of the femur, an angle with its apex directed inward, so that the malleoli cannot be made to touch. Genu varum is the reverse of the above.

There is always more or less of an angle, with its apex directed inward, formed on the outer side of the knee-joint by the femur and tibia. In some persons this is more marked than in others, being due to a greater slant inward, toward the median line, of the femur. This is more commonly found in females than in males, and is due to the greater breadth of the pelvis; but in these cases the internal malleoli can be made to touch when the limbs are placed together—a position they cannot assume in genu valgum. This condition is not a deformity, and should not be confounded with knock-knee.

If one examines a perfectly normal adult femur, it will be found that the internal condyle is about half an inch longer than the external, when the bone is held perpendicular; but when it slants, as it naturally does, the condyles are on the same plane. This must needs be, as the plane of the knee-joint is horizontal in adaptation to the erect position. Any lateral deviation of the tibia from the median line, the joint being healthy, must be due to changes taking place in the extra-articular tissue. Three theories have been advanced to explain the cause of genu valgum: namely, the ligamentous, the muscular, and the osseous. Those who advocate the first, attribute the deformity to relaxation of the internal and contraction of the external lateral ligament; those who adopt the second, consider that the malposition of the tibia is due to contraction of the biceps; those who hold to the osseous theory refer the deformity to inequality in the plane of the two condyles, or of the articular end of the tibia, while some attribute the deviation to a combination of the above theories. During the past year I have

examined carefully thirty-four cases of genu valgum and two of genu varum, with the following result:

In thirty-five cases the deformity showed itself before the fifth, and in one not until the thirteenth year. In twenty-five cases of genu valgum the internal condyle of the femur was on a lower plane than the external, and in two cases of genu varum the external condyle was on a lower plane than the internal. In one case the internal condyle seemed of normal length, while the external condyle was much smaller than that of the other limb which was not deformed. In four the internal condyle of the femur was on a lower plane than the external, and the *inner head* of the *tibia* was on a *higher* plane than the external head. In one case the internal condyle was on a lower plane than the external, the head of the tibia being normal, while on the other limb the inner head of the tibia was enlarged while the femoral condyles were normal. In two cases the femoral condyles were perfectly normal, but the inner head of the tibia was greatly hypertrophied. In twenty-eight cases the deformity affected both limbs; it was confined to the right in one, and to the left in four cases. In four cases the femur was curved, in one outward, in three outward and forward in its middle and lower third. In four the tibia was curved forward, and in two outward. I have seen two cases in which there was genu valgum of one limb and genu varum of the other, but I have no notes of these cases. In one case the epiphyseal line of the femur seemed tender on pressure. In some cases the ligaments about the knee-joint were very much relaxed, while in others they were quite firm, and considerable force had to be used to cause any yielding. I have seen two cases, one of genu valgum, the other of varum associated with excurvation of the tibia (bow-legs).

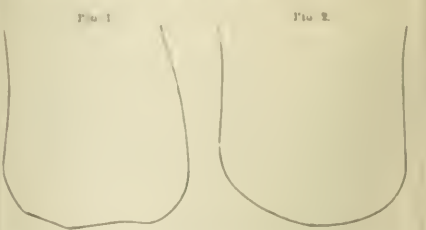
In none of these cases was there any disease of the joint, nor was there any contraction of the muscles about the knee-joint, nor any flexion of the leg on the thigh, when the patient was placed on his back.

In all these cases, except one, the deformity disappeared on flexion of the leg on the thigh.

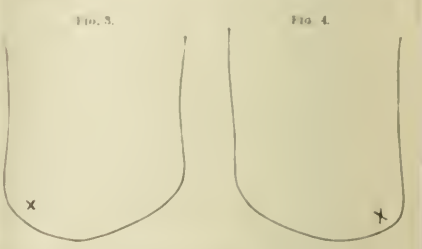
From the above statement it is evident that the malposition of the tibia was in all cases due to a change in the relations of the articular ends of the femur or tibia, or of both.

In twenty-five cases the deformity is said to have come on after the patients began to walk. Two at the time of first walking, and six before that period. These cases may be divided into two classes, namely: I. The infantile—those occurring before the fifth year. II. The adolescent—those occurring after the tenth year. Genu valgum is rarely, if ever, congenital.

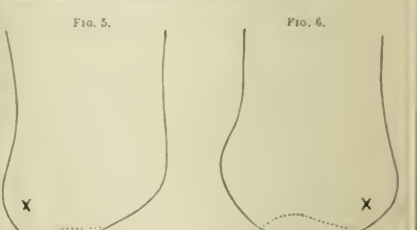
I. *Infantile.*—In thirty-one cases the children showed marked signs of a rachitic condition of the bones. There are but three ways in which one condyle can assume a lower plane than the other, namely, first, by incurvation of the inferior third of the shaft of the femur. That this is undoubtedly the sole cause in some cases, has been demonstrated at post-mortem examinations by Guéniot, Saurel, Barbier, and others. In some of the children I have seen this curvature of the femur at its lower third well marked, and evidently contributed to, if it did not entirely cause the malposition of the tibia, while in other cases it entirely failed to account for the deformity. Thus, in a woman thirty-six years of age, who had had a marked genu *varum* from infancy, there was a curvature of the lower third of the femur convexity *inward*. Secondly, there are a number of cases in which there is no appreciable bending of the shaft of the femur; yet the internal condyle is depressed even in children who have never walked. Thus, in a child two years of age who had never stood upon her feet, and in whom there existed a marked genu valgum, the internal condyles were much depressed, as shown by the following tracings:



Figures 1 and 2 exhibit the tracings of the articular end of the femur of two children free from any deformity.



Figures 3 and 4, from a child with double knock-knee, the x indicates the internal condyle.



Figures 5 and 6 are from a child who exhibited a marked knock-knee on the left side; none on the right. She was four years old, and had it from infancy. The dotted lines indicate the position of the patella.

The tracings were taken over the middle of the articulating surface, parallel with the long axis of the femur. The same thing has been demonstrated at post-mortem examinations (Guéniot). In the rickety skeleton it has been found that the external condyle was flattened and thickened, while the internal was increased in a vertical direction, or remained normal. There may also be a true hypertrophy of

the internal condyle in which it is longer and narrower than normal (Lannelongue). In the case mentioned above of genu varum the external condyle extended out as a long narrow outgrowth in a direction downward and outward, and was evidently the cause of the deformity.

The inner head of the tibia may be changed, occupying a plane higher than its outer head. I have seen two cases in which the deformity was due to this alone. In one case it occurred in a child fourteen months old, who had *never walked*. There was no bend of the femur, or tibia, the femoral condyles were in normal relation. The inner head of the tibia was three-eighths of an inch higher than its external. The inner portion of the articulating surface of the tibia seemed raised, as it were in a mass, and not gradually sloping to the plane of the outer head.

In four cases the deformity was due to the above changes taking place in the articular ends of both bones. Sometimes the changes in the shape of the bones about the knee-joint are more complicated—the tibia twisted so that its crest looked almost directly inward. In the examination of an adult skeleton (by Berger), the articular ends of the femur were normal, but the tibia was twisted inward from the middle of its diaphysis upward. The articular surface of the tibia was not horizontal, but inclined from without inward and upward, so that the styloid process of the fibula formed a part of the articulating surface of the knee-joint. I have seen one case where the tibia was much deformed, being twisted outward, and the articular ends both of the femur and tibia were greatly changed. Other changes have been found in the epiphyses of the femur in rachitic subjects. Thus, they may be twisted to one side on the diaphysis (Senator, Humphrys), they may be flattened and bulged out in all directions, etc.

The primary causes of these changes is evidently a rickety condition of the bones. The secondary or immediate, in some cases, is not so apparent. Mr. Barwell holds the opinion that the deformity of knock-knee is not due alone to change in the lower end of the femur, but that in all cases the tibia takes part in its production. Post-mortem examinations do not seem to warrant so sweeping a statement, although, in some cases, the articular ends of both bones are certainly involved. Relaxation of the ligaments of the knee-joint, or contraction on the one and relaxation on the other side, have been often assigned as the real cause of knock-knee, and that all changes in the bones are secondary. Billroth holds the latter opinion. Early in my study of these cases it became evident that the state of the ligaments was not the same. In many cases lateral motion in both directions was free. The tibia could be brought into its normal position, or even be carried beyond it, without the use of any force. In other cases there was no lateral motion either inward or outward, and no change could be made in the lateral position of the tibia without the use of considerable force. Active contraction of a ligament placed about a joint to limit motion or guard a position, is an impossibility. That they are shortened sometimes is a fact, but it is a secondary and not primary condition—not a cause, but an effect. In regard to contraction of the biceps as the cause of genu valgum, I have never seen it in this deformity, and the result of tenotomy in these cases does not seem to have been followed by success. Langenbeck, who formerly advocated this operation, has abandoned it as useless. There are cases reported in the medical journals where tenotomy has been rapidly followed by a cure; thus, Kelly, in the *Med. Press and Circular*, reports some cases cured by tenotomy and apparatus. What was the true pathological condition is not stated. Lately, Mr. Brodhurst (*Brit. Med. Journal*, June 14, 1879) exhibited, at the Clinical Society of London, a marked case of knock-knee in a patient of seventeen years in whom it has existed since childhood, and on whom he had done a tenotomy of the biceps and the external lateral ligaments, and then forcibly straightened and applied a splint with a cog-wheel, so as to gradually bring the tibia into its natural position. At the time of exhibition, four months had elapsed since the operation; the knee-joint was very lax, and the patient was still compelled to wear the splint. Mr. Brodhurst stated that the internal condyle was *not* elongated. Macewen (*Brit. Med. Journal*, Oct., 1879, p. 607) states that "in over one hundred cases in every case the articular surface of the internal condyle has been found at an abnormally lower level than the external." Parker, Barwell, Jones, and other English surgeons have expressed similar views.

A lax condition of the ligaments about the knee-joint may, in rickety children, by changing the direction of support, cause a bend of the lower end of the femur inward, and thus depress the internal and raise the external condyle. Undue mobility at the ankle-joint and talipes valgum will act in the same way, but the existence of a weak ankle, or a talipes valgum with genu valgum, should not always be accepted as a proof that it is an exciting cause. These deformities are often secondary to a knock-knee. In fact, it is seldom that we see a case of genu valgum in a rickety subject who has walked that is not accompanied with flat-foot. In children who have never walked this latter deformity is very frequently wanting.

That the deformity is not always due to too early use of the lower limbs in walking and standing is evident from the fact that genu valgum is found in a marked degree in children who have never used their limbs, and it has appeared before the period of walking. The case mentioned above is an illustration of this fact. There are some cases in which there is no bending of the femur or tilting of the epiphysis, but where there exists a real lengthening of the internal condyle, that must be attributed to true growth. The increase in the length of the internal head of the tibia mentioned above seems to point to this explanation.

Inequality in the length of the lower extremities has been mentioned as a cause. This condition, associated with weakened and lax ligaments, might aid in the production of the deformity in rickety subjects. I have seen one child whose left limb was three-eighths of an inch longer than the right, and in whom there existed a genu valgum of that limb, but none on the right side.

There is a deformity at the knee-joint that has been mistaken for knock-knee, namely, a contraction of the adductors and of the tendo Achillis, with some flexion of the leg on the thigh. The feet are turned inward. Any one can imitate this deformity. This is not genu valgum, and should not be so classed. May not some of the cases of rapid cure of knock-knee belong to this category?

II. *Adolescence.*—In a number of cases knock-knee does not show itself until after the tenth or twelfth year. When all danger from rickets has passed, a period corresponding to the time when the bones are rapidly lengthening, and active nutritive changes are

going on about the epiphysis. This period varies in different individuals, but may be said to extend from the tenth to the twentieth years. These patients have never been affected with rickets, as a rule, the development of the deformity is rapid. I have seen but one case belonging to this class. It occurred in a girl fourteen years of age. She had always been weak, but she was of fair size. It began to show itself eight months before I saw her, and then existed to a marked degree in both lower extremities. There was no abnormal bending of the femur or tibia. No enlargement of the epiphysis at the ankle or wrist joint. The internal condyles were enlarged. Both in England and on the Continent cases belonging to this class are often met, and various theories have been advanced as to their cause. According to the statistics of Mikutiez, bakers, factory-workers, locksmiths, and waiters, are most prone to this form of knock-knee. The statistics of English surgeons, as far as a careful reading of their cases goes, do not corroborate the above statement, although the vast majority of cases occurred among the laboring classes. In many of the reported cases no mention is made of the previous history of the patient, or the assigned cause. According to De Santi, the deformity is more common among boys than girls. The latter author reports a case in which the deformity came on at the age of ten, after an attack of articular rheumatism. Duval makes a similar statement. Some German surgeons have reported it common among bakers, and Wagner states that "this arises from want of resistance exercised from the corresponding portion of the tibia, standing for hours at a time with bent knees," but he does not state why the internal condyle alone should be thus hypertrophied, for both are placed exactly in the same condition, pressure being taken off from both when the leg is flexed. This elongation of both condyles is found in the persistent and long-standing flexion of the leg on the thigh from disease, and is one of the causes, if not the only one, of a failure to bring the tibia into its normal relations with the femoral condyles.

Some surgeons of the French school have advanced the theory that this deformity we are considering, occurring in children over ten years of age, is due to an epiphysitis situated over the internal condyle or below the inner head of the tibia, and refer to cases in which marked tenderness over the epiphyseal cartilage had been found (Vernenil).

In many cases the development of knock-knee had followed ill-health or a severe illness, as typhoid fever, the deformity coming on during convalescence.

Recently Mikutiez has made a careful examination of sections of the femur, taken from those who have had knock knee. He found that the deformity in genu valgum is just above the epiphyseal line; that in the cases he examined the epiphyses were not materially affected, and that the deviation was in the lower part of the shaft of the femur alone. In regard to the tibia, it was demonstrated that the obliquity affected only the upper part of the diaphysis and was caused by an uneven growth of the diaphysal junction. From an examination of the accompanying plate, the deposit would seem to occupy the space between the diaphysis and the epiphysis—namely, the cartilage.

This is certainly at variance with the result of the post-mortem examination of other surgeons.

Trippier, Vernenil, Lannelongue, Guéniot, and others have found a real lengthening of the internal condyle in a longitudinal direction and a narrowing in an antero-posterior direction, and not a simple depression of the condyle from a thickening of the cartilage above it.

Genu varum has been caused by an (acute) atrophy of the internal condyle. I know of but one case, and that is reported by Mr. Howse, of Guy's Hospital, who, in 1875, excised the joint in a girl fourteen years old for a genu varum in right limb, coming on after an attack of whooping-cough two years previous. The internal condyle was found to be greatly atrophied. The child, previous to her tenth year, had had straight limbs. She was a delicate, strumous-looking child.

Does true knock knee ever occur without changes in the articular ends of the bones? From my personal observation I should certainly answer this question in the negative. Nor have I ever read of a case where there has been absolute evidence of the absence of inequality in the plane of the condyles or heads of the tibia. Yet from the record of cases reported in medical journals, I must confess, if they were cases of true knock knee, there could not have existed any change in the articular ends of the bones, for it would have been impossible to rectify the deformity in the short time that is said to have been consumed in their treatment.

There are at least two other causes of genu varum and valgum—namely, disease of the bone near the articular end of the femur or tibia, and arthritis in those somewhat advanced in years. As these are strictly inflammatory in their nature, their consideration is omitted from this paper.

Conclusions.—Genu valgum and varum, as a rule, appear before the twentieth year.

The deviation of the tibia is due to changes taking place in the articular ends of the femur, or tibia, or of both.

The anatomical lesion in genu valgum is:

1. A depression of the internal condyle of the femur, due to a curvature with its convexity inward of the inferior third of the shaft of the femur.

2. To a flattening or atrophy of the *external condyle*.

3. To a true hypertrophy of the internal condyle.

4. To a hypertrophy of the inner head of the tibia, or a flattening of its external head.

5. To the above changes taking place in both the femur and tibia.

ON SOME IMPORTANT ADVANTAGES TO BE SECURED BY OBLIQUE SECTION OF THE SKIN IN SURGICAL OPERATIONS.

By JOHN H. PACKARD, M.D.,

OF PHILADELPHIA.

Read before the New York Academy of Medicine, May 6, 1880.

MR. PRESIDENT AND GENTLEMEN:—In the great majority of the cutting operations of surgery, it is an object to obtain as early and as effectual closure of the wounds made as possible. The exceptions are those which are undertaken for the purpose of establishing artificial openings, as for example tracheotomy, colotomy, gastrotomy, etc. And in ligation of arteries in their continuity, the presence of the ligature must of course prevent the closure of the track in which it lies. Yet in almost all even of these cases, the wound in the skin must be of such extent that a large portion of it may be healed without interfering with the result aimed at; while not only the comfort but the well-being of the patient is promoted by the

early exclusion of the atmosphere from the deeper tissues.

Another advantage is gained by the avoidance of unnecessary scarring. There are many cases of excision of tumors about the face, neck, or hands, in which the persistence of unsightly marks would give rise to a degree of mortification to the bearers of them, which it is not beneath the dignity of surgical science to endeavor to prevent. And I think it may be asserted that whatever adds to the precision of our procedures, or to the elegance and neatness of our results, is worthy of a place among the resources of our art.

Unless exception is taken to the correctness of these premises, an apology will hardly be needed for the suggestions to which your attention is now asked.

About six years ago, my attention was accidentally called to the fact that after oblique division of the skin, healing took place readily, and the resulting scar was small as compared with that usually left by vertical section. I was summoned to a woman who, while carrying a glass dish, had fallen and sustained a very severe wound of the hand from a sharp fragment of the glass. This wound was on the back of the hand, and extended from the wrist to the knuckle of the ring-finger. By the peculiar position of the edge of the fragment, the skin had been cleanly divided in an extremely oblique direction. Healing took place promptly, and to my surprise and the patient's gratification, the cicatrix was very much smaller than might have been expected after an injury so formidable in appearance as this had been.

It occurred to me to imitate this accident in surgical procedures, with the view simply of lessening the ensuing disfigurement—nor was I disappointed. On one occasion, having removed an old bursal tumor from over the patella, I was unable to find the line of junction between the edges of the section of the skin.

Now the mere lessening of scars has more than a cosmetic value. Every one knows how apt they are to be for a long time the seat of tenderness, sometimes exquisite, and how sensitive they often are to cold, as well as to barometric changes. By reducing the exposed portion of cicatrix, we do much to obviate these inconveniences, which are especially annoying to the working classes, among whom the accidents requiring operation are by far the most frequently met with.

Another danger to which scars are very liable is that of the development of keloid tumors; and the closer the union, the less of what a few years ago was called by microscopists *inodular tissue*, the less will be the probability of this very troublesome and intractable disease.

Quite recently it has occurred to me to develop another and I think much greater advantage of the oblique section of the skin, namely, the avoidance of suppuration, and the obtaining of very prompt and firm union between the cut surfaces. The rationale of this advantage can be easily seen. We have a close apposition of very wide surfaces, with exclusion of the air from the cavity of the wound, by means of a strictly valvular arrangement—the apposition of the edges being moreover favored by atmospheric pressure.

An application of the same principle in the arts affords an excellent illustration of the idea I am trying to urge.

It is often necessary to make belting, for the use of machinists, of a length much greater than could possibly be got from a single strip of hide. Hence several pieces have to be put together, and this joining or splicing must be done so as to be as strong as possible. For this purpose the ends of the pieces are bevelled off, or, as the technical phrase is, are *scarfed*. Sometimes they are said to be chamfered, a term borrowed from architecture, and usually corrupted into *chamfered*.

These scarfed edges being then applied to one another, and fastened either by gluing or by rivets, afford at the same time a very strong connection, and one which involves no thickening of the belt, which would interfere with its running. It is indeed often difficult to detect the exact line of junction.

The scarfing is done by means of a machine, with very great accuracy. I exhibit samples of it, and they will show the principle better than any description could.

Sometimes the scarf or bevel is made very long, and then of course it approaches much more nearly to parallelism with the surfaces of the leather. I measured the junction between two pieces of a belt in use, a few days since, and found it twenty-two inches.

Let me now briefly state a few typical cases in which I think I may claim that this procedure has been the direct means of effecting the best possible results.

A woman, æt. 52, came under my care with a mammary tumor requiring excision. The skin was very slightly involved. By means of two bevelled incisions I removed a mass equal in bulk to that of my two fists—going well into the healthy areolar and adipose tissue around the gland and tumor. A number of vessels which required ligation were secured with carbolized catgut, the ends of which were cut off short. The oozing of blood was thoroughly controlled by constant sponging with hot water, and the surface of the cavity, at the conclusion of the operation, was perfectly dry and clean. The wound was closed with three points of the hare-lip suture, and adhesive strips. Carbolized cerate was applied as a dressing, and gentle, equable pressure made with a wad of raw cotton.

On the third day the pins were removed. On the fifth the wound was found to be solidly united from one end to the other, there not having been a fluid drachm of pus formed.

Another case was that of amputation of the forefinger at the metacarpo-phalangeal joint, for injury by the thrust of a needle, causing cellulitis and wasting, with painful atrophy of the soft parts. The incisions were so made as to bring the cicatrix on the upper part of the stump, the outer flap being bevelled from within outward, the inner from without inward. Here there was some subsequent pain, and a dressing of hot laudanum was applied for about twenty-four hours. A perfectly dry healing ensued, with an absolutely linear cicatrix. No dressing whatever was used after the third day, a strip of dry lint only being put on as a protection.

Another case was one of strangulated inguinal hernia of the right side, operated on April 19th. The incision was made by carrying the knife in very obliquely, and dividing the skin in that manner for the requisite distance. The hernia was reduced without opening the sac. One vessel required ligation, which was done with carbolized catgut. Four or five hare-lip pins were employed for the closure of the wound, and one silver-wire suture, fastened with lead plates at either end, through the deeper tissues. A superficial silver-wire suture was also

used at the lower end of the wound. All these sutures were removed on the third day. No dressing was used but carbolized cerate, with a thin sheet of raw cotton over the whole of the region involved. The healing, although not absolutely dry, was very nearly so; there was never more than the $\frac{1}{4}$ of pus on the lint taken off. The cicatrix is a mere hair-line in appearance, and there is no tenderness, even on firm pressure.

No argument is necessary to show the advantage, in such a case as this, of a firm and deep union of the edges of the wound, with as small an amount as possible of cicatricial tissue to be pressed upon by the truss, which prudence will oblige this patient to wear for a time.

These cases have been selected as typical of the various classes of operations, and will answer as well as a much longer series in illustration of what I think is the value of this method.

Bevelling the edges of wounds made in rhinoplastic operations has been practised by many surgeons, notably by the elder Pancoast, of Philadelphia, whose "tongue and groove" suture was a marked element of the brilliant success of some of his procedures of this kind. It has not, however, been generalized in the practice of ordinary operative surgery, as in my humble opinion it may be to great advantage.

There are cases in which it is desirable to employ drainage, either by means of a tube of silver, rubber, or decalcified bone, by carbolized silk or by horse-hair. I am well aware that the need and advisability of this is doubted by many surgeons, and am ready to admit that drainage has been employed by some in a wholesale and routine manner, in every case, with perhaps injury to the patients, or at least to some of them. But when it is thought proper to establish an outlet, this may be done perfectly well with oblique section of the skin. Indeed, if desired, a sufficient portion of the incision may be made in the ordinary vertical method, at a suitable point, and the remainder may be made obliquely, so as to promote its healing.

I have not yet employed this oblique method of incision in any large amputation, as I have been experimenting with it in order to make sure of my ground; but should confidently look for like advantages in such operations as in those above mentioned.

It is a matter of much importance that the scalpel or bistoury used should be very sharp, in order to make the cuts with the utmost accuracy. The plane of incision should be as much inclined as possible. Of course the apposition of the cut surfaces should be most carefully and exactly effected, and where a cavity is left, as by the removal of a tumor, gentle and equable pressure should be so made as to close the tissues in and fill it up. Carbolized cerate forms an excellent immediate dressing, with or without laudanum, alcohol, dilute tincture of iodine, or other customary applications. My own preference is for the laudanum, with a wrapping of raw cotton, generally covered with waxed or oiled paper.

May I with much diffidence venture to hope that the modification which I have had the honor to urge upon your attention may be found really to be a contribution to that antiseptic surgery at which we must all aim?

Bills to Establish Marine Hospitals at New Orleans and Baltimore have been reported to the House of Representatives.

CONVERGENT SQUINT—CAUSES, RESULTS, AND TREATMENT.

By C. A. BUCKLIN, M.D.,

SURGEON TO NEW YORK EYE AND EAR INFIRMARY; LATE HOUSE SURGEON TO METROPOLITAN OPHTHALMIC HOSPITAL

In ninety per cent. of all cases of convergent squint, the eyes deviate by active muscular exertions, which are made for the purpose of obtaining distinct vision. The eye may deviate in consequence of a paralysis of one of the recti muscles. In another case it is drawn over by inflammatory contraction of one of these muscles. Exceptional cases are found where the eye, having lost its vision, and, therefore, having no incentive to direct its visual axis, wanders in the direction of an abnormally powerful muscle. Seventy-seven per cent. of all cases of convergent squint are far-sighted (Donders). It is, therefore, fair to conclude that there is a connection between far-sightedness and squint. This connection has been the darkest chapter in ophthalmology. The difficulties which the prevailing school of ophthalmologists meet, are contained in the following questions:

Why is it that seventy-seven per cent. of all convergent squinters are *far-sighted*, and not *one* per cent. of far-sighted individuals squint?

Why do many who are *not* far-sighted squint?

Let us explain the nature of *far-sightedness* (hyperopia), and then we will examine the prevailing reasons which are given why some far-sighted people squint, and also the reasons why they do not squint.

A far-sighted eye has so short an anterior posterior diameter that the inverted image formed by the crystalline lens falls behind the retina. A far-sighted eye, when at rest, only acquires as acute vision for distant objects as a normal eye by increasing the thickness of its lens by active exertion of its ciliary muscle.

It is a mistake to suppose that, when the term far-sighted is used, an eye is designated that is especially adapted for distant vision. The term is applied to an eye which, when at rest, is not adjusted for any distance either on the earth or in the heavens, and only becomes adjusted by active muscular exertion. The normal eye, on the contrary, is adjusted when at rest for all distances beyond 20'. It is, therefore, readily understood that when a near object is observed from which divergent rays of light are received, the far-sighted eye must increase the thickness of its lens to a much greater extent than the normal eye (accommodation), in order to bring the inverted image far enough forward to have it fall upon the retina.

In addition to accommodating to receive distinct images of the object, we must converge our eyes in order to bring both of them to bear on the object. The stronger we *converge* the stronger we can accommodate; there is, therefore, a connection between them. The far-sighted person may find, when he has fixed both eyes upon an object 12" distant, he cannot accommodate for this distance till he has converged his eyes at a point 6" distant.

But, when converged for the latter distance, although focused for the former distance (12"), his eyes are not directed at the object he wishes to observe, consequently he is unpleasantly situated.

Should he by any accident find out that by converging one eye for 6" and leaving the other fixed upon the object he wishes to observe, the necessary amount of accommodation will take place in that eye as well as in the converging eye, would he not be

foolish *not* to resort to this "trick" (Mauthner) when by so doing he sees with perfect distinctness, or would he, out of the desire to see the object with *both eyes*, prefer not to see it distinctly. I think he would see it distinctly if he knew how.

Prof. Donder's work on "Accommodation and Refraction of the Eye" is the authority most frequently consulted by my friends. I therefore will give what he considers factors, which will *prevent* a far-sighted individual from making use of this ingenious trick for obtaining distinct vision, and those factors which will favor his learning to squint.

I confess that, after long and careful consideration, I have not been able to convince myself that any of the factors which he gives in any way determine whether the far-sighted individual shall squint or not.

First.—"The necessity of seeing an object singly with both eyes is deeply felt. The direction of the visual lines is thereby forcibly determined. Of this I convinced myself years ago by observing the rapidity with which double images were made to vanish when a prism of glass was placed before my eyes, and also again when it was removed. This abhorrence of double images, or rather instinctive adherence to binocular vision, prevents most hyperopes from strabismus. They sacrifice the advantage of seeing accurately rather than seeing double. In this we find the reason why not nearly all hyperopes squint."

He would have made a more striking remark if he had said the necessity of *seeing* the object is deeply felt in every individual whose nearest point of distinct vision at which he can direct both eyes is farther away than his work. He thinks it follows because *his* eyes, which when directed at a point 12″ distant, can see distinctly, do not find it agreeable to look through prisms and see double that one who cannot see distinctly at 12″ will not learn to disregard one object, when it is the *only* way by which they can ever possibly see an object distinctly at that distance.

Because he has no incentive or advantage from allowing retinal images to fall on different or not corresponding parts of his retinæ, but only disadvantages, he concludes that the squinter meets with the same experience. Ask every squinter you see, who squints for the sake of obtaining distinct vision, if he sees or ever saw double. He who cannot squint without seeing double don't know how to squint, and will not squint. To show that it is the abhorrence of double vision which prevents hyperopes from squinting, he says, if you cover one eye with the hand (thus removing the possibility of double vision) the covered eye in "*most*" hyperopes will deviate inward. This is reasonable, but not true of "*most*" hyperopes.

I will give a most favorable case for this experiment. Miss G—— has hyperopia in one eye, $\frac{1}{10}$, she cannot accommodate with it sufficiently to see small and near objects distinctly. The other eye is normal. She knows how to squint in so far that, if you say squint, she will deviate the axis of one eye inward, but she sees double when she squints. If we deprive one eye of its vision by covering it with the hand we have all the conditions removed which present squint, and all the conditions present which favor squint. The theory of poor vision in one eye, be it due to "*cortical cataract*," "*corneal spots*," or *refractive conditions*, falls to the ground. The necessary amount of hyperopia is present in the other eye to make squint necessary for distinct vision, still the covered eye does not deviate. This proves that for a person to squint, there is something more necessary than that all the conditions which prevent it are *absent*, and all the conditions which favor it are *present*.

I was formerly very enthusiastic in trying to trace the relations between squint and corneal spots, and also tried to convince myself and friends of the absolute necessity of the visual image being less distinct in one eye before the other eye could sufficiently lose respect for the visual impressions of its fellow to allow it to wander toward the nose. A case of squint, where one eye was normal and the other had a corneal spot and squinted, was regarded as a great triumph in favor of our "solid science." At last I found a case of the purest kind of squint—there was no corneal spot; there was no difference in the refraction of the eyes; the acuteness of vision was alike in both eyes. Among the many "why's and wherefore's" I had always been able to find one that would fit the case in hand, but this case certainly is not explained by any one which Donders gives. We had formerly found conditions existing in squint which we had supposed caused squint, but to explain the above case some other theory must be advanced.

We must therefore accept Mauthner's explanation. Squint is a trick which is frequently learned by those whose near point of binocular vision is beyond their working distance, let the cause be what it may, provided increasing the power of the ciliary muscle of either eye can produce a distinct retinal image. If any child is in the above "fix" and does not squint it is simply because he don't know how to bring it about; if once taught he never will forget it. He may imitate his playfellow and learn. It may strike him while trying to look at a spot on his nose or over the rail of a steamer. It often takes place during an acute attack of sickness which has slightly reduced the accommodation of the hyperope, and made him incompetent to perform his abnormally large task.

People always believe that whatever the child was occupied with at the time he learned how to squint, is the cause of the squint. They think their children have caught it from mocking some other child, or the reflection from the water caused it. None of these causes would have been sufficient had the child been able to see distinctly without squinting. Let us now see how squinting really assists to acute vision.

A person whose nearest binocular point is 24″ distant wishes to observe a small object only 12′ distant, but when he converges both eyes at this point, he is not accommodated for this distance, and it is only when he is converged for 6″ that he can accommodate for 12″; he certainly is in an unpleasant predicament. He must either fix both eyes on the object 12″ distant, and content himself with indistinct retinal images, or he fixes one eye (always the best one, if there is any difference) upon the object, he then ignores the retinal image of the other eye as best he can, and converges it for a point 6″ distant. By this manœuvre he is enabled not only to bring about an unusual amount of accommodation in the deviating eye, but also in the fixing eye. The amount of accommodation that can be brought about in the fixing eye by a given deviation in the other, is as yet a factor which remains for future investigators to measure. There are a few other statements in Donder's work which I must be allowed incidentally to mention.

"He says the size of the angle which the visual line and the optical axis form, determines the amount of hyperopia necessary to produce squint. He believes the angle 1.07° greater by those who squint than

those who do not squint. Other investigators have been unable to substantiate this fact. Admitting it to be true, it is interesting to see how he reasons to his conclusion. When this angle is great, the visual line has an abnormal inclination inward, therefore a greater amount of divergence is required to bring the visual lines parallel.

"Now if, in looking at a distance, the requisite divergence of the axis of the cornea easily falls short, the convergence will likewise, under the influence of hyperopia in looking at near objects, be relatively too great."

The above is a piece of profound science which I have heard ambitious teachers of ophthalmology inflict upon those who very innocently have asked, "why do so few hyperopes squint?" He is overwhelmed by the answer, and wonders why others understand so easily what is to him so confused. Admitting that the above condition may exist, it is not plain to any one how a condition which makes the amount of convergence necessary to fix a near object so little less than normal, can in any way produce squint. Javal says a great theory has been constructed on this little angle, which is more respected the least it is understood.

Donders says again, squint is not found in high degree of hyperopia, because the difficulties to be overcome are so great that the advantage derived from squint is not sufficient to tempt him to try and squint. It is true when the above is the case he will not squint, but I find squint in all grades of hyperopia, and I can see no reason why it should not be so. A child has an accommodation of about $\frac{1}{4}$; suppose he has an hyperopia of $\frac{1}{4}$, if he does not have to squint to see distant objects, he certainly will have to do so to see near objects. If he can see distinctly by squinting, it don't make any difference what the degree of hyperopia is, he will do it if he know how. Finally he remarks that paresis of the accommodation by itself is as little liable to produce strabismus as is the diminution of the range of accommodation connected with the increase of years. This is partly true and partly untrue.

If the paresis is so complete that no advantage can be obtained by throwing the entire energy upon one ciliary muscle, he will not learn to squint, but it sometimes happens that he does derive advantage from so doing, in which case he is liable to learn to squint.

An old person has a hard lens, and it makes no difference how much contraction he brings about in his ciliary muscle, he cannot change the form of his lens sufficiently to be of advantage to him, consequently he never will think of learning such a useless art as squinting. He will rather hold a candle between his paper and eyes, and overcome the difficulty by making his pupils small, thus diminishing the circles of diffusion.

Any one will squint if they can learn how, provided they can see distinctly by squinting, and cannot see distinctly without. I have not been able to convince myself that they will learn any quicker with the vision of one eye reduced than they will with an equal amount of vision in each eye.

Pleuro-pneumonia has appeared in one of the large stables at Stapleton, Staten Island. Twelve or fifteen animals have so far been affected. Six of these have been killed, and the rest quarantined.

GASTRIC ULCER.

By HERBERT W. LITTLE, M.D.,

As ulcers of the stomach, which give definite symptoms during life, are not of common occurrence, with the exception of perforating ulcers, of which the termination is fatal, it will be interesting, perhaps, to read the case given below. This is presented for the following reasons, viz: *first*, on account of the great obstinacy of the case; *second*, the controlling influence of ingluvin; *third*, the tolerance of rectal alimentation.

The obstinacy of the case will be perceptible further on.

As far as the beneficial effect of ingluvin in this instance went, it certainly was, apparently, very satisfactory; but, whether or not the ulcer was cicatrizing at the time it was administered, and the improvement was a mere coincidence with its administration, or whether or not the improvement was due directly to the effect of the remedy, is hard to say. In either case, improvement promptly followed the use of the remedy.

The patient was supported exclusively by rectal alimentation for three consecutive months, proving the tolerance and absorption of enemata, the rectum acting as a second stomach. This would seem to show the fallacy of Dr. Tully's statement that, inasmuch as there are no lacteals in the colon and in the rectum, the idea of introducing nourishment into the system by means of *enemata nutrientia* is a perfect chimera. It seems, as Bodenhamer says, that the nutritious elements are taken up by the absorbents, and conveyed by them to the *receptaculum chyli* or *reservoir of Pecquet*, and thus soon find their way into the economy, and produce their assimilative and nutritive effect. Bodenhamer, in his excellent treatise on rectal medication, further states that there are lacteals both in the colon and rectum, and that the late and lamented Prof. Horner, of Philadelphia, stated, from minute researches, that the office of the follicles of Lieberkühn is that of absorption, and not secretion. Therefore, absorption takes place principally through the lacteals and follicles of Lieberkühn. In my position as house physician at the Presbyterian Hospital, I have had opportunity to test the tolerance and absorptive powers of the rectum and colon to a considerable extent, both for food and for medicine, and have great confidence as regards their efficacy; and, moreover, am safe in saying that in a number of instances I have seen life saved by resorting to rectal-colonic alimentation.

The patient, a female, aged 36, unmarried, and a seamstress by occupation, came under my observation October 1, 1879, with what was supposed to be gastric ulcer. She stated that she had always been stout and healthy, with the exception of a general peritonitis which she had two years ago. Her weight when in health was about 160 lbs.

The present trouble began eight months ago with nausea and vomiting after eating; at times she vomited a little blood. The vomiting had increased so much that for the last two months it had been almost continuous, being excited by the ingestion of food. She knew of no cause for her ailment. She had been from the first under medical care, but had derived no benefit. Almost all the remedies in the materia medica employed for that purpose had been used to check her vomiting, but without avail —ipecac, opium, pepsin, bismuth, soda, oxalate of cerium, hydrocyanic acid, eucalyptus, carbolic acid,

calomel, salicylic acid, nitrate of silver, Carlsbad water, ice, etc. She was gradually getting worse, having lost twenty-five pounds since the inception of the trouble, and the vomiting still increasing.

When she came under observation she was emaciated and feeble; had not had her menses since July last; bowels constipated; vomited everything shortly after being ingested, not being able to retain either solid or fluid food, although coarse and solid food gave her more distress than fluid; threw up a little blood three or four times. Always felt relieved after emesis had taken place. Complained of tenderness, confined to the centre of the epigastric region, and a burning pain (coming on soon after eating) in the same location. At times she would complain of a dorsal pain or cardialgia. No tumor was felt through the abdominal walls. The diagnosis of gastric ulcer was founded on the following symptoms: great tenderness at a localized point in the epigastrium; a burning pain in the same location; vomiting of both solid and liquid food, and always experiencing relief after emesis. As the nausea and vomiting was more severe in an hour or so after eating, it seemed to point to the pyloric end of the stomach as the seat of the disease.

She was given a liquid diet consisting of milk with lime-water and beef-tea, occasionally chewing rare pieces of beef and swallowing the juice. To control the vomiting, powders of subnitrate of bismuth and morphia were administered. This plan of treatment was kept up for five days without any beneficial result, the milk being thrown off as well as the beef-tea. Various remedies were then tried, but still she vomited and retched until everything was thrown off her stomach—even bile, blood, and mucus being expelled. A whitish discharge which had been vomited occasionally was examined microscopically, and found to consist of squamous epithelium and blood-corpuscles, with mucus and extraneous matter. She was then put on enemata of milk, beef-tea, and defibrinated blood. Ice, soda, and subcarbonate of bismuth in twenty grain doses, with blistering over the stomach, were all employed to relieve the retching, but with no amelioration. In fact, all the symptoms were aggravated. The burning pain was getting more intense, the tenderness and vomiting increasing, and now insatiable thirst tormented her, but everything she took to relieve this only aggravated the emesis. As a last resort, ingluvin was employed, to be given three times a day. Within a week she felt better. The vomiting was greatly relieved, now occurring but twice a day, whereas formerly it was almost continuous. The burning, gnawing pain was gradually eased. Improvement rapidly progressed; in ten days the vomiting had entirely disappeared, the tenderness and burning diminishing. The enemata were now discontinued (having been used three months). The patient got out of bed, and thereafter ate three meals a day without any inconvenience. She began immediately to gain flesh, and her menses again appeared. Shortly after she went home in excellent condition, with the ulcer probably cicatrized.

As mentioned above, this case is interesting partly on account of the long-continued use of rectal injections, showing the value of them in prolonging and saving life. They are of service after operations on and in diseases of the tongue, pharynx, œsophagus, and stomach; after removal of cancer of the tongue, of tumors of the jaw, and in cases of diphtheria, tumors of the pharynx, stricture or obstruction in the œsophagus, tumors of the larynx, pressing upon the œsophagus, or in any disease interfering with deglutition; also in cancer or ulcer of the stomach, gastritis, and in marasmus of children. Of the latter, Dr. G. M. Smith, of this city, had a case, the subject of which was a little girl in a deplorable condition. She was supported entirely by rectal injections, until gradually she was restored to perfect health.

These injections may be used almost without limit, although there is a prejudice against them on the part of the patient. Dr. Austin Flint, in his "Practice of Medicine," mentions three cases which were supported by nutritious enemata. The first was sustained three weeks, the second one month, and the third and longest three months.

Reports of Hospitals.

BELLEVUE HOSPITAL, NEW YORK.

SERVICE OF DR. LEWIS A. SAYRE.

A CASE FOR DIAGNOSIS—OSTEITIS AND PERIOSTITIS MISTAKEN FOR DISEASE OF THE HIP-JOINT.

THE patient was a lad sixteen years of age, who had been thrown from a cart two years previously, and thus had received the injury from which he was still suffering. It had been supposed by a number of excellent surgeons that he had hip-disease, because many of the prominent signs of that affection were present; but a careful examination showed that, notwithstanding this fact, the diagnosis was erroneous. To all appearances, the patient was in the second stage of disease of the hip-joint when effusion has taken place. The affected limb (the left) was markedly flexed, abducted, and everted, and when the attempt was made to press it down upon the floor, so that the popliteal space would touch (the patient lying flat upon the back), the pelvis at once became tilted, and a distinct arch was made in the line of the lumbar vertebræ.

There were, however, several important points which showed that this disease could not be present here. In the first place, the general appearance of the lad was too much that of good health for the second stage of hip-disease, presenting a marked contrast to that of other patients who had arrived at this period in the affection. Again, the jamming of the head of the femur against the acetabulum with great force produced no pain whatever, and the patient was able to stand alone upon the affected limb without any inconvenience or suffering, which would have been utterly impossible with a diseased hip-joint. On the other hand, the use of extension gave him no relief, which would, of course, have been the case if he had had this. In addition, the thigh of the affected limb, instead of being smaller than the other, was actually half an inch larger in circumference, it being probable that a cold abscess was forming in this position.

The real condition which was determined to be present was osteitis and periostitis, which had resulted from the injury mentioned, and at the point where there was now the greatest tenderness (the pain on pressure being very marked here) the patient stated that the skin was much discolored immediately after the accident. This point was on the outer aspect of the thigh, about four inches distant from both the anterior inferior spinous process of the ilium and

the great toe-blister. Seguin's surface thermometer indicated a marked increase of temperature at this locality, as compared with that of the surrounding parts.

CLUB-FOOT.

A case of very bad club foot was shown which had been operated on two weeks previously by subcutaneous section of the *tendo Achillis*, and in which the most marked improvement had taken place. The rule of restoring the foot completely to its normal position at the time of operation, upon which Dr. Sayre always lays great stress, had been observed, and the result was very satisfactory. Immediately after the division of the tendon, the small external wound had been sealed up by adhesive plaster, in order to prevent the entrance of air, and it had now entirely healed up without any suppuration whatever. Instead of any degenerative changes taking place, there had been organization of the exudation poured out, and the development of new tissue; so that the gap (which was of considerable size) between the cut surfaces had already been filled up by this, and union in the tendo Achillis had actually taken place in two weeks. This was demonstrated by the fact that the patient was now able to draw up the heel voluntarily, even when some slight resistance was opposed to it.

A somewhat similar case was then shown, in which there had as yet been no operative interference, and attention was called to the blueness and coldness of the surface of the part, which is so common in club-foot, on account of the obstruction of the circulation in the part. In this instance it was found that the heel could be brought down until the foot was almost at right angles with the leg, and that while the *tendo Achillis* was thus upon the stretch no reflex spasm was produced by making pressure upon it with the finger. It was not necessary here, therefore, to divide the tendon, in accordance with the rule laid down by Dr. Sayre, that when a tendon or fascia is being stretched to its fullest extent, and pressing upon it at the same time with the finger or thumb produces no *reflex* contractions, it is not necessary to cut it, as the contraction can be overcome without this by the application of constant elastic tractile force. Here there was deformity of the front part of the foot, constituting what is known as

TALIPES PLANTARIS,

and since, when the plantar fascia was put upon the stretch, this additional point-pressure produced reflex contractions of the same, it was determined that it was necessary to divide the fascia. This was accordingly done subcutaneously, and as soon as the wound had been covered with adhesive plaster, the foot was at once brought into its normal position. On account of the feebleness of the circulation, cotton was put around the instep and ankles before the dressing was applied, in order to protect the parts from sloughing. A piece of thin board, cut to the required size and left square at the toes, having first been provided with a broad strip of moleskin adhesive plaster, one end of which was allowed to remain loose, so as to be applied to the anterior surface of the leg, was then bound to the foot by a roller-bandage, care being taken to leave the toes exposed, so that the activity of the circulation might be observed. The strip of adhesive plaster passing from the toes to the anterior surface of the leg was further held in position by the roller, and the foot was thus firmly secured at right angles to the leg. In addition, another strip of plaster, which almost encircled the front part of the foot, was carried from its external surface to that of the leg, and secured by a roller.

The next case seen was one of

VALGUS EQUINUS

in a very young child, the foot being inverted and the heel turned up, while the *varus* deformity was more prominent than the *equinus*. It had been operated on six months previously by some other surgeon, both the *tendo Achillis* and the plantar fascia having been divided, but the after-treatment, upon which success wholly depends in such cases, had not been properly carried out. On account of the former operation, it was impossible to say now whether the deformity had originally been of a paralytic or a spastic character. In cases where there has been no cutting, the paralytic is distinguished from the spastic by the fact that the foot can be restored to its normal position, while in the latter this is impossible. Attention was called to the great redundancy of integument on the outer portion of the foot, beneath and in front of the external malleolus, and it was recommended that constant frictions with spirits and water should be made over the part, so as to harden the skin and cause it to contract sufficiently to assist in keeping the foot in its proper position. Sometimes, it was stated, it was necessary to cut out a piece of skin and stitch the edges of the wound together, in order to secure this.

In many cases, when taken sufficiently early, a cure could be effected by means of a simple piece of adhesive plaster, though it was very important that it should be put on properly. One end of the strip should be applied to the upper surface of the foot and then passed around to the ball, great care being observed in doing this not to completely encircle the foot by leaving an open space between the attached end of the plaster and the portion passing up from the ball of the foot. The free end should next be carried up the leg as far as the knee, and the whole then secured by a roller-bandage. This dressing was applied in the present instance, and as the material used was the ordinary adhesive plaster, instead of Mau's moleskin (which is the best), a similar strip was put on outside the roller, lest the first should not be sufficiently strong to answer the purpose desired, when a second roller was applied outside of all. In very young infants it was advised that the foot and leg should be neatly wrapped with a soft flannel bandage before applying the adhesive plaster, on account of the danger of its chafing the delicate skin. Here an appropriate club-foot shoe was also ordered for the child.

ULCER OF THE LEG.

The patient was of advanced age, and ten years before he had fallen through a hatchway into a cellar, a number of stories below, and received the most serious injuries in several parts of the body, but from which he had recovered in a truly marvellous manner. Notwithstanding the fact that both the thigh and the patella had been badly fractured, he was able to walk eight or ten miles with comparative ease; but still the venous circulation of the limb had never been in such good condition since the accident as previously, and, in consequence, a chronic varicose ulcer of the leg had resulted. Although this affection is such a common one, Dr. Sayre thought there was very little of value taught in the books in regard to it. Yet the correct treatment was very simple,

and, if properly carried out, would almost invariably result in a cure; so that in cases which had been given up by most of the practitioners of the neighborhood a young surgeon could often make a reputation for himself by adopting this.

Such ulcers resulted from a varicose condition of the veins. The bursting of the latter was followed by erosion of the cutaneous surface, and a continual exudation. Thus the ulcer formed, and the edges became more and more indurated, while their boundaries gradually extended. Unless appropriate measures were taken, the trouble would last for many years or a whole lifetime; and hence the affection had come to be regarded as the opprobrium of surgery. In an instance mentioned by Dr. Sayre, the ulcer had lasted for more than thirty-two years.

The treatment in this case had been commenced four days before. At that time a number of parallel incisions through the *cutis vera* had been made over the affected part, and, in consequence of the salutary depletion thus accomplished, it was always noticed in such instances that the blue and unhealthy color of the surface, due to venous engorgement, was at once changed to a natural ruddy hue. When the congested vessels had been sufficiently relieved, the limb was strapped with adhesive plaster in the manner known as "basket-strapping," until the parts were all completely covered. This consists simply in the alternate application of two series of adhesive strips at right angles to each other. When this dressing is properly applied, the patient experiences no pain whatever afterward; but in the present instance it had, unfortunately, been neglected to have the foot at right angles to the leg at the time the dressing was made, which is a point of very considerable importance. In consequence of the plasters being put on when the foot was extended, a little chafing at the tendo Achillis had been produced, and more or less pain had resulted. When the ulcer has been dressed in this manner, the rule is to instruct the patient to return when the moisture exuding from the part had soaked through the plaster and the bandage covering it. When this had occurred, one would find on removing the dressing, instead of the thin, unhealthy secretion which ordinarily characterizes such ulcers, a thick and tenacious exudation covering the part. When this is found to be present it should be removed, with the exception of the portion directly over the sore, which should be allowed to remain, as it makes the best possible dressing for it. In the present case, if the mistake above noticed had not occurred, the leg could probably have been allowed to remain untouched for another week.

The dressing having now been removed, the marks of the straight incisions through the skin could still be perceived, although they had rapidly healed up, and the union of the divided tissues was complete. Already it was found that the sore was nearly well; an ulceration in the upper portion of the part being entirely cicatrized, while one lower down, which had previously been quite large, was now not more than the size of the nail of one's little finger. Over the *tendo Achillis* could be seen a little abrasion, which was due to the chafing produced, as above stated, in consequence of the plaster being strapped on while the foot was in a position of extension. The plaster dressing was then reapplied; the secretion having first been wiped off, with the exception of that directly over the sore, and care being taken that the foot was at right angles to the leg. The great secret in putting on the strips was stated to be drawing them so smoothly that there should be no creases or folds. The horizontal strips were to alternate with the perpendicular ones, and each was to overlap its predecessor by from one-half to one-third the width of the plaster. It did not matter where the ends of the strips went; each one being allowed to take the direction into which it naturally fell, in order that the dressing might be perfectly smooth.

One point of importance was, that no spot should be left uncovered.

In the permanent cure of such ulcers of the leg, the after-treatment was of much consequence, as that adopted for the purpose of healing up the lesion. This consisted simply in the patient's wearing for the rest of his natural life, a proper support for the part, so that the blood might be drawn away from the cutaneous veins to the deeper-seated vessels; and unless such a precaution were taken, the trouble was sure to return sooner or later.

Martin's rubber bandage afforded us a very excellent means for carrying out the indication; but the elastic stocking answered quite as well, while being less clumsy. The essential point was to properly support the circulation of the part. In the present instance a roller-bandage was applied outside the adhesive plaster, commencing at the ankle, so that the boot could be worn. The dressing was now perfectly comfortable to the patient, and its removal would probably not be necessary for ten days or a fortnight.

VARICOCELE.

The patient was a young man of twenty-two years of age, with a varicose enlargement of the veins on the left side of the scrotum; giving rise to a dull, aching pain and a sense of weight and fulness in the part, as well as considerable pain in the back. Dr. Sayre said that he had never met with a case of varicocele on the right side, and remarked that there was an anatomical reason for this uniformity of position, viz.: that the renal and scrotal veins on the left side were at right angles to each other (which was not the case on the right side), and hence there was a column of blood in this position which was very apt to produce engorgment of the spermatic veins.

While the operation by subcutaneous ligature of the veins was ordinarily quite successful and free from danger, occasional instances had been reported in which a fatal result had ensued, and hence Dr. Sayre preferred to operate by removing a portion of the scrotum, with the assistance of a curved clamp, which he had devised for the purpose. Accordingly, this procedure was adopted in the present case. Care having been taken that the testicle was well up in the scrotal sac, the lower and outer portion of the latter was included in the clamp, which was not not unlike the metallic mouth of a purse in shape and appearance. Before the removal of the redundant portion, the precaution was adopted of passing a number of stout pins through the scrotum along the outer border of the clamp, in order to prevent the testicle from being uncovered when the part was removed.

The first time that Dr. Sayre operated in this way, this accident occurred, owing to the unexpected contraction of the dartos muscle, and hence it should always be guarded against. The pins now having all been inserted, the portion of scrotal tissue outside the clamp and pins was cut smoothly off with the scissors, and then, while the pins were still in position, the edges were united by a continuous

[illegible] ture. This operation had always proved quite as effectual as the lancet ordinarily resorted to, and it had never been followed by any serious consequences.

[illegible] and the patient was discharged [illegible] operation.

REMARKABLE GUNSHOT WOUND OF THE HEAD.

A patient was shown, who while fighting in our army at the battle of the Wilderness, in 1862, was shot just behind the left ear with a rifle-ball. The missile, which was nearly two inches in length, had been extracted, and a portion of it was still in the man's possession. When an examination was made of the seat of injury, a circular orifice more than half an inch in diameter was seen back of the ear, and on looking into this, a canal was discovered extending through the entire thickness of the temporal bone; so that in a good light the pulsations of the *dura mater*, at its base could be as readily distinguished as those of the anterior fontanella in a young infant. Notwithstanding the gravity of the lesion, however, the hearing had remained unimpaired, and altogether the patient had made a most extraordinary escape.

Progress of Medical Science.

THE ANTIPYRETIC TREATMENT OF RELAPSING FEVER.—Dr. Riess, of Berlin, in a paper on a recent epidemic of relapsing fever in that city, states that he, like other observers, never saw any good results follow the use of large doses of quinine either during the attacks or before the relapse. The salicylate of soda, however, proved decidedly efficient as an antipyretic in a large number of cases. He gave it, as a rule, in doses of ninety grains, both during the first attack and the relapses, and found that, in the majority of the cases, the temperature fell almost to the normal point in from two to six hours. When the drug was administered shortly before the time the crisis was expected, it seemed to shorten the attack. In a few of the cases the drug had but little or no effect. In twenty-six cases the salicylate was administered methodically during the apyrexia, in the hope of preventing the relapses; these patients took ninety grains once or twice a day for from eight to fourteen days, beginning a day or two after the crisis of the first attack. In eight of these cases the relapse set in at the usual time, but it was neither very severe nor very prolonged. In four of the cases there was no relapse at all, while of fifty cases in which the salicylic treatment was not methodically employed only one escaped the relapse. In thirteen of the cases the relapse seemed to be delayed, shortened, and rendered less severe by the treatment; in these cases the duration of the relapse varied from twelve hours to two and a half days, the temperature rarely exceeded 102.8°, and instead of showing itself on the seventh or eighth day after the first crisis, the relapse set in in six cases on the ninth day, in two on the tenth, in three on the eleventh, in one on the twelfth, and finally in one on the twenty-first day. It was noticed that in some of these cases, about the time the relapse was expected, the patients suffered for some days from malaise, headache, and loss of appetite, with rapid and shallow breathing, but without any elevation of temperature. This was particularly noticeable in one of the four cases that entirely escaped the relapse, and also in the case in which the relapse appeared on the twenty-first day; in this case the second attack of fever lasted only one day. Finally, in one of the twenty-six cases, the temperature rose on the fifth day after the crisis, and the patient died on the same day with cerebral symptoms. The autopsy revealed the usual lesions of a recent relapsing fever, and the possibility of death from poisoning by the salicylate could be excluded. In all of these twenty-six cases the salicylate was well borne, in spite of the large doses, the only unpleasant symptom noticed being the usual tinnitus aurium. In one case the patient took an ounce of the drug in one day through a mistake, without any marked ill effects. The conclusion drawn by Dr. Riess from these observations is, that the salicylate of soda, when given in large doses for a sufficient number of days, will, in many cases, greatly lessen the duration and severity of the relapse in relapsing fever, and will, in some cases, entirely prevent it. He admits his inability to account for this power of the salicylate over relapsing fever. It is at least certain that the drug does not act by destroying the spirilla, as they were found in the blood during the salicylate-apyrexia.—*Deutsche Med. Wochen.*, No. 52, 1879.

ON THE SECRETION OF URINE.—At a recent meeting of the *Schlesische Gesellschaft, etc.*, Prof. Heidenhain read a very interesting paper on the physiology of the secretion of urine. There are two principal theories extant with regard to this process. Bowman's and Ludwig's. Bowman's theory is to the effect that the malpighian tufts secrete essentially only the water of the urine with a small part of the crystallizable salts, such as the chloride of sodium, while the specific elements of the urine, such as the urea and the uric acid, are excreted by the epithelium of the tubuli contorti. Ludwig, on the other hand, asserts that all the constituents of the urine are secreted in the glomeruli. This theory presupposes three important points, viz.: 1. That the secretion of the fluid in the glomeruli is a purely mechanical filtration through the walls of the capillaries; 2. That the filtrate contains all the constituents of the urine in a very dilute state; and 3. That this fluid, in passing through the urinary tubules, loses water, by diffusion to the lymph surrounding the tubules, and thereby becomes concentrated. This theory is supported by many plausible arguments, but it cannot stand the test of a rigid scrutiny, and of comparison with the processes by which other secretions, *e.g.*, the bile, are developed. Prof. Heidenhain claims that a proper interpretation of the physiological and experimental data necessitates the conclusion that the secretion of urine is not a mere filtering process, but that the epithelium covering the capillary tufts in the glomeruli possesses active secreting powers. It has been proved that both an increase in the rapidity of the blood-current through the kidneys, and an increase in the percentage of water in the blood, augment the secretion of urine, an effect which is due in both cases to the increased amount of water passing over the epithelium of the glomeruli in a given time. The filtration theory would not explain this fact satisfactorily, and neither can it account for the known fact that an increased percentage of urea in the blood augments the secretion of urine. This has been shown by Nussbaum to depend on this, that the epithelium of the tubuli contorti, which secretes the urea, secretes also a large quantity of water, whenever the percentage of

urea in the blood is high. In regarding the epithelial cells of the glomeruli as active secreting agents, whose activity depends on the rapidity of the blood-current passing over them, Prof. Heidenhain shows that we place the secretion of urine on the same standpoint with all other glandular secretions, for the activity of all the secreting glands depends more or less on the rapidity of the blood-current through them. The glands differ only in this: that some require a special irritation through their own special nerves to set them in action (lachrymal, salivary glands), while others act automatically (liver, kidneys).

The secreting epithelium of the glomeruli possesses some interesting peculiarities: 1. It reacts with great sensitiveness to any change in the quantity of water passing over it; 2. It presents an impassable barrier to any small solid bodies that may make their way through the capillary walls of the tuft; 3. It is very sensitive to even temporary interruptions of the blood-current. Overbeck saw the secretion of urine stop for a considerable time, sometimes for as long as three-quarters of an hour, after a mere transitory obstruction of the renal artery. A regular, unbroken supply of nourishing blood seems to be essential for the secretory activity of this epithelium, even a brief interruption of the supply rendering it impotent for a longer or shorter period. Prof. Heidenhain referred to the fact that when the blood-supply falls below a certain point, the epithelium takes up albumen as well as water from the blood. Remeberg has lately attempted to prove that this pathological albuminuria depends on a mechanical cause, viz.: the diminution of the blood-pressure in the glomeruli. The facts, however, on which he relies to support his theory, will not bear scrutiny. It is almost certain that the albuminuria is due not to a decrease of the blood-pressure, but to a decrease in the rapidity of the blood-current through the glomeruli.—*Allgem. med. Cent.-Zeit.*, Dec. 3 and 6, 1879.

Researches on Hearing through the Medium of the Teeth and Cranial Bones.—In a paper with this title, read before the Philadelphia County Medical Society, Dr. Thomas asserted that the audiphone and dentiphone supply to the deaf but a very small fraction of normal hearing—much less, he believes, than a hundredth part. Neither instrument adds anything to the hearing of persons with perfect ears, except when the latter are securely stopped. Repeated tests have convinced him, moreover, that only those deaf persons who can hear their own voices without the audiphone, are enabled with it to hear the voices of others. One great objection to both the audiphone and dentiphone is, that they require the constant service of one hand during their use. To remedy this defect, he has had the receiving diaphragm attached to a rod of wood or metal bent in the form of a pipe stem. One end of this rod is held in the teeth, and the user is then able to listen to the sounds about him, with his hands at liberty. The substance of which the diaphragm is constructed is a matter of importance. Fuller's board, or press-board, coated with shellac, varnish, and thoroughly dried, is the best substance for the purpose, as it is neither under nor over-resonant. The simplest osteophone—a name which Dr. Thomas proposes for all appliances intended to aid hearing by the transmission of articular sounds to the ears, through the medium of the cranial bones or teeth—and one which excels either audiphone or dentiphone in the volume of sound transmitted, consists simply in a rod of hard wood about two feet long and a quarter of an inch thick, one end of which is held against the teeth of the speaker, and the other against the teeth of the deaf person. It is a known physiological fact that the voice produces sensible vibrations in the hard palate and base of the skull of the speaker, and that these vibrations are transmitted with varying intensity throughout the skull, notably to the upper front teeth, the forehead, and the top of the head. By means of the rod osteophone applied to these parts, the vibrations may be transmitted as articulate sounds. The voice-vibrations are also transmitted to the upper part of the chest, whence they may likewise be conveyed by the rod-osteophone.—*Phila. Medical Press*, Feb. 28, 1880.

Posture in the Treatment of Intestinal Colic and Ileus.—On May 1, 1879, Prof. F. H. Hamilton read before the New York Academy of Medicine a paper on "Posture in the Treatment of Strangulated Hernia," as a supplement to which he now publishes a short article urging the value of posture in the treatment of the so-called "spasmodic colic" and ileus. He dissents from the view, that "spasmodic colic" is due to spasm alone, and believes that the true explanation of that affection is as follows: In consequence of an unusual accumulation of gas in the intestinal tube, certain portions of the gut are expanded and elongated, until, under the counter-pressure of the abdominal walls, insufficient room is left for their normal repose and relative adjustment, and they become, at certain points, doubled upon themselves and possibly upon each other, and the sharp angular reflections interrupt or actually occlude the passage. This doubling may be favored by a certain amount of narrowing of the tube from spasm below the dilated portion, or by the presence of a small quantity of hardened fæces. He does not believe that the weak, circular muscular layer of the intestine can possibly do more than slightly narrow the canal, when in a state of spasmodic contraction; complete occlusion from spasm, except at the anus, and pylorus, and perhaps at the ileocæcal valve and the junction of the colon and rectum, is impossible. In the cadaver, moreover, he has often witnessed the doublings spoken of above; while attempting to inflate the intestine, it would become doubled on itself and the passage of air would be suddenly and completely arrested, and the obstruction could then only be overcome by pulling out the intestine, or by disturbing it in some way. He cites several cases, where simply raising the hips has been followed by an escape of gas, and the immediate cessation of the colic. With regard to drugs in the treatment of colic, he has found that a full dose of some aromatic and stimulant cathartic, such as the tincture of rhubarb with ginger, is often more successful than opiates.

In ileus, as in colic, there is a mechanical obstruction from displacement of the gut, but the twisting of the tube, which exists in the former, is less easily rectified than the simple doubling of colic, and is more likely to lead to a fatal issue. It is probable, however, that the two forms of displacement are often combined. Dr. Hamilton believes that posture may occasionally overcome an ileus or disengage an intussusception, and urges that it should at all events be given a trial in addition to the other means of treatment.

The German Pharmacopœia is to be revised, and the new edition will be ready next year.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, May 22, 1880.

THE NEXT MEETING OF THE AMERICAN MEDICAL ASSOCIATION

The next meeting of the American Medical Association will be held in this city, commencing June 1st. From present indications more than the usual number of members and delegates will be present. It is also safe to say that all concerned in the success of the meeting will have reason to be satisfied with the preparations which are made to that end by several of the leading members of the profession of this city. In another place we give a detailed account of the arrangements for the entertainment of the members. A large number of papers are promised for the different sections, and an unusually wide range of subjects will be presented for discussion. It is not necessary to urge upon such gentlemen as intend to read papers to present them in abstract. By this means the subjects are thus made more interesting, the salient points are clearly brought out, and the discussion which follows is apt to be of great practical value. No abstract should be of greater length than would occupy fifteen minutes in its presentation. It has been said of a very successful preacher that his most effective sermons were very short: in fact, he maintained that he never succeeded in convincing a sinner after the first ten minutes of his discourse. The average medical man who attends the meetings of societies is accustomed to take his mental food in very concentrated doses. In this age of rapid thought there is no risk in making any paper too brief. Any new idea that is practical can always be stated in very few words, and easily invite discussion. And after all, the interchange of ideas among the audience stamps the real value of the views of the author. Aside from saving the time in the sections, abstracts are often more valuable than the papers in full; at least, such abstracts are always more widely read because they must be brief and to the point.

Of the general sessions of the Association little can be suggested to make them more profitable, except perhaps to insist upon the same general rule, as to brevity of presentation of subjects, as that suggested for the sections. Fortunately, much of the detail work is now done by committees, and much valuable time is thereby saved. There will come up for consideration by the Association in its general sessions one or two matters of importance. The proposed amendment to the constitution, admitting the Marine Hospital Service to representation in the Association, is one which will doubtless be favorably acted upon.

Dr. T. G. Richardson's proposed amendment to the by-laws regarding the award of prizes will be called up. As will be recollected, the proposition is to the effect that an annual prize of two hundred and fifty dollars be offered by each of the four sections for the best original contribution to medical and surgical progress; also that a committee for the selection of the subject be appointed by the chairman of each section, and also, by the same officer, a committee of experts who shall award the prize. This proposed change is a very good one, and will doubtless be adopted.

In the regular order of business the pending amendment to the code of ethics, which was laid over from last year, will also be called up on its passage. It will be recollected that this forbids the teaching of medicine to such students as have homœopathic or other irregular proclivities, and is virtually intended to apply to the present methods of education as practised at the University of Michigan. The propriety of rejecting the amendment was very ably discussed at the last meeting, held in Atlanta, in an exhaustive argument by Prof. E. S. Dunster, of Ann Arbor. It was hardly necessary that such pains should be taken to show the absurdity of the position taken by the council of the Association. The thinking and progressive men of the profession have long ago decided that medicine is a liberal profession, and that it can lose nothing by allowing its light to shine anywhere and everywhere. The mere fact that a student is likely to become a homœopath or eclectic has nothing whatever to do with his medical teacher, and the Association has no power, legally, morally, or ethically, of calling to account any such teacher, or any school to which he may belong. The Association has really no more to do with a graduate's belief in the action of medicine than it has with his belief in any particular form of religion. Any man can use his knowledge as he sees fit, provided, by the exercise of such a privilege, he does nothing contrary to the laws of the land. It is the height of presumption, for even the American Medical Association, to declare that, unless a man promises to use the knowledge he may receive in a particular way, he shall not be educated. But it is useless to pursue the subject, inasmuch as the defeat of the proposed amendment is a foregone conclusion.

THE STOVER-CATLIN MALPRACTICE SUIT.

On the 9th of May, 1878, Mrs. Amelia Stover, aged forty-nine, fell from a piano-stool, upon which she was standing, to the floor. This fact, which would seem to have little significance except to herself and immediate friends, in the end excited a considerable stir in the medical profession, and drew out some very exhaustive discussions upon the diagnosis and morbid anatomy of fractures of the neck of the femur. Mrs. Stover immediately called in Dr. Elmendorf, and subsequently, Dr. Catlin, both reputable young physicians of Brooklyn. These gentlemen examined her and pronounced the injury only a severe contusion. After treating her for a week, they ceased to call, considering further attention unnecessary, unless specially summoned by the patient. She had refused to be chloroformed, and had used a lotion of cayenne pepper and whiskey, prepared by a relative, instead of the applications prescribed by the attending physicians. A bone-setter, of the name of Sweet, was then called in. He gave the limb a number of wrenches and pronounced the trouble a fracture. At the end of eight weeks, Dr. Ayres, a regular physician, took the bone-setter's place. Dr. Ayres considered the injury a fracture also, and declared that he heard crepitus. He invited Dr. Jas. S. White in as a consultant. Dr. White did not, we believe, examine the case with special care, but took Dr. Ayres's diagnosis and instituted treatment for fracture of the neck of the femur. We may note, at this point, the improbability of crepitus being heard at the end of eight weeks, when it was not heard at the time of the injury. If crepitus really existed, it can only be explained by supposing that the bone-setter, Sweet, broke the limb with his manipulations, or loosened an impacted fracture.

The patient, after suffering for a long time, finally, at the instigation of her friends and seconded by the friendly and disinterested sympathy of her lawyer, brought suits against Drs. Catlin and Elmendorf for damages to the amount of $100,000, at which trifling sum she placed the injury done to her limb by the alledged unskilfulness of those surgeons. A number of eminent surgeons were summoned as experts, and the trial, which recently came off, lasted several days and excited much interest among medical men. Drs. Ayres, James S. White, Carnochan, and the bone-setter, testified that the leg was fractured. Drs. Frank P. Hamilton, Sands, Geo. K. Smith, Johnson, Hutchinson and others, testified that there never had been a fracture, or most probably never had been. The injured limb, when examined a few months ago, was found to be three-eighths of an inch shorter than the sound one; it was somewhat shrunken, and there was the slightest possible eversion. Dr. John G. Johnson, one of the medical committee appointed by the Court to examine the case, was of the opinion that the woman affected more pain than she really had, also that she tried by tilting the pelvis, to make the injured limb measure less than it should. He did not believe that there was a fracture.

We have given these facts somewhat at length, as the case is an instructive one, and we should wish each reader to form his own opinion upon its merits.

It does not seem, however, as though a candid study of the facts could lead to any conclusion other than that the prosecution was an uncalled-for and unjust one. It is barely possible that there was a fracture in the beginning.

If this was so, it was, nevertheless, shown that a diagnosis at the time was absolutely impossible by any ordinary skill; and further, that the final result was really much better than usually occurs in such cases.

The supposition, however, that there never was any fracture had the weight of surgical authority on its side, and appears, from the facts given, to be much the more probable one. The slight difference in the length of the limbs might easily be normal. The patient was of a strumous constitution, and it is quite possible that a chronic inflammatory condition of the joint was excited by the original injury, or the manipulations of the bone-setter.

Whatever view be taken of the pathological condition, it was the fall that brought it about; and it was a condition in which no ordinary skill could have made a different diagnosis from Dr. Catlin's, and in which even extraordinary skill could not have furnished more relief than was eventually obtained.

But there is still a large class of persons which demand a revolution of the course of nature from physicians. Mrs. Stover had a strumous constitution. Mrs. Stover could not balance herself on the piano-stool; therefore, two young physicians must be impoverished and have their hopes of professional success blasted. That is the real relation of facts upon which the plaintiff would insist. By no twisting of these facts can it be shown that the defendants did not exercise reasonable skill.

Much more was proved for the defendants, but this is enough in law, and equity also.

The trial produced a diversion on the subject of intra-capsular fractures that is worthy of noting. The general belief that in intra-capsular fracture union is never osseous was stoutly denied by Dr. Carnochan. This gentleman showed in court a specimen of what he called intra-capsular fracture, in which he claimed that there was osseous union. This specimen has been, we believe, a pet and pride for many years. On examining it, Dr. Frank H. Hamilton declared his belief that either the union was fibrous, or the fracture was extra-capsular. The court permitted him to saw the bone in two, and it was shown at once that there was an extra-capsular fracture, with osseous union.

There was a great deal of other talk on the subject of extra and intra capsular fractures, the attachment of the capsular ligament, and the difficulty of diagnosing fractures of the neck of the femur. It is doubtful, however, whether anything new was added to science, unless it was the confounding of the intracapsular union party. The shameful injustice of most malpractice suits is, unfortunately, an old, old story. The jury in this case disagreed, nine being for and three against Dr Gathu. The charge of the judge was favorable to the defendant; but that did save the doctor with a crippled woman against him and the average juryman to weigh the evidence!

It is not likely that the plaintiff will ever secure a verdict; but even if she does not, and the defendants are fully vindicated before the law, they will have suffered a great injury, without justice or reason.

CURES BY FAITH.

It is stated that an institution has been started in Springfield, Mass., for the cure of diseases by the prayers of faith, the laying-on of hands, and sometimes anointing with oil. All persons afflicted in body or mind, who believe that they can receive physical or spiritual help, are welcome. The Home is under the charge of two ladies known as "Sisters Orpha and Rosa." One of these says that she was healed by faith of a grievous disease of long standing a few years since. As a large number of persons are cured who put their faith in glucose pills or the assurances of a favorite physician, we ought not, perhaps, to deny entirely the therapeutic usefulness of the new Home and faith in prayer. It would be well, however, for the Sisters to know of a recent decision in the English courts regarding treatment of the sick by prayer alone. There is a sect in London known as The Peculiar People. The members never call in a physician, but treat their sick with good food and prayer to God. A little boy, suffering, we believe, from dysentery, was so treated. He grew worse; the father would not send for a medical man, and the child eventually died. The father was indicted in the courts for manslaughter and was convicted. The case may not be entirely applicable to the Springfield Home, as it is intended only for those who voluntarily present themselves for treatment. These must have full faith. Very likely many of the persons who would present themselves to the institution belong to the class who could be benefited by the system of mental therapeutics to be established there.

REQUIREMENTS FOR THE DEGREE OF DOCTOR OF MEDICINE IN GERMANY.—A commission has been appointed by the Chancellor to determine what reforms are needed in the requirements exacted of candidates for the degree of Doctor of Medicine. An examination in ophthalmology is already required, and Professor von Troeltsch has drawn up a petition asking that otology be added to the list of requirements.

Reviews and Notices of Books.

THE HYSTERICAL ELEMENTS IN ORTHOPÆDIC SURGERY. By NEWTON M. SHAFFER, M.D. New York: G. P. Putnam's Sons. 1880.

DR SHAFFER has made a valuable contribution to orthopædic surgery in the present short work. The subject of the hysterical element in joint-diseases, first mentioned by Brodie, has been touched upon more or less fully since then by Paget, Shey, Esmarch, Berger, and others. A tolerably good description of articular neuralgias is to be found in Ziemssen's Cyclopædia. Nevertheless, no adequate prominence has ever been given to the subject of late even in orthopædic text-books. In the work before us, the symptomatology of the neuromimetic joint-affections is discussed with especial fulness, and is illustrated with a number of striking cases. The differential diagnosis between chronic synovitis, chronic osteitis, and the chronic neuromimetic conditions is given with much care and fulness. The author describes the muscular conditions in joint-diseases, and concludes with a summary of the diagnostic points in emotional contractions, hysterical contractures, and the reflex spasms of inflammatory disease.

The value of Dr. Shaffer's book lies in its bringing into distinct notice a series of pathological conditions that have been heretofore in part unknown and in part ignored.

A GUIDE TO THE PRACTICAL EXAMINATION OF URINE, for the Use of Physicians and Students. By JAMES TYSON, M.D. Third edition, revised and corrected, with illustrations. Philadelphia: Lindsay & Blakiston. 1880.

THIS little work acquired a solid reputation on its first appearance in 1874, and it has been used as a text-book in a number of medical colleges since then. The present edition contains no especial changes or additions, but shows the popularity of the work.

STUDENTS' AID SERIES: PHYSIOLOGY. By B. THOMPSON LOWNE, F.R.C.S. Therapeutics and Materia Medica. Part II. (Double Part): The Vegetable and Animal Substances. By C. E. ARMAND SEMPLE, B.A., M.B., Cantab., etc. New York: G. P. Putnam's Sons. 1880.

THE above volumes of the Student's Aid Series are carefully prepared, and present a good deal of information in a condensed form. We have before expressed our opinion of the present fashion of multiplying students' aids of various kinds, which really only encourage cramming and superficiality. If such books must be published, doubtless the present series is as good as any.

POST-MORTEM EXAMINATIONS, with especial Reference to Medico-Legal Practice. By Professor RUDOLPH VIRCHOW, of the Berlin Charité Hospital. Translated from the Second German edition, by Dr. T. P. SMITH. Philadelphia: Presley Blakiston. 1880.

THE value of this useful little manual should not be judged from its size. Although it is small, not to say diminutive, it is sufficiently clear, concise, and withal comprehensive, to form a complete guide toward a thorough performance of autopsies. In this country especially, where the records of post-mortems are commonly incomplete or otherwise deficient, the adoption of Virchow's system would

prove very beneficial to the progress of pathology. Deputy coroners would do well to study his method and make it their own. Of course it is impossible, in every instance, to devote three hours' time to the performance of a necropsy. But the system might at least be profitably imitated, which would secure a desirable uniformity in the manner of conducting investigations and drawing up reports. We heartily welcome this excellent little work from the pen of Germany's distinguished pathologist.

THE HAIR: ITS GROWTH, CARE, DISEASES AND TREATMENT. By C. HENRI LEONARD, M.A., M.D. Detroit: C. Henri Leonard. 1880. 8vo, pp. 316.

IT will depend much upon the temperament of the reader whether this book appear curious and interesting, or only ridiculous. It consists of a mass of facts, calculations, anecdotes, legends, and speculations about the hair, gathered from all kinds of sources, including the Zend Avesta and Mr. Darwin, and presented in a sufficiently readable form. There is a great deal of information that is trite and unimportant; and a great deal of speculation that is absurd. We may instance the remarkable computation concerning the hair of the people of New York and Brooklyn. If these hairs were placed end to end they would make a line so long that it would take a railroad car, travelling at the rate of a mile a minute, for sixty years to pass its whole length. This is a remarkable fact, and gratifying to the people of New York and Brooklyn; but it is more adapted to the atmosphere of a Museum of Anatomy and Art than to a presumably scientific work. The author has devoted much time to similar calculations, taking, for the most part, the people of Detroit as his basis.

The latter part of the book, in which diseases of the scalp are treated, is more satisfactory, and the reader is likely, on the whole, to be considerably entertained by its perusal.

There are numerous illustrations, and these, as well as the printing, are very well done.

EYESIGHT: GOOD AND BAD. By ROBERT BRUDENELL CARTER, F.R.C.S. With numerous illustrations. London: Macmillan & Co. 1880. 12mo, pp. 267.

THIS little book is intended, as the author states in his preface, to spare the surgeon the trouble of constantly repeating to his patients the precepts and injunctions which it is desirable they should know and understand.

After a careful and, we may add, profitable perusal of the work, we can safely say that he has succeeded very well. We have caused some of our more intelligent patients to read it, and find that they generally appreciate the author's ideas. If systematically read, nothing will appear obscure to the intelligent reader, but there are few except specialists, who would thoroughly comprehend any special chapter without reading the book from the commencement to that chapter. This is due to the nature of the subject. The author, whose reputation has been made by his popular writings on ophthalmology, has avoided the use of technical terms as far as possible, and his manner of presenting the facts has made the book a very pleasant one to read.

It contains much information not found in the text-books, and no subject of importance appears to have been omitted. The illustrations are quite simple, though adequate to their purpose. Frequent quotations from the author's note-book of cases, which are remarkable and certainly very unusual, increase the interest of perusal.

HOW TO EDUCATE THE FEELINGS OR AFFECTIONS, and Bring the Dispositions, Aspirations, and Passions into Harmony with Sound, Intelligence, and Morality. By CHARLES BRAY. Edited, with notes and illustrations from the Third London edition, by NELSON SIZER, of New York. New York: S. R. Wells & Co. 1880. 8vo, pp. 226.

IN this work the author undertakes to show those feelings and affections which should be cultivated, as well as those that ought to be repressed. General rules are given as to the management of children, with especial reference to the proper education of their minds and the elimination of the baser passions. On the whole, the book is worthy of consideration by those who are interested in the subject of phrenology.

A HANDBOOK OF HYGIENE AND SANITARY SCIENCE. By GEORGE WILSON, M.A., M.D., and C.M. (Edin.), F.C.S. Fourth edition, enlarged and carefully revised. Philadelphia: Lindsay & Blakiston. 1880. 8vo, pp. 468.

THIS book is intended chiefly for the use of medical officers of health, but will no doubt prove to be of great advantage to all those who are interested in the study of the subject of sanitary science. The chapters worthy of special mention are those on "Preventable Disease," "Examination of Food," "Ventilation and Warming," and "Water Analysis." A chapter is also devoted to the Sanitary Construction of Dwellings. The author has treated his subject in a masterly way, and the work is one which can be read with great advantage by all members of the medical profession.

SORE THROAT: ITS NATURE, VARIETIES, AND TREATMENT, including the Connection between Affections of the Throat and other Diseases. By PROSSER JAMES, M.D. Fourth edition, illustrated with hand-colored plates. Philadelphia: Lindsay & Blakiston. 1880. 8vo, pp. 318.

THE sale of a third edition of this work in the space of three months would show that it possessed more than an ordinary degree of merit. The author enters very fully into the different forms of sore throat, and in a concise manner gives the best methods of treatment.

In regard to the greatly disputed point of the identity of croup and diphtheria, the writer states that he considers them to be separate and distinct diseases: in the former death taking place by blocking up the air-passages and suffocation; in the latter death is occasioned by blood-poisoning. The work is well gotten up, and we hope to see it pass through many more editions.

THE HYPODERMIC INJECTION OF MORPHIA: Its History, Advantages, and Dangers. (Based on the Experience of 360 Physicians.) By H. H. KANE, M.D. New York: Chas. L. Bermingham & Co. 1880. 8vo, pp. 354.

THE author says, in the preface of the work, that on commencing the study of the above subject, it had been his intention to write only a few short journal articles, but from the number of replies he received in answer to a series of questions, which have already been published in this journal, he was enabled to write a small book. He begins by giving an account of the discovery of the method of injecting morphia hypodermically, and a description of several minor details in connection with the operation. In treating of the subject of narcotism, he cites cases in which one-sixth of a grain of the drug employed hypodermically produced unfavorable results, and

where death was averted only after several hours of incessant labor, with the electric battery, etc. He advocates the use of all the means at our disposal of an antidotal character, and gives a table of drugs which may be employed for this purpose. The author strongly urges the use of a tourniquet in case of hypodermic injection, especially when a vein is accidentally punctured. The tourniquet consists of a heavy tape or strap, at the end of which a patent buckle is attached, and this is placed on the arm above the point of puncture. By having this loosely applied, it will be ready for use in cases of emergency. The merit of the book lies in the fact that it is based on the experience of several careful observers. It is a work that every practitioner of medicine should have in his library.

A Lecture on Median Lithotomy. Delivered before the Brooklyn Anatomical and Surgical Society. By Dr James L. Little. New York: G. P. Putnam's Sons. 1880.

Dr Little's paper contains a very interesting account of the history of median lithotomy, with a statement of its special advantages. Dr. L. describes the staff with a bulging curve and deep groove which he is accustomed to use in the operation. Referring to lithelapaxy, he states that while it will undoubtedly decrease the number of cutting operations, it is really a more dangerous operation than lithotomy, except in very skilful hands.

Reports of Societies.

OBSTETRIC SECTION OF NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 22, 1880.

Dr. Salvatore Cardo, Chairman; Dr. Henry E. Crampton, Secretary.

REST AFTER DELIVERY.

Dr. H. J. Garrigues read a paper which was a revised edition of his former paper on the subject, read Sept. 8, 1877, and published in the "Proceedings of the Kings County Medical Society." The question was "How long should a woman remain in bed after confinement?" It was desirable that practice, in this particular, should be as uniform as possible, and the author believes that the views entertained should not be so divergent as at the present time.

The chief representative of those who recommended that the time should be shortened as much as possible, was Dr. Wm. Goodell, of Philadelphia. At this point Dr. Garrigues referred to a case in which the woman was urged by her medical attendant to rise early, and she rose on the fourth day after delivery; and on the fourteenth day she was induced to ride in a carriage, but it was nearly at the cost of her life. From that single illustration, however, he did not wish to draw any definite conclusions.

At the time Dr. Goodell's paper was read, 756 cases were reported, with a total mortality of only six; and the chief reasons why its author recommended early rising after delivery were the following: 1. Labor, if it was a physiological process, should not be made to wear the livery of disease. 2. The upright position excites the uterus to contract and thereby lessens the amount and duration of the lochia. 3. Uterine diseases are not known among the nations where women rise early after delivery, and I. Taperner has shown that convalescence is far more prompt and sure than when the woman is kept in bed for a prolonged period. To those points Dr. Garrigues directed the attention of the Section. He maintained that although parturition was a physiological process, it was one in which the transition from the normal to the pathological condition was extremely common, and that was especially true of women of modern times. Again, if the upright position favored the discharge of lochia and diminished its amount and lessened its duration, it must also be borne in mind that serious displacements were liable to be produced by placing the woman in that position before the changes incident to the puerperium state had gone on sufficiently to enable the tissues of the pelvis to resist properly superincumbent weight and pressure; and therefore by other means should the influence of the lochia be modified. While it might be true that uterine disease did not apparently exist among the women of nations where early rising after delivery was commonly practised, there were two factors by which such a conclusion must be modified when applied to modern civilized women, first, not much was known of uterine disease in ancient nations, and, second, modern women, with all the enervating influences of what is termed civilization, cannot resist disease as did the ancient or the modern uncivilized matrons.

With reference to the good results obtained by Dr. Goodell, he thought they were due to the general excellent care given to his patients, rather than to early rising, and besides he thought it impossible to judge of final results by those obtained in the average length of time which the woman remained in the retreat after delivery.

Dr. Garrigues then quoted from leading authorities in the three chief countries in Europe, all of whom recommended absolute rest in the horizontal position for one, two, and even three or four weeks after parturition. In New York, also, most obstetricians favored the long period of retention in bed after delivery.

The author of the paper then directed attention to anatomical and physiological facts relating to the measurements and weight of the uterus after parturition. As given by different observers, Berner, Henschell, and supplemented by Küstner in the *Archiv für Gynecologie*, Funfzehnter Band, 1879. He also referred to Dr. Van de Warker's paper in the *Am. Journ. of Obstetrics* for July, 1878, and Dr. Frank P. Foster's paper on the "Topographical Anatomy of the Uterus and its Surroundings," in the same journal for January, 1880, and then spoke of the changes that occur in the uterine mucous membrane and the muscles and skin of the abdomen.

In the language of the author of the paper, "anatomy and physiology teach us that the puerperal uterus is large, heavy, flabby, anteverted and anteflected; that all the surrounding parts destined to support it are distended, soft, and yielding; that its interior presents one large wound, bathed in a fluid rich in disintegrated tissue-elements; that the placental site is pervaded by large venous sinuses, filled with recently formed blood-clots; that at least the vaginal orifice and often other parts of the obstetric canal present open wounds; that the process of transformation, absorption, and regeneration required at least two months; and that the retrogression is most active during the second week."

It was not necessary that the woman should lie upon her back after the first twenty-four hours, but

her position might be changed to that upon either side. The liability to hemorrhage, displacement of thrombi, causing sudden death, and the occurrence of septicæmia, was regarded as sufficient reason for insisting upon rest in the horizontal position for several days at least after delivery. The vagina should be kept clean with disinfectant injections. It was with reference to rest after delivery in normal childbirth that it was desirable to reach a unanimity of opinion. Upon that point Dr. Garrigues had reached the conclusion, from the combined teachings of experience and physiology, that the woman should be kept lying quietly in bed, alternately upon the back and side, until the uterus has contracted sufficiently to be behind the symphysis, and for two months she should avoid any great exertion.

Dr. Isaac E. Taylor remarked that the views held by Dr. Goodell were substantially those entertained by Hamilton and White, and published several years ago. The important point, however, was with reference to the management of the woman after normal natural labor, and he did not agree with Dr. Goodell, because he believed that we must be guided by the nature of the case under observation: what was the woman's physiological condition? what was the condition of the uterus as regards its length, weight, and position? etc.

Dr. Taylor then referred to a case in which the uterus returned to the pelvic cavity within five days after delivery, and the woman made a rapid and good recovery; but not every case progressed so favorably as that one. He kept the woman in bed until the uterus had returned to the pelvic cavity, whether it required one or four weeks. So far as rest after delivery was concerned, we must judge by the constitution of the woman. Rising within two or three days and sitting on a vessel would, doubtless, facilitate removal of clots and also the lochia; but if the woman suffered formerly a good deal from the discharge, etc., he kept her in bed three or four weeks. There could be no line drawn or rule laid down which could be made applicable to every case.

Dr. Sell remarked that if the woman was properly bandaged and a pad was worn, getting up and down would not displace the uterus, and would favor discharge of the lochia. But the management of the puerperal period must be left to the judgment of the physician at the bedside of the woman. So long as the uterus could be felt above the brim of the pelvis, women in Vienna were not allowed to leave their beds.

Dr. F. V. White spoke of the efficacy of washing out the vagina with Labarraque's solution, in disinfecting the lochia and preventing the development of puerperal fever.

Dr. S. T. Hubbard remarked that he had found a great difference among women with reference to the time after delivery at which they could get up without injury. His rule had been to keep them in the recumbent posture, if possible, nine or ten days, and prevent them from walking for two weeks. He thought the time must be regulated by the attending physician, without reference to any rule.

Dr. Tausky fully agreed with Dr. Garrigues, and also believed that an important factor in preventing the development of puerperal fever was maintaining the recumbent posture after delivery for a week or more. He referred to a case in which the woman, feeling perfectly well on the fifth day after a normal labor, arose, and puerperal fever immediately followed. Some women might get up on the first day after delivery and no harm follow; and so it occasionally occurred that a person fell from a third-story window and received no serious injury, but he regarded such as exceptional cases, and thought that no woman should rise before the eighth or ninth day after a normal labor. He also approved of injections of the cavity of the body of the uterus as recommended by Hegar, whenever the internal os was patulous.

Dr. O'Sullivan practised retention in bed after delivery for nine or ten days, and as much longer as possible. He did not approve of vaginal or uterine injections, believing that if proper contraction was secured the uterus would be properly emptied.

Dr. J. N. Merrill endeavored to keep the lying-in woman in bed from nine days to three weeks. He believed that uterine disease was very prevalent among the poor classes.

The Chairman remarked that we not need go to Rome to study Roman women, for they were here; and he then referred to his experience among Italian women in the city of New York, which had been that early getting up after delivery frequently destroyed the life of the woman, and was a most prolific source of all kinds of pelvic disease. He never allowed a woman to rise, if it could be prevented, before the ninth or tenth day. He regarded cleanliness as godliness, but it was a virtue which most of the Italian women discarded; and doubtless their habits in that respect contributed largely to the development of diseases among them.

Dr. Garrigues, in closing the discussion, remarked that he took it for granted that there were injuries more or less severe to the obstetric canal in every case of labor. The injury might be very slight, but it was sufficient to permit the absorption of septic material; hence the care that should be taken to keep the passages properly cleansed and the discharges properly disinfected.

The minimum time which he would keep the woman in bed was eight days, a period long enough to allow granulations to form for the repair of injury done to the tissues of the obstetric canal.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 6, 1880.

Fordyce Barker, M.D., LL.D., President, in the Chair.

Dr. J. C. Peters delivered a memorial address upon the late Dr. Freeman J. Bumstead. At the close of the eulogy, a portrait, in crayon, of Dr. Bumstead was presented to the Academy.

OBLIQUE SECTION OF SKIN IN SURGICAL OPERATIONS.

Dr. John H. Packard read a paper entitled, "On some important advantages to be secured by oblique section of the skin in surgical operations." [The paper appears in full in another part of this journal.]

The paper being open for discussion,

Dr. Jas. R. Wood said that the late Dr. Valentine Mott had advocated, especially in operations on the scalp and face, oblique incisions. To stop the hemorrhage, he did not use torsion, but he left his wounds open until hemorrhage had ceased. He then closed the wound, if on the scalp, by twisting the hair and tying it, so as not to make punctured wounds with the needle. In this way he would get union by the first intention. Dr. Mott used to teach that this bevelling of the integument was very important, especially in operations on the face of females. We can now, however, make this method more uniformly applicable, because we have hot water and carbolized catgut with which to staunch

hæmorrhage. Dr. Wood advocated the method suggested by Dr. Packard, although he, as a rule, believed in the open treatment of wounds. Dr. Wood had used catgut, but he had not always been able to prevent suppuration. He was satisfied that there was a good deal in the catgut ligature, but it was not perfectly reliable. Dr. Wood said that he once witnessed a beautiful operation in Philadelphia, many years ago, in which Dr. Pancoast, Sr., made a new nose. He bevelled off the integument of the forehead, then grooved the edges of the nasal opening where the new nose was to be. The two parts were then fitted into each other, and the union was rapid and perfect.

Dr. Frank P. Hamilton said that he could see one objection to Dr. Packard's plan, viz.: that by making oblique incisions where the skin was very thin there might sometimes be sloughing. On the other hand, better apposition might be secured, and a larger part of the incision would be in the more vascular part of the tissues. These were two very apparent advantages.

Dr. Alfred C. Post said that he had not practised this method, but he had long been satisfied that broad surfaces should be applied to each other in closing wounds. He had been in the habit of bringing such surfaces together, using deep sutures and keeping the parts in place by splints. In this way he had secured union in fistulæ, etc., where the edges alone would have healed together with difficulty.

In operations about the vagina the method of bringing broad surfaces together, as suggested by Dr. Post, was absolutely necessary.

Dr. Leste said that he thought the suggestion of Dr. Packard would be a very useful one. In reference to closing up wounds at once, he thought it preferable not to do this in country practice, where the patients could only be seen once in two or three days. In was safer, he thought, to carry out the open treatment, and thus lessen the possibility of accidents.

Dr. A. C. Post said that in cases where a large cavity is left after the operation there is no question about the necessity of keeping the wound open; but there was often an error in keeping the drainage-tube in too long. If not removed in two or three days after the operation, it was likely to become only a source of irritation.

Dr. Webster said that some six or eight weeks ago he witnessed the removal of a deeply seated orbital tumor. The incision was made vertically, the tumor enucleated, and the wound closed with silk sutures. The wound closed immediately, there was a very slight scar, and the result seemed to be quite as good as that in the case reported by Dr. Packard.

Dr. Robert F. Weir had twice used Dr. Packard's method, and thought favorably of it. As regards the possibility of sloughing, he said the incisions in cornea for cataract had for years been made obliquely, yet there had been no sloughing in such cases, so far as he was aware, although the tissue was a non-vascular one.

Dr. F. P. Hamilton said that Mr. Pierson, in his directions for opening cold abscesses, stated that the incisions should be made obliquely. He had followed this direction a few times with satisfactory results.

Dr. Harwood related a case of removal of tumor of the face. The wound was closed with sutures and dressed with carbolized oil. The next day the union had taken place, and a week later the scar was very slight. In this case the incision was vertical, and the dressing applied in the ordinary way.

Dr. Packard, in concluding the discussion, said that, 1st, as regards Dr. Wood's open method, he was entirely in accord with him. He regarded the open, fresh air a very positive malignant element. But it did not seem to him that the idea of the open method militated against his theory of oblique incision at all. There were classes of cases for which each was most applicable. The remarks of Dr. Wood reminded him of what Dr. Paget says of the distinction between immediate union and union by first intention. He thought the distinction an important one. In immediate union, there is union with no effusion of lymph. Now by the oblique method, this union is more likely to be obtained. And the point is, in the method, to secure the skin as to have the edges closely in apposition, and the sides of the cavity so brought together as to prevent the formation of any cavity; the atmospheric pressure helps to secure this result.

2d.—In reference to the danger of sloughing, he referred to case of skin grafting. The facts regarding this were a sufficient answer to the suggested danger.

3d.—In regard to how much bevelling of the skin there should be, a case was necessary to show it perfectly. The incision must be made very obliquely. It should be made at an angle of 30° or more. There is all the difference in the world between such extreme obliquity and a slight amount. Some surgeons had totally misapprehended him on this point.

4th.—Dr. Packard was aware that the idea of oblique incisions was not new. He recollected Dr. Pancoast's operation for rhinoplasty, referred to by Dr. Wood. This was, however, for a special operation only. The points he (Dr. Packard) urged, were the uniform advantages of the oblique incision in securing accurate apposition of the skin, and in preventing the formation of a cavity.

5th.—In reference to whether it should include the subcutaneous tissue, he did not mean it to include this, except, perhaps, in tumors of the breast. The use of hot water, as a hæmostatic, he considered one of the greatest additions to modern surgery.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 24, 1880.

Dr. Satterthwaite, President, in the Chair.

Dr. Gibney presented a specimen of lupus of the conjunctiva on behalf of a candidate for admission to the society.

Dr. Briddon presented a leg removed by amputation at the knee-joint, from a male mulatto, who suffered from senile gangrene. The line of demarcation had formed half way up the leg. The cause of the gangrene was supposed to be arteritis, but no opportunity had been afforded for a careful examination of the vessels of the part.

He also exhibited a specimen of cancer of the breast, removed by Dr. Harrison, house surgeon of the medical department of the Colored Home.

Dr. Briddon lastly presented a negro child upon whom he had performed Reeve's operation for genu valgum. The history was given as follows.

CASE OF "REEVE'S OPERATION" FOR GENU VALGUM.

Ida Christian, brown-skinned, rachitic child of four years, has been an inmate of the institution for some time. In walking, the feet are separated about eight inches, and the knees alternately cross each other; the deformity is not so marked in the recumbent position.

November 5, 1879, under the influence of ether, and with the spray directed on the parts, an incision, vertical in direction, was made three inches above the internal epicondyle of the right femur, long enough to admit a chisel three-quarters of an inch wide. The instrument was carried down to the bone, and then rotated so that its edge was directed transversely to the shaft, and was then driven by successive taps of the mallet in an oblique direction, toward the inter-condyloid notch, until it was presumed that it had approached to within a quarter of an inch of the articular surface; the instrument was then withdrawn, and again introduced along the anterior and posterior borders of the first section; the condyle was then detached, with an audible snap, by forcibly straightening the limb, and the wound was protected by the antiseptic dressing.

The same operation was then repeated on the left limb, but before it was possible to detach the condyle on this side, the end of the chisel was driven into the joint, and could be felt underneath the skin; this was also put up with the same precautions as the other, and they were both secured in the straight position by long, padded splints, reaching from the axilla to the side of the foot.

There was scarcely any local or general reaction; the temperature went up one degree the day after the operation, and then subsided to the normal.

Twenty-four hours after the operation the dressings were removed, and found stained with bloody serum; after this there was very little discharge; the drainage tubes were removed on the sixth day; by the sixteenth day the wounds were healed, and passive motion was commenced and was subsequently used every day, but the side-splints were kept applied until the forty-sixth, when the child was put upon her feet; for a couple of days after the attempt at walking, there was a little tumefaction of the joint, and upon its subsidence, passive motion was again used. January 8, 1880, nine weeks after the operation, the limbs are perfectly straight, and the child walks well but stiffly; passive motion is painful, and resisted by the extensors and by a general effort of the child, but the leg can be flexed to a right angle with the thigh.

I directed the house surgeon that passive motion be done under the influence of ether, so as to forcibly break up any adhesions; two days after, I was informed that even under the anæsthetic the limbs could only be flexed to a right angle, and that on making an effort to increase the range of motion something was felt to snap in the right joint. I saw the child on the following day; found some heat and slight swelling in both joints. I advised that rest should be enforced for a few days, and that on the subsidence of local disturbance, passive motion should be resumed.

March 22d I again examined the patient; the limbs were perfectly straight, she could flex them to a right angle, and walked about with ease; on examination, there was complete evidence that there had been separation of the epiphysis of the tibia on the side on which the snap had occurred during the forced flexion under ether, and that union had occurred whilst the child had been on its feet, and in spite of the passive movements that had been regularly used during the same period; the evidence was a slight anterior angle at the junction of the epiphysis with the shaft, and a bony fusiform swelling, prominent to the eye, but not interfering with the movements of the limb, and I regarded it as a remarkable and interesting feature in the case, that such good results should have obtained under such circumstances.

RECOVERY FROM KNOCK-KNEE.

Dr. Gibney asked if any of the members had seen a case of knock-knee recover without operation or instrumental aid. Dr. Briddon did not believe such a thing possible in any case of genu valgum, although he had seen recoveries from the ordinary bow-leg.

Dr. Gibney remarked that when the genu valgum depended merely upon relaxation of the internal lateral ligaments of the knee, recovery was possible when suitable support was made, but when the same deformity was due to rachitic enlargement of the internal condyle, a surgical operation was the only trustworthy method of treatment. Dr. Gibney believed, in the case of bow-legs said to have recovered, it would always be noticed that the tibia retained its bend. The latter, however, by the growth of the bone, became of comparatively small size, appearing as a slight localized bulging forward and outward just above the ankle.

Dr. Blumenthal stated that he was accustomed, in all cases of bow-legs, to assist nature by supporting the outside of the limbs by a suitable steel splint.

Dr. F. V. White referred to the case of a child who suffered from bow-legs, but who recovered perfectly without mechanical treatment. The patient was nineteen years of age, had perfect limbs, and was somewhat of an athlete.

Dr. Sell exhibited a silver coin (25 cent piece) which was passed per rectum and without treatment three days after it had been swallowed. Dr. White asked if any of the members had seen a case of poisoning from copper after swallowing the ordinary cent, remarking that he had met with one such in his experience.

Dr. Sell presented a small polypus of the cervix removed from a patient aged twenty-nine years, who had suffered from uterine hemorrhages for several years. The growth was removed by the ecraseur and recovery resulted.

A third specimen presented by Dr. Sell consisted of a tænia solium discharged per rectum from a woman who had been ailing for nine months with the usual symptoms attending the presence of the worm. The passage of the tænia was effected by a paste formed of pumpkin seed, sugar, and etherial extract of male fern taken fasting.

The Society then went into Executive Session.

Correspondence.

THE CURE OF CATARACT BY ELECTRICITY.

To the Editor of The Medical Record.

Sir:—I hasten to correct the statements in your last issue of Dr. Agnew and Dr. Webster concerning the case of Mrs. M.

The patient came to me July 26, 1878, with cataract of both eyes. The diagnosis was made by Dr. Webster, who informed her son that an operation would be indispensable, and that the cataract would be ripe for it in about two years. After the galvanic treatment, however, all the symptoms of cataract, which had been gradually increasing *during several years*, entirely disappeared, and the patient became

able to read the smallest print, and see as well as before. She then presented herself to Dr. Agnew, who, on examining her eyes, said that there was no cataract, and that her vision was as good as could be expected at her age. Recently, after the lapse of nearly two years, Dr. Webster made a new examination, and found that some opacities still exist, although her vision in both eyes, since my treatment, continued to be very good, and she could read the smallest print, which she was unable to do before. As regards any opacities that may have remained in the lens, I have no doubt that they can be dispelled by additional treatment, as in a number of other cases where the treatment was more prolonged.

In my article in Virchow's Archiv * I quoted this case as authentic, entirely relying on Dr. Agnew's statement to the patient, not having seen his notes. I therefore leave the responsibility for the alleged discrepancy in the diagnosis to Drs. Agnew and Webster, referring them and the reader to the patient and her son.

This case, however, cannot change the fact that cataract yields to galvanism. The method, which I fully described, is now tested by disinterested and competent judges, and will, undoubtedly, soon be adopted by the profession.

The remarkable effect of the galvanic current in cataract, and especially in diseases of the choroid and retina, even in some incurable diseases, will soon render the use of the galvanic apparatus as indispensable to the ophthalmologist as that of the ophthalmoscope.

W. B. Neftel, M.D.

To the Editor of The Medical Record.

Sir:—I have, this day, had the first opportunity of examining the eyes of Mrs. H. B. W——, whose case was published with so much *éclat* in the *Churchman* and *Virchow's Archiv*, my name being connected with it in the latter journal. I saw the lady, who appears to be over sixty years of age, for the first time May 16, 1878. The record in my book states: Diminution of sight and dazzling for a year: S. B. ♀, L. ⅝ : reads finest print with her glasses; posterior pole of lens, opaque: periphery beginning also, etc. In the course of a year she paid me two other visits. I noticed that her sight at distance grew worse, though the cataract made little progress. Under Dr. Neftel's treatment she became able to read without her glasses, though, as she informed me, her sight at distance was dull. The examination of to-day showed about the same vision for distant objects as she had when I examined her last, June, 1879. She could read, near by, ordinary, but not finest type. She read without glasses, but lately found that her sight for the distance was improved by concave glasses. On examination with oblique light and the ophthalmoscope, I found that in the left eye there was very marked opacity in the central region of the posterior corticalis and at the equator in both the anterior and posterior cortex. The details of the fundus, which I could formerly see and found normal, have become invisible by the cataract. In the right eye the same condition exists, but less advanced.

The cataract, therefore, has neither been cured nor arrested; nor has her acuteness of vision improved.

The deception was caused by the fact that the patient, during the slow development of a posterior cortical cataract with sclerosis of the nucleus, became nearsighted, which frequently takes place, as is well known to every oculist. The so-called "second sight" of old people, which means that they get able to read without their glasses, is always an indication of incipient cataract, but what they gain in near they lose in distant vision.

Respectfully, H. Knapp, M.D.

New York, May 16, 1879.

* Dr. W. B. Neftel: Ueber die galvanische Behandlung der Cataracta incipiens. Virchow's Archiv, Bd. 79, p. 165.

RED PERSPIRATION IN AXILLÆ.

To the Editor of The Medical Record.

Sir:—The extract in your last issue entitled "Red Perspiration of the Axillæ" brought to mind *several* cases which I have seen within the past two years.

In each instance the patients were afflicted with pediculi pubis, and the axillæ were inhabited. The hairs in the armpits were invariably matted together with the "honey" secretion, and microscopic examination revealed what might, in truth, be called "glittering spores."

At first I concluded that the "honey" secretion was a sebaceous matter, but now am quite sure it bears some relation to the nutrition of the ovi, as in the case of spiders' eggs.

As for treatment, a little soap and water *will prevent*, or a little blue ointment *will cure*, any case where there is "red perspiration of the axillæ."

W. A. Dayton, M.D.

123 W. 125th Street.

CONCERNING MEDICAL LEGISLATION.

To the Editor of The Medical Record.

Sir:—The April number of the *Archives of Comparative Medicine and Surgery* contains an editorial criticism on a bill now before the legislature, entitled "An Act to Regulate the Practice of Veterinary Medicine and Surgery in this State," and the writer pungently states the results of such legislation upon the medical profession in this city. He characterizes all such enactments as worse than failures, and, of course, predicts that the same consequences will be entailed upon veterinary medicine by legislative interference.

Such a criticism, if true, certainly reflects discredit upon our profession, which has been the author and promoter of all medical legislation in the State.

After declaring that legislation has driven the practitioners of almost every form of quackery to thoroughly organize for self-defence, the writer proceeds as follows: "The New York County Medical Society practically bears witness to this, as it has recently been obliged to admit to membership persons coming from irregular schools, which have been outgrowths from these organized bodies of quacks. This humiliation has been clearly effected by the stringent legislation referred to."

Such a public statement as the above should be sufficient to excite the earnest consideration of those who regard the welfare of the County Medical Society and the profession. It is said that many other graduates of irregular schools are about to claim admission *under the law*, and one is to be elected or rejected at the next stated meeting of the Society. Either we are bound to admit them, or the Comitia Minora has been the victim of unsound legal advice on the subject. It seems more reasonable to believe the latter, for it is very improbable that the legislature would pass a law depriving a chartered society of its inherent right to be the judge of the qualifications of its own members.

Every medical graduate may join the county medical society of *his own kind:* the regular may join the regular society; the graduate of homœopathy the homœopathic society; and the eclectic become a member of their county society; and that is so clearly the intent of the law, that no legal advice to the contrary should influence the Comitia Minora for a moment.

It is high time the entire Society should awake to the importance of this question, and promptly vote against the admission of such discordant elements, which must ultimately destroy its usefulness.

From my knowledge of the gentlemen composing the Comitia Minora, I do not believe they would feel aggrieved by such a solution of this question.

COUNTY MEDICAL.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from May 9 to May 15, 1880.

KING, WM. S., Lieut.-Col. and Surgeon. His leave of absence on account of sickness still farther extended six months. S. O. 101, A. G. O., May 7, 1880.

WOODWARD, J. J., Major and Surgeon. To proceed to Europe under special instructions to be communicated by the Surgeon-General of the Army. After completion of the duties assigned him, to return to his station in Washington, D. C. S. O. 105, A. G. O., May 12, 1880.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending May 15, 1880.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
May 8, 1880.	0	11	41	9	76	33	0	0
May 15, 1880.	0	10	42	5	118	47	1	0

THE CARE OF SMALL-POX IN CHICAGO.—The city of Chicago provides no place for its sick with epidemic diseases, except cases of small-pox. Within a week two cases of measles, turned out of their boarding-places and unable to gain admission into any hospital, have been in danger of death from starvation and exposure upon the streets. One case, a man, was found by a policeman on the sidewalk; the other was a woman, with a nursing baby in her arms.

Both patients were taken into the office of Commissioner of Health Dr. Wolfe, and generously fed and nursed at his personal expense.

It is the intention of the Health Department to prosecute the man who turned the woman into the street, as this is an offence under a city ordinance, punishable with a fine not to exceed $100, and imprisonment in the House of Correction not to exceed sixty days.

DEATH FROM CHLOROFORM. Within a few weeks, two deaths from the use of chloroform, used for anæsthetic purposes, have occurred in Chicago.

One was a young man, undergoing an exploratory operation for necrosis, at the Eclectic Medical College. Only a little chloroform was used, and it was used with caution. No heart disease was found post-mortem, but the brain was thought to be softer than natural, but, of course, was not in the condition of mallitus cerebri proper, as no symptoms of cerebral disease had preceded.

The other case was a weakly man, under middle age, with organic heart disease, who had been an invalid for several years. He received a crushing injury of the hand (thumb), and was taken by a friend to a drug-store kept by a physician, to have it dressed. Amputation being necessary, ether was first tried, but anæsthesia not being promptly induced, chloroform was substituted. After a few inspirations the patient died. The quantity of chloroform used was small. The heart was found fatty, as well as to have valvular disease.

PROF. LEWIS A. SAYRE, M.D., has been elected a corresponding member of the Edinburgh Medico-chirurgical Society.

ERRATA.—In Dr. Poole's article, p. 513, third line of second paragraph, the words "tonic or chronic" should read "tonic or clonic"; and in the eighth line of the same paragraph, the word "contracted" should be "controlled," the line being, "the muscle is still controlled by the spinal nerves," etc.

CREMATION AND FULL GRAVEYARDS.—On the night of May 12th the body of Gustave Poetz was cremated at Washington, Pa. The body was reduced to ashes in three hours.

Apropos to this event come a number of newspaper stories concerning the overcrowded condition of many graveyards, The London *Times* recently declared that for 300 years English graveyards had been so full that, like the one in Hamlet, Yorick's bones have had to be dug out in order to put Ophelia's in. A London florist purchased two cart-loads of mould a short time ago, and found it full of legs, arms, skulls, etc.; he brought suit against the person who supplied him for misrepresenting his goods.

In this country, two cemeteries—one in New England, the other in Pennsylvania—recently caved in, and the thickly crowded bones of many generations were exposed to sight. Facts like these go a good way to endorse the practice of cremation.

THE STATE BOARD OF HEALTH OF MARYLAND has been organized under the law recently passed. The Board consists of three physicians, Drs. E. L. Howard, C. W. Chancellor, and J. R. Ward; J. C. Neilson, civil engineer; C. J. McGwinn, attorney; and J. A. Stewart, health commissioner of Baltimore. Dr. Chancellor will probably be elected secretary, and another member be added to the Board.

THE THIRTY-FOURTH ANNUAL MEETING OF THE ASSOCIATION OF MEDICAL SUPERINTENDENTS OF American Institutions for the Insane will be held at the Continental Hotel, Philadelphia, at 10 A.M., Tuesday, May 25, 1880.

THE N. Y. STATE DENTAL SOCIETY held its annual session at Albany, May 13th and 14th. Dr. C. E. Francis presided. About 100 members were present. Four, out of ten applicants, received the degree of M.D.S.

PRODUCTION OF SEX AT WILL.—Mr Liquet, a cattle-breeder of Texas, claims to have discovered a way by which either sex can be produced at will. His theory is that when the female at time of coition is comparatively cold, and the male very passionate, a female will be the result; a reversal of the conditions will produce a male. Mr Liquet secures the proper conditions by feeding the bull, for example, on rich food previous to the coition; the cows at the same time being kept on low diet, and submitted to the gallantry of a castrated bull, until the excess of their passion has worked itself off. In all the experiments, numbering fifteen or twenty, so far tried, he has been successful in predicting the sex.—*Bost. Med. and Surg. Journ.*

HYOSCYAMIA IN INSANITY.—In the *American Journal of Insanity* for April, Dr John P. Gray gives the result of his experience with hyoscyamia. He uses one-sixth of a gr of the dark preparation of Merck, or one-twelfth of a gr of the white crystals. In acute mania, and melancholia with frenzy, no remedy acts so well in calming the high nervous and muscular excitement. In certain similar cases in which the patients refuse to eat, the remedy has acted admirably. As a sleep inducing remedy, in cases of furious insanity, hyoscyamia will often succeed when other remedies fail. In high excitement associated with plethora and in epileptic mania, the bromide may be combined with it. The drug is beneficial in hysteria and chorea, but not in chronic insanity with quiet delusions. The alkaloid is better than the other preparations.

THE LOUISIANA STATE MEDICAL SOCIETY held its annual session at New Orleans, March 31st. A larger number of members than usual was present, and the meeting was in every way successful. The annual address was delivered by the President, Dr. J. W. Dupree; the annual oration by the Rev. H. M. Thompson, D.D. Seventeen new members were admitted to the Society. The Society declined to appoint a committee to confer with other committees for the purpose of making arrangements for the next meeting of the American Public Health Association.

A resolution was passed endorsing a petition for a law regulating the practice of medicine, and urging the greater consideration by and greater union of the profession in regard to the securing such a law.

Dr. G. M. Stirnberg, U.S.A., read a paper on microscopy, in which he gave some of the results of his investigations in Havana last summer.

Dr. L. F. Salomon reported ten additional cases of leprosy in the State.

Papers were read on "Morbus Coxarius at the International Medical Congress, Philadelphia," on "Incised Wound of the Stomach," "Medical Hydrology," "Hydrophobia in Louisiana."

The Hon. Thos. J. Semmes was elected honorary member and annual orator for 1881.

The following officers were elected for the ensuing year: President, Dr. C. M. Smith; Vice-Presidents, Drs. D. R. Fox, J. P. Davidson, P. S. Postell, A. A. Lyon, G. M. Brumby, and O. P. Langworthy; Recording Secretary, Dr. L. T. Salomon.

The Society adjourned, to meet in New Orleans on the last Wednesday in March, 1881.

SURGEON JOHN F. RANDOLPH, U.S.A., died at his residence, in Philadelphia, May 14th, at the age of fifty-three. Dr. Randolph joined the army in 1855. He gained much distinction in the expedition against the Indians in Washington Territory in 1858. At the time of his death he was full major.

THE TENNESSEE STATE MEDICAL SOCIETY held its forty-seventh annual session at Knoxville, April 6, 7, and 8, 1880. About forty members were present. Dr J. H. Carriger delivered the opening address of welcome. The annual address was delivered by the retiring President, Dr L. M. Wight. An interesting letter was received from the venerable Dr J. G. M. Ramsey. Dr. R. is in his eighty-fourth year, and has practised medicine for sixty years.

A committee of five was appointed to memorialize the next legislature to pass laws regulating the practice of medicine in the State of Tennessee.

Certain charges preferred against the President by the Shelby County Medical Society for alleged unprofessional conduct in some of his rulings were investigated, and Dr. Wight was exonerated from any intentional misdeed.

A somewhat novel departure was the appointment of a committee of three to write up sanitary medicine in the public press. About twenty members were added to the Society's roll.

Papers were read by Dr. W. P. Jones on Insanity; by Dr D. J. Roberts on Cholera Infantum; by Dr. W. R. Sevier on Toxæmic Disease; by Dr. Van S. Lindsley on Hypermetropia. Numerous other papers were read, there being fourteen or fifteen in all.

The following officers were elected for the ensuing year: President, Dr. R. B. Lenoir, of Lenoir's; Vice Presidents, Drs. Alexander W. M. Clarke, T. J. Tyner; Corresponding Secretary, Dr. T. A. Ramsey, of Knox; Recording Secretary, Dr. Morrison; Treasurer, Dr. J. D. Plunket.

The Society adjourned to meet at Nashville on the first Tuesday in April, 1881.

A NEW REMEDY FOR HYDROPHOBIA AND LEPROSY.—A pamphlet has been recently published by the Director of the French Foreign Missions Seminary, entitled *Le Hoang-Nan, Remède Tonquinois contre la Rage, la Lèpre et autres Maladies*. It describes the properties of a yellow powder made from the bark of the hoàng-nàn, a vine growing in Cochin China. There are a large number of medical reports from the various hospitals and dispensaries of the missions, showing that the drug is invaluable in leprosy and snake-bites. The evidence of its efficacy in hydrophobia is not so positive.

THE RIGHT OF PROPERTY IN THE BODIES OF THE DEAD.—A suit was recently tried in the Superior Court of Cincinnati, which brought up a question never before decided. One Mrs. Ann Farley claimed to recover $5,000 from Dr. Wm. Carson, one of the medical staff of the Cincinnati Hospital, for operating with a dissecting-knife upon the corpse of her husband, without her consent, or that of her children. The man was a charity patient who had died from hepatic abscess. It was claimed by the defence that the body was not cut for dissecting purposes, nor for the purpose of post-mortem examination, but to relieve it of a large accumulation of pus.

The judge, in passing on a motion to arrest the case, said that the question was simply this: Has a widow such a right in the body of her deceased husband that she may have action for damages against any one who injures the body? Neither counsel nor judge were able to find any authorities or precedents directly on this point. In all previous cases, it was conceded that the relatives had a right of property in the garments and ornaments of the dead, but not in the body. That was the common law. In the present case there was no actual damage, or, at least,

the only damage was to the feelings of the plaintiff. But the court knew of no case in which action was permitted on account of injury to the feelings. As there was, therefore, no right of property and no actual damage to the plaintiff, the case was dismissed.

Medical Education of Homœopaths.—The following illustration of the homœopathic method of teaching is taken *verbatim* from the papers of a recent examination of the students of a western homœopathic medical college:

"Tuberculosis it is a disses of malnution tow varito the yelow and gray. Natur is ente and chronic the sines is dulness on percution. Rem mureatimonia Phos."

This is one specimen out of half a dozen equally bad. They form the text of an appeal for higher education in homœopathic colleges.

The Cincinnati Board of Health has been reorganized. The position of Health Officer was tendered to Dr. T. C. Minor, who declined a reappointment. Dr. A. J. Miles was then elected to the position.

Bad Characters in Medical Schools.—In a letter from Mr. Arthur Gamgee, Dean of the Owens Medical College, to Dr. Acland, he states that at the last session the college expelled a student because he had been convicted of a felony. At present they were about to expel another student, who had been convicted "of the abominable offence of indecently exposing his person." The Dean is anxious to secure some arrangement by which those who have thus been expelled from one school shall be prohibited from entering any other. Such an arrangement must be desirable, since it is at present impossible to prevent a felon from becoming a physician, although, if a physician becomes a felon, his status as a medical man can be taken away. The cases cited to illustrate the necessity of this movement do not speak well for the character of the English student—at Owens college, at least.

American Medical Association.—The thirty-first annual session will be held in New York on Tuesday, Wednesday, Thursday, and Friday, June 1, 2, 3, and 4, 1880. The following are the chairmen and secretaries of Sections:—Practice of Medicine, Materia Medica, and Physiology: Dr. J. S. Lynch, Baltimore, Md., *Chairman;* Dr. W. C. Glasgow, St. Louis, Mo., *Secretary.* Obstetrics and Diseases of Women and Children: Dr. Albert H. Smith, Philadelphia, Pa., *Chairman;* Dr. Robert Battey, Rome, Ga., *Secretary.* Surgery and Anatomy: Dr. W. T. Briggs, Nashville, Tenn., *Chairman;* Dr. C. Powell Adams, Hastings, Minn., *Secretary.* Medical Jurisprudence, Chemistry, Psychology, State Medicine, and Public Hygiene: Dr. Jas. F. Hibberd, Richmond, Ind., *Chairman;* Dr. Thos. F. Wood, Wilmington, N. C. *Secretary.* Ophthalmology, Otology, and Laryngology: Dr. Bolling A. Pope, New Orleans, La., *Chairman;* Dr. Eugene Smith, Detroit, Mich., *Secretary.* The following Committees are expected to report:—On Prize Essays: Dr. Austin Flint, New York, *Chairman;* On Necrology: Dr. J. M. Toner, Washington, D. C., *Chairman:* On Catalogue of National Library: Dr. H. C. Wood, Philadelphia, *Chairman;* On Ozone: Dr. N. S. Davis, Chicago, Ill., *Chairman;* On the Metric System: Dr. T. Parvin, Indianapolis, Ind., *Chairman;* On State Medical Societies: Dr. S. D. Gross, Philadelphia, *Chairman.* The following proposed amendments of the constitution will come up for action: Article II., second paragraph, after "Army and Navy" insert "and the Marine Hospital Service of the United States." Article II., fourth paragraph, at the end insert "the Marine Hospital Service of the United States shall be entitled to one delegate." The following proposed amendments of the by-laws will be acted upon: 1. Expunge from Section III. everything relating to prize essays and the committee on prize essays. 2. Introduce into Section II. the following laws: *Prize Essays. a.* There shall be four annual prizes of two hundred and fifty dollars each, which shall be awarded at the close of the second year after announcement, as hereinafter explained, for strictly original contributions to medical and surgical progress. *b.* It shall be the duty of the chairman of each of the following four Sections—1. Practical Medicine, Materia Medica, and Physiology; 2. Obstetrics and Diseases of Women and Children; 3. Surgery and Anatomy; 4. State Medicine and Public Hygiene—to appoint annually before the adjournment of the meeting of the Association three members of ability and good judgment, who shall constitute a committee of selection, and who shall, within thirty days thereafter, select and publicly announce for competitive investigation and report a subject belonging to one or other of the branches of medicine included in the title of the section. *c.* It shall also be the duty of the chairman of each of the sections mentioned to appoint annually a committee of award, consisting of three experts, who shall carefully examine the essays offered for competition, and, if any one shall be found worthy of the prize as a substantial contribution to medical knowledge, to recommend the same to the Association. *d.* All essays placed by their authors for competition should be in the hands of the chairmen of the respective committees of award on or before the first day of January preceding the meeting of the Association at which the reports of the committees are required to be made. *e.* All prize essays shall be considered as the property of the Association. *f.* The names of the authors of the competing essays shall be kept secret from the committees by such means as the latter may provide. *g.* Membership in either of the two committees shall not debar from membership in the other; nor shall membership in the Committee of Selection exclude a member from the privilege of offering a competing essay.

So far as can be determined at present date, the proceedings of the American Medical Association will take place as follows: The meetings will be held in the hall and other rooms of the Young Men's Christian Association, at the corner of Twenty-third street and Fourth avenue, and in the amphitheatre of the College of Physicians and Surgeons, which is near the Association building. The general meetings will be held in the Association Hall, whose floor will be given to delegates and the galleries to spectators. The various sections will meet in adjoining rooms of the building, except the Surgical Section and that on State Medicine, which will meet in the College of Physicians and Surgeons.

The work of the session will be done in a general meeting, which will begin each morning at 10 A.M., and in special sections, which will meet in the afternoons at 2 o'clock.

It is impossible to say now on what day particular papers can be heard. At some time, however, during the four days, the following papers will be read:

In the Section on Practice of Medicine, papers on The Classification of Medicines, by Dr. William H. Thomson; on Progressive Muscular Atrophy and

Pseudo-Hypertrophy, by Dr J. D. Kerlin and Dr. Chas. K. Mills, of Philadelphia; on Microscopic Sections from Cases of Diseases of the Brain and Spinal Cord, by Drs. Chas. K. Mills and Carl Seiler, Philadelphia, Pa., on the Use of Sulphur and its Compounds in the Treatment of Diseases of the Skin, by Dr. L. Duncan Bulkley, New York; on the Diphtheritic Poison, by Dr. J. T. Everett, Sterling, Ill.; Artificial Inflation as a Remedial Agent in Diseases of the Lungs, by Dr. W. T. Gadbury, Yazoo City, Miss. (read by Dr. J. Solis Cohen); The Electrical Treatment of Exophthalmic Goitre, by Dr. A. D. Rockwell, New York; A Case of Recovery from Occlusion of One or More of the Cerebral Sinuses, by Dr M. O'Hara, Philadelphia, Pa.; The Therapeutics of the Natural Mineral Waters, by Dr W. C. Van Bibber, of Baltimore; on the Strong Galvanic Current in the Treatment of Sciatica, by Dr. V. P. Gibney, New York; on Epilepsy, by Dr Leonard W. Pitkin, New York.

In the Section on Surgery, there will be papers on Spinal Extension, its Modes, Means, and Motives, by Dr. Benj. Lee, Philadelphia, Pa.; on Phymosis, as a Cause of Nervous Symptoms, with Results of Operations, by Dr. George M. Beard, New York; on Laparotomy and Colotomy, with Formation of Artificial Anus, for Obstruction of the Intestines, by Dr. W. A. Byrd, Quincy, Ill.; A New Inhaler, by Dr. D. M. Barr, Philadelphia, Pa.; Thoracentesis, by Dr. C. A. Lee, New York; Cystotomy for Cystitis of the Male, by Dr. Robert F. Weir, New York; on Hip-joint Disease, First Stage, with Microscopic Sections, by Dr. De Forest Willard, Philadelphia, Pa.; Reparative Processes of Osseous Tissue, Illustrated by Microphotography, by Dr. H. D. Marcy, of Cambridge, Mass.; a New Method of Treating Spinal Disease, by Dr. E. H. Coover, of Harrisburg, Pa.; on Some Points in the Treatment of Hemorrhoids, by Dr. W. D. Blackwood; on the Treatment of Fractures of the Long Bones, Involving Joints, by Dr. Jas. S. Green, of Elizabeth, N. J.; on the Foramina of Monroe, in Man and the Domestic Cat, by Dr. Burt G. Wilder, Ithaca, N. Y.; on Newly Devised Orthopedic Appliances, including the Seaton Splint, by Dr. C. F. Stillman, Plainfield, N. J.; on Compound Complicated Hare-Lip, by Dr. Jas. L. Little, New York; on Lupus, illustrated with magic lantern, by Dr. H. G. Pitard, New York.

In the Section on Obstetrics, there will be papers by Dr. J. Marion Sims, on Battey's Operation in Epileptiform Affections; by Dr. Montrose A. Pallen, on the True Import of Oöphorictomy for Reflex Symptoms, more particularly in Epilepsy and Catalepsy; by Dr. T. Gaillard Thomas, on Ablation of the Uterus; by Dr. Wm. M. Polk, on the So-called Malaria of Puerperal Fever.

In the Section on Ophthalmology, Otology, and Laryngology, papers by Dr. W. H. Daly, Pittsburg, Pa., on Stenosis of the Larynx; by Dr. Carl Seiler, of Philadelphia, on Lesions of the Larynx in Pulmonary Phthisis; by Dr. F. H. Bosworth, New York, on Bilateral Paralysis of the Abductors of the Larynx; by Dr. D. H. Goodwillie, on the Surgical Treatment of Naso-Pharyngeal Catarrh; by Dr. W. H. Daly, on the Therapeutic Value of the Galvano-Cautery in Diseases and Growths of the Naso-Pharynx.

In the Section of State Medicine, papers will be read on the Death-Rate among the Rich and Poor, by Dr. Drysdale, London; on Hygiene and Fevers, by Dr. Jos. J. Jones, of New Orleans; on the Psycho-Physiological Training of Idiotic Eyes, by Dr. E. Seguin.

The evenings will be occupied by social entertainments, as follows. Tuesday evening a grand reception will be given to the Association by the profession of New York, in the Academy of Music. The parquet will be floored over, as is usual in such entertainments. Music will be furnished by the Seventh Regiment band, and a supper, of which Delmonico is to be caterer, will be served in Nilsson Hall adjoining.

On Wednesday evening a complimentary theatrical entertainment will be given in Booth's Theatre; Mr. Booth will act "Iago," in Othello.

On Thursday evening, receptions will be given by Drs. Fordyce Barker and T. Gaillard Thomas, in the Academy of Medicine, also receptions by Mayor Cooper and by Mr. August Belmont, at their respective residences.

On Friday, at 1 P.M., after the final adjournment of the Association, a grand steamboat excursion will be given by William Wood & Co., Medical Publishers, New York. The steamboat "Grand Republic" will start from the foot of West 24th street, and take the following route: up the Hudson River to Yonkers, affording a view of the Palisades, thence returning, will pass around the southern portion of Manhattan Island, up the East River, around Blackwell's Island, and thence through the bay to the ocean and landing on the New Iron Pier at Coney Island, where a luncheon will be served. Music will be furnished by Gilmore's band.

During the sessions of the Association there will be displays of drugs, chemicals, surgical instruments and appliances, medical wares, &c., in the stores on Fourth Ave. under the Coll. of P. and S. It is requested that all persons wishing to make any exhibit apply at once to the Chairman of the Committee of Arrangements, Dr. Montrose A. Pallen, No. 18 East 29th street, New York City.

Books Received.

Original Lectures.

THE PULSE.

By T. A. McBRIDE, M.D.,

LECTURER ON SYMPTOMATOLOGY, SPRING COURSE, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

GENTLEMEN—We begin to-day with the study of the pulse. The word pulse is derived from the Latin *pulso*, I strike, and expresses the striking or lifting of the finger by the distending vessel, as, with each contraction of the heart, blood is forced into the vessels. The significance of the word has also been extended, so as to be applied to the appearance of a lifting up of the coverings over a distending vessel, so that the word *pulse* is applied not only to that which is felt, but to that which is seen.

There are two kinds of pulse—the arterial and the venous. The arterial is appreciated mainly by palpation, the venous by inspection. We have to study especially the arterial pulse.

In the writings of the old school of physicians, even to the days of Hippocrates, the pulse was regarded as one of the most important symptoms, and although some of the distinctions that these observers made were too fine and subtle to be really appreciated at the bedside, there can be no doubt that their observations of the changes in the pulse were often extremely acute and accurate. So accurate, indeed, that Dr. Broadbent, referring to these observations, says: *"It was with astonishment that I learnt when I first took up the study, that every single element of the pulse revealed to us by the sphygmograph had been previously recognized by the old school of physicians, and that a nomenclature existed ready made for all of its teachings."

The radial pulse is the one usually selected, since it answers all of the requirements. It is of moderate size, is superficial and can be readily compressed against the radius. The pulse in vessels elsewhere must sometimes of necessity be observed, as in the brachial, the facial in front of the masseter muscle, the temporal, posterior tibial, dorsalis pedis, the carotid and femoral arteries.

When the pulse is to be taken, the patient should be either sitting or lying down. The observer should place his index, middle, and ring fingers lightly upon the pulse, and should then appreciate the state of the coats of the artery and should next note the frequency, the rhythm, the tension, volume and force of the pulse, and lastly, any peculiarities if present. Moreover, the pulse of one side of the body should always be compared with the other. It should also be remembered that forcible extension or flexion of the forearm will sometimes arrest the radial pulse. In taking the pulse in children and infants, it is well to count the pulse, if possible, while they are asleep. This can often be done nicely in the temporal artery. In taking the pulse at the wrist, asleep or awake, there are often involuntary movements of the arm and twitchings of the muscles, which render it difficult to keep the finger of the observer on the pulse. The difficulty may be overcome in a great degree by grasping the entire hand of the child and then extending the index finger upon the pulse.

* Lancet, vol. ii., 1875, p. 441.

It is also advisable not to take the pulse of the patient until some little time has elapsed after the appearance of the physician.

The factors of the pulse and the several phenomena dependent upon them, are shown in the following table:

1. Heart.	*a.* Rate or frequency.	
	b. Rhythm—intermittency and irregularity.	
	c. Force or strength.	
	d. Quantity of the blood.	
2. Degree of resistance to the passage of blood through small arteries and capillaries.	*a.* Degree of tension.	Hard or long. / Soft or short.
	b. Size of vessels.	Large. / Small.
3. Elasticity of vessels.	*a.* Dicrotism, hyperdicrotism.	
	b. Non-dicrotism (senile pulse).	

In health, changes in the frequency and rhythm of the pulse are often met with.

I subjoin a table of the variations in the frequency of the pulse in health which is taken from Hooper's "Physician's Vade-mecum," edited by Drs. Guy & Harley, and from this work is also taken most of what follows on the changes of the frequency of the pulse in health.

Infant asleep at birth	140
Infancy	120
Child five years of age	100
Youth	90
Male adults	72–80
Female adults	80–85
Old age	70

Heberden records 42, 30, and 26 beats to the minute, in an old man of eighty, apparently in perfect health; Fordyce, another of 26 (Hooper's "Vade-mecum," p. 179, London, 1869). Great frequency in health is not often met with, but I have under observation a case where the pulse ranges from 100 to 120, and the individual states that this frequency has existed all his life.

Sex has some influence. Up to seven years of age the frequency is about the same in both sexes, but later the female pulse is from 6 to 14 beats—average 9, greater than in the male.

Posture also affects the pulse. It is most frequent in the standing, and least in the recumbent position. The pulse of a man is twice as much affected by change in position as that of a woman. When the pulse is much increased in frequency, change in position has but little effect, and for the higher numbers entirely disappears. When the head is lower than the body the pulse falls (a hint for the treatment of some forms of palpation). The general law as to the degree of frequency of the pulse as affected by position is as follows—the frequency is directly proportioned to the amount of muscular effort required to support the body in different positions.

The pulse falls in sleep as much as ten beats. Sleeplessness increases its frequency. On awakening from sleep there is usually a decided increase in frequency.

Food increases the rate. Mental excitement and activity of the emotions increase the frequency; mental depression is often accompanied by a decrease. Cold lowers and heat raises the rate. Among other causes producing an increase in the frequency of the pulse in health may be mentioned spirituous and warm drinks, tobacco, diminished atmospheric pressure. Among the remaining causes producing diminished frequency there are fatigue, long-continued rest, debility without disease, and increased atmospheric pressure. Occasionally the pulse is

occasional in health, but when that is so it is usually congenital.

Intermittency is not infrequent in health, and it is then either congenital or, as Dr. B. W. Richardson* has shown, may be due to terror, anxiety, grief, passion, mental or physical fatigue, adverse fortune, and old age. The intermittency may be only temporary, or it may become permanent; and if it becomes very frequent, may be pathological.

I now ask your attention to the pulse in disease, and I shall consider the subject under the following heads:

1st.—The condition of the walls of the vessel the seat of pulsation.

2d.—Changes referable to the several factors of the pulse.

3d.—Names and significance of certain pulses.

1st.—The condition of the walls of the vessel the seat of the pulsation. In health, an artery of the size of the radial should not be felt in the interval of pulsation. When the artery can be easily appreciated in this interval, the coats of the vessel have undergone some pathological change, or else the vessel is over-distended with blood; the blood pressure is greatly increased. The artery sometimes feels like a rubber tube with thick walls, or a pipe with rigid walls, or, again, resembles a string of beads. It is often tortuous or serpentine, and may be traced up almost the entire forearm. These changes in the walls of the artery are the result of chronic inflammation with subsequent degeneration—deposition of calcareous matter. Usually these changes are widely distributed in the arteries throughout the body. The temporal arteries especially are tortuous and serpentine, and sometimes the ophthalmoscope reveals thickening of the arteries at the fundus oculi. Changes in the coats of the arteries are observed in cases of Bright's disease, in the rheumatic and gouty, in the syphilitic, and sometimes in athletes as the result of overstrain, and in lead-poisoning and scurvy. Excessive use of tobacco and alcohol occasion these changes. Certain infectious diseases besides syphilis seem also to excite pathological alterations in the walls of the vessels, as for example, diphtheria and typhus fever. Exposure to cold and heat, want of food, or good air, also, may produce these changes; and, lastly, they may appear as among the earliest of the degenerations incident to senility.

It is important to appreciate the abnormal conditions of the walls of the artery in the following: in the diagnosis and prognosis of cerebral hemorrhage and thrombosis; in the prognosis, diagnosis, and treatment of changes in the aortic valves of the heart; and in the prognosis and just estimation of many diseases when found associated with this sign of beginning degeneration, and which may be the only positive sign of beginning decay.

I have already alluded to the fact that in pulse of high tension the vessel may be felt in the interval of pulsation, and one may be so deceived as to mistake such a condition of things for a vessel with diseased walls, whereas the artery is over-distended with blood and the walls may be normal. This is not so infrequently met with, and very often we find that disease of the walls eventually does supervene, apparently by reason of this condition of high tension. It may be necessary sometimes to differentiate these conditions, and Dr. Broadbent, in his interesting and valuable lectures on the pulse in the *Lancet*, 1875, to which I shall often refer, has demonstrated how perfectly this can be done by having the patient inhale some nitrite of amyl. If the pulse be one of high tension only, the thick cord-like vessel disappears in the interval of pulsation, and is only felt during pulsation, and is then very soft. If the walls of the artery are actually thickened or diseased, very little change takes place. But, as I have said, you may find both combined, and the difference is in the change in the compressibility of the pulse.

2d.—The phenomena referable to various factors of the pulse.

The Heart.—Increased and diminished frequency of the pulse.

a. Increased frequency.

I ask your attention to the following schemes of the causes of increased frequency of the heart as determined by experiment on animals. It is taken from Lauder Brunton's book on the "Experimental Investigation of the Action of Medicines," Part I., Circulation, London, 1875. I do this so that you may, if possible, explain to yourselves the probable cause of a frequent pulse in many conditions. I should be overstepping my limits of time were I to attempt it.

Paralysis of vagus roots or vagus fibres
" " " ends in the heart.
Stimulation of the cardiac sympathetic } by lowered blood pressure
Stimulation of the cardiac ganglia } by increased temperature of the body.

A pulse of 90 or more may be regarded as a pulse of abnormal frequency in an adult. There are exceptions to this, but they are rare.

In the following pathological conditions a frequent pulse is of importance in diagnosis or prognosis.

1. Fevers.—"In fevers the pulse is generally quickened in proportion to the elevation of temperature, though the proportion between the pulse and the temperature varies in different fevers. In scarlet fever the pulse is quicker than in typhoid fever with the same temperature, hence a quick pulse is of less serious import in scarlet than in typhoid fever. The same elevation of temperature quickens the pulse relatively much more in children than in adults."

"If a pulse is quicker than the temperature will explain, it indicates cardiac weakness—the weakness being proportionate to the want of ratio between the temperature and the pulse. In this way the pulse affords important information in prognosis and treatment."

"A pulse that day by day progressively increases in frequency, the temperature remaining the same, shows increasing cardiac weakness."

"In all febrile diseases a pulse in adults over 120 is serious and indicates cardiac weakness. A pulse of 130 or 140 indicates great danger, and with a pulse at 160 the patient almost always dies."*

a. In eruptive fevers, just before the appearance of the eruption, the pulse becomes sometimes very frequent.

b. In relapsing fever, during the febrile periods, the pulse is of very great frequency and is often 130 to 140. It attains a greater degree of frequency than in any other fever, without being of grave significance (Murchison).†

c. In typhoid fever the prognosis is usually bad when pulse persistently exceeds 120 (Murchison).†

* Discourses on Practical Medicine: On Intermittent Pulse and Palpitation. London, 1871.

* A Hand-book of Therapeutics, by Sidney Ringer, M.D. William Wood & Co., New York, 1879. pp. 7 and 8.

† A Treatise on Continued Fevers, by Charles Murchison, M.D. London, 1873.

d. In the convalescence from all fevers the range of increase in the frequency of the pulse in changing from a recumbent to a sitting or standing position, or the range of decrease in its rate in changing from a standing or sitting to a recumbent position, is a measure of the debility of the patient. During the pyretic period such changes in position have little or no effect. The rate of the pulse may therefore be of importance in gauging the strength of the patient.

2. Inflammations:

a. The occurrence of a sustained frequency of the pulse after confinement is a very suspicious symptom, and may betoken advent of puerperal peritonitis.*

b. Diseases of the lungs and pleura.

1. Under the age of fifteen any disease of the lungs is almost invariably accompanied by great frequency of the pulse, so that a pulse of 120 to 140 would not be considered as so serious in significance as if it occurred in an older person.

2. When a frequent pulse is present in pneumonia it is always of bad significance, even if only a small portion of the lung is involved. Moreover, when a pneumonia occurs in the cachectic or debilitated, the pulse is especially apt to be frequent, often 120 to 160, and such cases usually die.

3. When complicated with heart disease, the frequency of the pulse is significant. Traube asserts, when in a strong robust person you find a pneumonia with a pulse of 120, you may be sure that there is present some form of heart disease.†

c. In the diagnosis of incipient phthisis a sustained frequency of pulse is thought to be of importance by Sir Thomas Watson, and others.

d. In pleuritic effusions the pulse may be very frequent, especially when there is displacement of the heart.

e. In pericarditis and myocarditis very great frequency of the pulse is observed at times—especially on any movement by the patient—130 to 160. The change in rate may be very sudden and is of some importance in diagnosis and prognosis.

f. In acute articular rheumatism unaccompanied by peri-, endo- or myocarditis, a pulse of 120 or more indicates great danger (Ringer).

g. In the last stages of meningitis of the convexity, and particularly in tubercular meningitis, a very frequent pulse is often observed.

3. Diseases of the nervous system:

a. In diseases affecting the medulla oblongata—in glosso-labio-laryngeal paralysis the pulse is quite frequent.

b. In the early stage of locomotor ataxia a frequent pulse is a quite constant symptom.

c. In Basedow's disease a pulse of 120 to 140, and even of 200, is often observed at times.

d. In hysteria an exceedingly frequent pulse is not uncommon, 130 to 160 and more.

e. In puerperal mania, Sir James Y. Simpson insists upon the very great importance of the frequency of the pulse in prognosis, and he states that where the pulse is 110 or over, the outlook is very bad, and that in his experience no case had ever recovered.

f. In certain cases of peripheral irritation a very great increase in the rate of the pulse has been observed:

1. Where tumors in the neck have pressed upon the pneumogastric or sympathetic nerves.

2. In cases with intra-thoracic tumors.

3. Where there has been some inflammatory process in the sheaths of the pneumogastric or sympathetic nerves.

4. In cases of irritation of nerves in the abdominal cavity as by over-distention of the intestines by gas; in the passage of hepatic and renal calculi; worms in the intestines, etc. As showing the very great disturbance of the pulse, which may be occasioned by the presence of entozoa in the intestines, a case was reported in the *British Medical Journal*, June, 1867, in which attacks of palpitation of the heart with a pulse of 240 were observed, and after the expulsion of a tænia from the intestines the attacks entirely disappeared.

g. In nervous exhaustion the result of venereal excesses, of over-indulgence in alcohol, coffee, or tobacco, or from excessive mental or physical labor, or as the result of previous disease, a very frequent pulse is often observed, and this may, when very frequent, have an alarming significance. Dr. Latham, in the new Sydenham edition of his works, vol. ii., p. 538, describes most eloquently the significance of the very frequent pulse. Likening the heart to the finger of the clock, he says: "We have already seen in these two cases the index hurrying rapidly round the dial-plate, and telling that, from some cause or other, the mechanism within was running down, and if it were not arrested that it would quickly stop. Even prior to any outward presentments to give assurance of disease, even earlier than its known beginning, we have seen countless fluttering of the heart and arteries give token of the nervous system already under trial of mortal suffering, and ready to let life go for ever."

The slow pulse will be our next subject.

TRAUMATIC ABSCESS OF THE LIVER.

A Clinical Lecture, Delivered at the Good Samaritan Hospital, Cincinnati,

By Prof. JAS. T. WHITTAKER, M.D.

Gentlemen:—We do not often have the opportunity to see a traumatic abscess of the liver. So far as I remember, this is the first case I have ever been able to present to a class. Indeed, so rare are these cases that I was unwilling to admit that the liver was implicated here until I was assured by the house physician—an assurance which I made doubly sure myself—that the discharge from the wound examined under the microscope showed the presence of liver-cells. If you look at the statistics as to the frequency of this origin of hepatic abscess, you will find it to be very rare indeed. Thus, Budd says: "A blow or other mechanical injury is by no means a frequent, though the most obvious cause, of abscess of the liver." In the sixty cases to which he makes reference, "there is only one—a case recorded by Andral—in which the disease was clearly traced to a blow. In this case there were two large abscesses on the convex surface of the right lobe—the usual seat, probably, of abscesses produced in this way." Budd says further that the rarity of inflammation and abscess from accidental injury shows how effectually the liver, when of its natural size, is shielded by the ribs.

Frerichs states also that "cases are rare where the disease is induced by an external injury, such as a wound." Medical literature contains, he continues, but a single observation of traumatic pylephlebitis, which is recorded by Lambron, *Arch. gèn. de méd.*,

1842, p. 124. The author quotes this case and the report of the autopsy of it in full in his work on Diseases of the Liver. And Murchison evidently considers trauma to be so little productive of abscess that, in his work on Diseases of the Liver, he does not mention it at all. I need hardly say that I refer here to direct trauma of the liver. Everybody knows that among the most frequent causes of pyæmic abscesses of the liver are traumata of distant parts, as, for instance, of the skull. In these cases the abscesses are, of course, metastatic in the true sense of the term.

Laboring-men frequently suffer contusions of other organs, but cases of inflammation of the liver from contusions are among the curiosities of clinical experience. What is the proof here that we have to deal with an abscess of the liver? There is nothing in the character of the external wound that would indicate the extent of the lesion. It is, as you see, a large, irregular trauma, freely covered with pus. But when the discharge is examined microscopically it is found to contain pigment and liver-cells, and we have here the same proof of their origin that we get sometimes in the sputum when a hepatic abscess bursts into the lungs.

Ordinarily, as in this case, we are aided in the recognition of an abscess of the liver by the cachexia and general prostration. Here is profound cachexia and pallor, whence I suspect we have to deal not only with abscess of the liver, but also, as a result of the prolonged suppuration, with amyloid degeneration in addition. We have, however, no proof of this complication until we shall have examined the urine.

When we have a case of abscess of the liver we look for its cause. Usually it arises from an internal cause, from a thrombus or an embolus, from a dysentery, an ulcer, suppurating hemorrhoids, or, in the case of multiple (pyæmic) abscesses, from some distant trauma or other cause of blood-poisoning. But here is a case in which we do not have to invoke a distant cause. The cause is, as Budd has said, most obvious.

As usual in all cases of hepatic abscesses, the liver is enlarged. By palpation, I feel it extending down an inch or two below the level of the lowest ribs; while distinctly the upper border of dulness begins at the level of the second rib.

Is this a solitary abscess, or have we many? We would expect this abscess to be alone; yet we might have secondarily from this suppuration multiple abscesses throughout the liver. In other words, we may have here a single, like the tropical, abscess, and, dependent upon it, numerous or multiple pyæmic abscesses. We could only answer this question satisfactorily by making explorations with the needle of the aspirator—operations which are not justifiable so long as the vent is so copious as here.

Strange to say, an enormous abscess may exist in the liver, and the individual may yet recover completely on its evacuation. I have seen cases where the right lobe of the liver was hollowed out to almost a shell, judging from the amount of pus removed, and yet the patient made a perfect recovery. One wonders why such an amount of liver-tissue exists if the individual can be deprived of so much of it and survive. But the physiologists teach us every day how lavish nature is in the construction of the important internal organs, like the kidneys and the liver. Indeed, a man may have a large abscess in the liver and show no signs of it at all during life.

The treatment here does not resolve itself simply into relieving pain and sustaining strength. There is one other element, of the treatment of which we must speak. Amyloid degeneration, if it has not already, must inevitably finally ensue from this prolonged suppuration. Can we do anything to prevent it? It has been noticed, in a series of experiments in the treatment of tuberculosis by the benzoates of soda and magnesia, that, notwithstanding the fact that suppuration had existed in some of them for years, no case thus treated ever had amyloid degeneration. Now, inasmuch as phthisical patients are carried off most frequently by amyloid degeneration of the liver, kidneys, and spleen, it is a great discovery, if it receives confirmation, that we possess agents to prevent such a dire complication. With our present knowledge of this curious process we are forced to look upon it as a product of blood-poisoning; hence the efficacy of the administration of the benzoates, salicylates, etc.

Now, I think it would be advisable in these cases of threatened or commenced, but as yet limited, amyloid degeneration, to make a trial of these new remedies. They are said to combat the infectious principle in the blood, but the blood must be saturated almost with the remedy to secure perfect prophylaxis. We may begin with a half-teaspoonful of the salt dissolved in a wineglassful of water, three times a day, and gradually increase it to a tablespoonful or two per day. Unfortunately, the benzoate preparations are as yet too expensive for the long-continued use necessary in the cases which call for its use.

Further than this, we shall continue the use of the thick, hot poultices you see applied, and we shall freely administer alcohol, and milk, and eggs. If under this treatment the pus shall not freely escape, we shall assist the escape of it by the use of the aspirator.

TRAUMA OF THE ULNAR NERVE SIMULATING PROGRESSIVE MUSCULAR ATROPHY.

We have seen this session four cases of progressive muscular atrophy, and we have had so much to say about atrophy of the interossei muscles in these cases as the favorite seat of the first expression of the disease, that I have no doubt, if I should ask the question, "What is the matter with this man?" every one in the class would answer, "Progressive muscular atrophy." Our patient can straighten out this hand, as you see, but not the last phalanges of the fingers. Now it is a late anatomical contribution, the discovery that it is the little muscles of the hand—the interossei—that extend the two last phalanges of the fingers. The extensor communis suffices to extend the first, but not the last. Hence we have here "the clawed hand" from paralysis of the interossei muscles. The extended hand looks like a bird's foot as it is lifted from the ground.

But the atrophy here does not belong to the cases of progressive muscular atrophy. For, in the first place, it came on too rapidly. Then, having reached this profound degree of atrophy, it did not progress—that is, it did not invade other muscles. The deltoid acts perfectly, as you see. There is no wasting of muscle elsewhere. Especially you notice there is no wasting of the interossei in the other hand. So we look then for a local cause of this atrophy. Here is a cicatrix over the olecranon process; it crosses the track of the ulnar nerve. The wasting dates from the receipt of the injury at this point. Now, every one of these interossei muscles is supplied by the ulnar nerve. So a cross-section of the

nerve paralyzes every muscle. If no reunion occur, or if it be prevented by a bad cicatrix, atrophy of the muscles must result from their disuse. Here is a condition in which the spinal nerves are intact from the cord to the elbow. The interruption to the nerve-force occurs at the elbow. Here is simply a solution of continuity of the ulnar nerve, and this is a case of atrophy, not from a polymyositis or a patch of sclerosis in the cord, but simply from lack of uninterrupted nerve-fibre. You will therefore not be content to diagnosticate progressive muscular atrophy from "the clawed hand" alone. Two of them are much more significant than one. No case is recorded, so far as I know, where an accident crippled both nerves, or the interossei exclusively in both hands.

The prognosis here is bad. The atrophy is so profound that we get almost no response to either galvanization or faradization. Some time ago, before such long disuse had wasted away the muscles, there would have been a chance for this patient in exsection of the cicatrix and apposition by sutnre of the divided ends of the ulnar nerve.

Original Communications.

THE CAUSE AND TREATMENT OF GENU VALGUM.

By CHARLES T. POORE, M.D.,

SURGEON TO ST. MART'S FREE HOSPITAL FOR CHILDREN, NEW YORK.

PART II.

THE treatment of genu valgum may be divided into the mechanical and operative, and the latter into section of the soft parts, and osteotomy.

Mechanical Treatment. — If the cause assigned for knock-knee in the first part of this paper is correct, then its treatment should have for its end the restoration of the condyles to their normal relation. It has been demonstrated that the tibia may be displaced: 1, by a bend in the lower third of the femur; 2, by a flattening of the external condyle from the superincumbent weight; 3, by a true hypertrophy; 4, by changes taking place in the interior of the head of the tibia; 5, by a combination of the above changes.

In regard to the statement that we sometimes hear, that children will "outgrow" this deformity, dependent on osseous changes, it should be said that it is very hard to obtain reliable data. Barwell, Little, and those who have had any experience with this deformity, deny its possibility. The mere report that one has known of a patient who was knock kneed and who now has straight limbs, should be received with a certain amount of doubt. In order to remove this deformity, mechanical appliances must act directly on the tissue at fault in causing the change in the long axis of the tibia, or we must produce a curve in the opposite direction, compensating for the abnormal one. Let us see how this can be accomplished. First, in regard to femoral curves. All splints used to correct genu valgum consist of a long steel bar, extending on the outer side of the limb from the upper part of the thigh, or pelvis, to the foot, with or without a joint opposite the knee; to this is attached a band or pad placed on a level with the knee, embracing that articulation so as to draw it outward, or, surrounding the lower end of the femur and upper portion of the tibia, to act in the same manner. The effect of such a brace is to tend to throw the tibia inward, toward the median line, the weakest tissue yielding. If the femur is still soft and pliable, and the external lateral ligament strong, it will be bent outward, and correct the curve at its lower third; if the external lateral ligament yields, the tibia will be brought into a straight line with the long axis of the femur; but the cause of the deformity will not be corrected, the whole tibia will rotate inward upon the internal condyle as a centre, leaving a space between its external head and the corresponding condyle of the femur; and as soon as the splint is removed the tibia returns to its former relation with the femur. In this position there can be no direct force applied to the femur. If the tibia be held in its normal position by the splint, and the patient be allowed to go about, the whole weight of the body in walking will be thrown upon the inner condyle, and provided the tissues are still soft, it will yield, and the deformity be corrected. Braces for the correction of genu valgum should have no joint opposite the knee, for as soon as any flexion of the leg on the thigh takes place, pressure is taken off from the internal condyle, and it ceases to act on it. In the second class of cases, namely, where the external condyle is flattened, the action of a splint would be the same as in the last class; our aim is either to bend the femur or flatten the internal condyle. Perhaps the external condyle may take on more rapid growth from the removal of pressure. In either of the above class of cases, mechanical appliances must be used early, while the bones are soft. As soon as rachitic bones calcify, they become very hard, and splints will prove of little avail, as the bone is more unyielding than healthy osseous tissue. The question naturally arises: At what period do the bones become hard and sclerosed? In quite an extensive experience in osteotomy for bow-legs, I have found that there does not seem to be any rule. I have seen the tibia very hard in a child of two and one-half years, so that section was made with difficulty, while in older children, ossification was not as advanced. I think that the amount of elasticity in the tibia is an index of the hardness of the bone. If you can, by the use of moderate force, spring this bone, sclerosis is not marked. As a rule, not much benefit can be expected from braces after the fifth year, and often after the fourth.

When there is a real lengthening of the internal condyle in young children, it is claimed that continuous pressure will cause atrophy of the internal condyle, and that in time it will assume its normal plane; in adolescence it is generally considered that mechanical treatment is useless in cases where the internal condyle is hypertrophied. Those who consider that the increase in the inner portion of the femoral epiphysis is secondary to ligamentous relaxation, and that the deformity is due partly to the lessened pressure on the internal condyle, causing its abnormal growth, and partly from atrophic changes taking place in the external condyle from increased pressure, propose by mechanical means to reverse the process; but the ill success that has followed the use of splints after the fifth or sixth year, does not seem to substantiate this theory. In cases where the deformity is due to tibial hypertrophy, either alone or associated with femoral changes, I do not know the result of protracted mechanical treatment; cases have not been under observation long enough.

In the use of braces in the deformity, they should extend from the pelvis to the sole of the shoe; there should be no joint opposite the knee. The use of a

rubber bandage to keep up continuous pressure has been found to work well, and is much more efficacious than metal straps.

Treatment, to be of any use, must be commenced early, for our only hope of success is in acting on the bones while soft.

I must confess that my experience in the treatment of genu valgum by splints has not been very satisfactory; patients have been brought to me when too old. I have been able to bring the tibia into a straight line with the femur and to hold it there, but it was simply a stretching of the external lateral ligament, as soon as the brace was removed, the deformity returned to as great a degree as before treatment. No effect was produced on the true cause of the deformity, namely, the internal condyle. I have divided the tendon of the biceps and the external lateral ligament, with the result in one case of a fatal termination from phlegmonous inflammation of the whole thigh. I have tried it in other cases, but with no benefit.

Mr Brodhurst exhibited a case before the Clinical Society of London, on whom he had performed a tenotomy of the biceps and lateral ligaments. Four months had elapsed since the operation, yet the patient was still unable to stand without the use of crutches. The limb, with the apparatus removed, could not be flexed beyond a right angle. There was free lateral motion at the knee-joint, and patient could only stand when supported by both hands. (*Lancet*, June 7, 1879, p. 812.)

Operative Treatment.—1. Section of the soft parts.—Tenotomy of the biceps and the external lateral ligament has been advocated. Mr. Brodhurst is now almost the only advocate of it. Mr. Barwell considers it worse than useless, and in this opinion most orthopædic surgeons agree. Mr. Lattle, in "Holmes's Surgery," says, "we were formerly accustomed, in severe in-knee of adolescents, to aid the mechanical treatment by section of the outer ham-string; but observation of the length of time occupied in the treatment, notwithstanding the tenotomy—and, indeed, a conviction forced upon us that the operation did not appreciably shorten the treatment—has caused us for many years to discontinue recourse to it. . . . . Division of the external lateral ligament is unnecessary."

These cases of contraction of the adductors and tendo Achillis, which simulate knock-knee, are often cured by tenotomy and an apparatus.

Mr. T. B. Fisher states, that the deformity of genu valgum, in an aggravated form, may be effectually relieved by manipulations of the limb, and the use of proper mechanical apparatus; but he gives no cases.

It is true that in aggravated and long-standing cases of this deformity the biceps is found shortened, so that, after an osteotomy, its tendon has to be divided before the tibia could be brought into its proper position; but this contraction is a secondary one, due to the difficulty in walking. If the cause of the deformity resides in the bone, it is evident that in order to act to the best advantage on it, the soft parts on the outer portion—ligaments and muscles of the knee—should remain intact, in order that force should act on the femur—any section of these tissues is a hinderance and not an aid to treatment.

In 1851, Meyer, of Wurtzburg, made a section of the shaft of the femur and tibia in both extremities, with good result, in a patient twenty years of age, for genu valgum, due to rachitic curvature of these bones.

Billroth, in 1872, partially divided the tibia one inch below the spine, and then fractured it for the relief of a genu valgum, and in the following year performed a similar operation for genu valgum.

Schede, in 1876, removed a V-shaped piece from the inner aspect of the tibia, at the same time performing osteotomy of the fibula, for the relief of a marked case of genu valgum, in a patient twenty-three years of age, with a good result.

These operations aimed to correct the malposition of the tibia, by giving it a bend in the opposite direction, the real deformity remaining.

Delore, in 1874, advocated, in a paper read before the Association Française pour l'Avancement des Sciences, the operation of "redressement brusque," in cases of genu valgum in patients under twenty years of age, or before the epiphysis had become consolidated to the diaphysis. The operation consists of forcibly bending the tibia inward, using the femur placed on the edge of the table as a fulcrum. The result was to separate the epiphysis of the femur from the diaphysis, often to rupture the external lateral ligament. In some cases the styloid process of the fibula has been torn off; in other cases, the epiphysis of the tibia has been separated, and not that of the femur. The time required to accomplish this varies from five minutes to half an hour. The ultimate result of the operation, M Delore states, is as follows. "During two or three months after the operation, the knee is stiff and movements are painful; but after about one year, all traces of discomfort and pain have disappeared in flexion and extension, and the re-establishment of the function of the joint leaves nothing to be desired." "Du mécanisme du genou en dedans," par le Dr. X. Delore, p. 7. He states that he has operated four hundred times without an accident. There is a liability of the deformity to return. I am not aware that the operation has been practised out of France, except once in England, when it proved a failure.

Mr. Annandale, in March, 1875, excised a portion of the femoral condyles for a marked case of genu valgum, due to a curve in the lower end of the femur; there resulted a stiff joint.

Mr. Howes made a total resection of the knee-joint in a girl, fourteen years of age, for genu varum, due to rapid atrophy of the internal condyle. (*Guy's Hospital Rep.*, 1875.)

In May, 1876, Mr. Ogston performed the first operation of detaching the internal condyle of the femur, and then sliding it up, so as to bring it on the same plane as the external. The following is the mode of operating: "A long and strong tenotomy-knife (Adams) was introduced through the skin three and a half inches above the tip of the internal condyle, on the inner side of the thigh, and so far back as to be opposite the ridge of bone running between the linea aspera and the condyle. Its blade was carried forward, downward, and outward over the front of the femur, with its cutting edge directed to the bone. When its point could be felt under the skin, in the groove between the condyles where the patella would normally have been lying in the flexed position of the limb, the cutting edge was pressed against the bone, and the soft parts divided by one slow movement in withdrawing the knife. . . . . An Adams saw was then introduced into the tunnel thus formed, and the condyle sawn off by directing the edge of the saw straight backward. . . . . As soon as it was estimated that the condyle was almost entirely separated, and that the saw had arrived near the popliteal space, it was withdrawn, and the remaining connections were broken by forcibly bend-

ing the tibia inward. The limb was then put up in a splint in a straight position." The operation was performed, and the wound dressed antiseptically.

In 1877, Mr. Chiene performed the following operation, in order to obviate the necessity of opening the joint: An incision, two or three inches long, is made over the tubercle for the insertion of the adductor magnus; the tendon of this muscle is exposed, and the incision continued between it and the vastus internus, some fibres of which are divided; the periosteum is incised and turned aside, and a V-shaped portion (the apex being turned downward toward the intercondyloid notch) is struck out of the internal condyle with a chisel and mallet, just above the adductor tubercle, and on a higher level than the epiphyseal line. The tibia is then pulled inward, and the leg so straightened; the sides of the V-shaped gap are brought into apposition. A few weeks later Mr. Macewen performed a similar operation, although in ignorance that Mr. Chiene had preceded him. Later Mr. Macewen adopted another mode of operating, namely: "Seeking a point half an inch above the upper border of the patella while the leg is in a state of extension, an incision is made just in front of the tendon of the adductor magnus, reaching the femur at one cut, the length of the wound being about three-quarters of an inch, and equal to the breadth of the largest chisel used. The shaft of the femur is then divided for the inner two-thirds of its thickness by three chisels, the largest of which is used at the commencement; thus a wedge-shaped opening is produced without removal of osseous material. The remaining outer third of the shaft of the femur either snaps or bends when the leg is straightened. The operation is performed antiseptically, and the limb treated like a simple fracture."

Mr. Barwell, who considers that in all cases of genu valgum the deformity is produced by changes taking place in both femur and tibia, divides the femur with a chisel just above the epiphysis, and corrects half of the deformity. Three weeks later he makes a section of the tibia just below the tubercle, and corrects the rest of the deviation.

Mr. Reeves makes a section of the internal condyle with a chisel in the same line as in Ogston's operation, but does not enter the joint with the chisel, his aim being to cut down to the articular cartilage, and after the condyle has been loosened to forcibly straighten the limb. He does not use the carbolic spray, but simply dips his chisel in carbolized oil.

Mr. H. S. Taylor (*British Medical Journal*, April 7, 1877, p. 429), for femoral curves, divides the femur with a chisel a hand's breadth above the joint from the outside, and then treats as a fracture.

Mr. Macewen finds that in some cases the femoral section does not correct sufficiently, and he then makes a section of the tibia, performing the four osteotomies at one time.

The immediate result of these operations is as follows: In Ogston's and Reeves's the internal condyle is slid up, so that its lower edge shall be on a higher plane than before. The re-entering angle thus formed on the free surface of the lower end of the femur is in time filled up partly by osseous material derived from the bone, and partly by connective tissue, derived from the serous surface of the condyle (Thiersch). In Macewen's, it is intended that the section shall be wedge-shaped, its apex directed outward, and that in fracturing and straightening the limb the two surfaces of the V-shaped section shall be brought into apposition. In Barwell's and Taylor's operations, when the limb is straightened, there is left a V-shaped interval, with its apex directed inward when the bone is brought into position, which, in time, is filled with new osseous material, the same as after osteotomy for bow-legs.

These operations may be divided into two classes —those in which the operation is performed on the condyle alone, and those in which the section is made above the epiphysis, through the shaft of the femur. To the first belong Ogston's, Chiene's, and Reeves's; to the second, Macewen's, Barwell's, and Taylor's.

Osteotomy, for the relief of genu valgum, has probably been performed over three hundred times. I have been able to collect the record or reference to about two hundred and fifty cases, namely: ten Chiene's; seven Taylor's, eighty-three Ogston's; sixty-four Reeves's; ninety Macewen's. I can only find two of Barwell's recorded, or any reference made to them.

A strict analysis of these cases is impossible, because they are not given in detail.

In forming an opinion in regard to the choice between different operations having the same end in view, attention should be paid—1. To their fatality; 2. Tendency to accidents (necrosis and suppuration); 3. Time occupied in treatment; 4. The final result. There have been but four fatal cases reported, namely: one by Thiersch, from uræmia, six weeks after an Ogston; one by Dunlap, fatal on second day, after a Macewen, from cellulitis of the thigh from bad bandaging; and one by Barker, from septicæmia, following an Ogston.

The joint is, of course, entered in all cases of Ogston's operation, probably fractured into in Reeves's in the majority of cases, so that it cannot be called strictly extra-articular. It has been opened in Chiene's. As a rule, it is not entered in Macewen's, although in Dunlap's fatal case the fracture was found to run into the joint. Taylor's and Barwell's section being made farther away from the knee would not probably involve it.

Theoretically, those operations in which the joint is involved should be more liable to complications than those in which it is not disturbed; but, practically, there does not seem to be any increase of danger, and it is astonishing how much disturbance the knee will tolerate without the least reaction following; even effusion or collection of blood in the joint after Ogston's operation is often absent, and their presence does not seem to interfere either with the progress of the case or the ultimate result. The application of ice and a rubber bandage about the joint is all that is requisite. In a few reported cases there has been some stiffness remaining for a time, but whether it was due to intra-articular adhesions or from being kept up in splints too long, is not stated.

There are no cases on record, as far as I can ascertain, where there has been any caries or necrosis following any of these osteotomies.

Suppuration.—Out of thirty-three cases Macewen states that only in two did the rectal temperature rise above 100.8°—namely, 103°. He only reports one case where there was any suppuration. (As a rule, after osteotomies any reaction or rise in temperature is rare. In an experience of thirty osteotomies I have seldom found any elevation of temperature.) But other operators have had some purulent discharge after section above the condyles. Reeves has had suppuration in three cases after his operation, and in one case an effusion into the joint, lasting three or four weeks.

Cases of suppuration after Ogston's are reported, but the number is not given. In all of these the pus was extra-articular, being between the muscles.

The time elapsing after the section, and before the patient is able to use his limbs with safety, differs in the various operations. After an Ogston's it varies from five to six weeks. In Ogston's first case the patient began to use his limb five weeks after the last osteotomy; the age of the patient was eighteen years. Fowler's patient, aged nineteen years, began to use his limbs in three weeks.

Macewen states that it is necessary to keep the limbs in splints five or six weeks.

Chiene did not allow his patient to walk for a month. In one of Taylor's cases of section, some distance above the condyle, the patient did not attempt to walk for two months.

In a case of Barwell's, performed by Benton, where there was section of the femur and tibia of both limbs, in a patient ten years of age, nine weeks elapsed after the last operation before walking was permitted. After a Reeves's, patients have been walking in three weeks. Mr Reeves states that many cases may be safely *discharged* in five weeks. Barwell's and Macewen's operations are more formidable, from the fact that more bone has to be divided; and, notwithstanding the statement of Macewen, there is more liability to suppuration after the operation advocated by him than after either Ogston's or Reeves's; at least I find more cases of suppuration and less rapid closing of the wound than after condylotomy. Mr. Barwell's operation does not seem to have been received with favor, probably from the number of sections required.

In regard to the ultimate result, the universal experience seems to be that equally good results have been obtained after any and all of these operations. There are no cases on record in which there has been any return of the deformity, or any genu varum produced by over-correction, although Mr. Brodhurst says he has seen such cases; but they are not on record.

It should be added that, in some old-standing cases, tenotomy of the biceps and lateral ligament have been necessary in order to permit the tibia to be brought into line.

In both Ogston's and Reeves's operations the section should not be made too slanting, as difficulty will be experienced in sliding the condyle up. The direction of the chisel should be as near the perpendicular as possible.

Strictly antiseptic methods are not generally adopted in osteotomies. In some of my earlier cases of this operation for bow-legs I used the spray, and followed the Lister rules strictly. I have since abandoned the use of the spray, and simply syringe out the wound with a one to forty solution of carbolic acid, and my results, *in every respect*, have been just as good as when I performed my operation antiseptically.

Osteotomy for genu valgum has been performed five times in this country, as far as can be ascertained as follows: in 1878 Dr. Fowler, of Brooklyn, two Ogston's, with good results; in 1879 Dr. Wilmarth, of Newark, N. Y., a Macewen; in November, 1879, I performed a Reeves (MEDICAL RECORD, April 10, 1880); and shortly after my friend Dr. Briddon, another.

There is an impression in the profession that section of bone, or the entering of a joint, is a very serious operation, and one that should not be undertaken except in very extreme cases. A careful study of a large number of cases reported in the foreign medical journals, and quite an extensive personal experience, have convinced me that it is no more serious than a simple fracture, and that recovery takes place about as rapidly.

The question as to the age when osteotomy should be performed depends upon the age when calcification takes place, and the date beyond which all hope of rectifying the deformity by mechanical means has passed.

Many surgeons consider that about the seventh or ninth year is the best age to operate in those cases in which the deformity has appeared during infancy, and after the deformity has become marked in the adolescent cases. But the real question in the former class is, At what age is a cure by mechanical appliances not to be expected? because as soon as splints cease to do good they do harm by causing atrophy of the muscles and by excoriations of the skin. For my own part I think that an early operation is to be advocated, because it perfectly corrects the deformity at once, and is devoid of all danger, and allows our patient to take part in the sports of other children, and thus insure a more perfect development.

In hospital cases, or in children of the laboring class, I would operate, in proper cases, as early as the fourth or fifth year, because it relieves the parents of much care and expense; for we all know how difficult it is to keep braces in good order and have them properly applied. Another argument in favor of an early operation is that it prevents secondary changes taking place in the feet and knees. I am as strong an advocate of the mechanical treatment of genu valgum as any one, in appropriate cases, and am satisfied that perfect results can be obtained if the cases are taken in hand early. I am also satisfied that if there is no gain after months of careful treatment with a properly applied brace, then nothing will be gained by further persistence in the use of splints, but that osteotomy should be performed.

A REMARKABLE INSTANCE OF PERIODIC OBSTRUCTION OF A URETER IN A SOLITARY KIDNEY—AUTOPSY.

By D. M. WILCOX, M.D.,

LEE, MASS.

THE person presenting this abnormality was a native of Ireland, 42 years of age, weighing about 145 lbs.; about 5 ft. 6 in. in height; of nervous temperament, active habits, and strictly temperate.

From the patient himself the following brief history was obtained: Some twelve years ago he had an attack of severe pain in the left side, extending from the hypochondrium to the inguinal region, accompanied by complete suppression of urine, and continuing for two days. After an attack of vomiting he felt relieved, and soon voided a large quantity of pale urine.

Similar attacks, lasting from a few hours to two days, followed at irregular intervals for about four years, his general health, however, continuing good. He then changed his occupation from that of a papermaker, working half-day and half-night, to that of undertaker and furniture dealer, hoping to find, in a less laborious employment and by an avoidance of night-work, some relief from the distressing attacks. From that time the seizures were less frequent, and for three years preceding the final seizure he had complete immunity.

At no time was there blood or any abnormality of the urine, nor was he conscious that any concretion had been voided with it.

I was called to see the patient February 29th, and found him with, as he expressed it, a "pressing" pain in the left abdominal and inguinal regions, its focus posteriorly just below the twelfth rib. The testicle upon the same side was painful and retracted; some nausea, but no vomiting; pulse moderately full and 66 in frequency. Two days before, he had exercised unusually hard, and a few hours after he was unable to pass urine.

I told him there was, doubtless, gravel passing from the kidney to the bladder, and trusted the trouble would terminate as happily as his former attacks had done. I could account for the complete suppression only on the hypothesis of some abnormality or loss of function of the right kidney. Prescribed an anodyne, and was told that I need not call again unless sent for.

I was awakened at 2 A.M., March 2d, about thirty-six hours after my first call, and my attendance requested. Found patient walking about the room, moaning from pain. No urine had yet been passed. Had slept but little since the attack commenced; some, but not severe, headache; had vomited several times since my first visit. The temperature was normal and pulse 66; skin gently perspiring.

A desire was expressed by the family to call in Dr. Holcombe, of this place, in consultation, and I appointed nine o'clock that morning for the hour of meeting. Gave ¼ gr. morphia, and ordered it repeated every two hours while severe pain should continue.

At the appointed time I was present, and found patient much easier. He was dressed, and declared he was able to look after his affairs; said he did not then wish the consultation. The nausea had ceased, and he had taken a light breakfast.

I was then obliged to be out of town for a day, and during my absence the pain and nausea returned and Dr. Holcombe was called, under whose care the patient remained a fortnight, during which time I did not see him, but from the doctor I received the following history: He was called about 9 P.M., March 2d, and found the patient vomiting and complaining of pain, both of which were speedily checked with small doses of morphia. Micturition did not occur until March 4th, six days after cessation.

The doctor did not see the urine passed, but patient said there was a large quantity, and it "looked all right."

There was no further trouble until March 9th, and though somewhat depressed, patient attended to his business as usual, and on one occasion rode about four miles.

Suppression again occurred March 9th, followed by the same *ensemble* of symptoms as in the previous instance.

March 16th I was called in consultation. Found the patient in bed, though he was able to sit up some of the time; depressed in spirits and mind, at times slightly wandering. Pulse slow and regular; temperature natural; skin gently perspiring; tongue coated, brown, and moist; vomiting frequent, prohibiting the retention of much nourishment. Some pain in left side and testicle as when I saw him a fortnight before.

March 17th.—As Dr. H. was obliged to be absent for a few days, the patient came under my charge again. Very little change in symptoms and appearance since yesterday.

March 19th.—Little nourishment has been retained on the stomach for several days, and there is considerable prostration. Very fretful and irritable, and mind frequently wanders; abdomen tympanitic; skin moist.

Thus far not much medicine has been given. The bowels have moved several times from patient drinking occasionally Congress water, and the pain, though not entirely removed, was easily made bearable by a small amount of anodynes.

The friends insisting on more active medication, Dr. Wright, of this place, was called in, and to him I resigned the treatment. Being requested to continue in attendance, I had, however, opportunity to watch the case.

Dr. W. administered syrp. fer. iodidi, gtt. x., every hour; quinine, grs. ij., every three hours; and by enema, ol. terebinth and tr. opii. ää gtts. xx., suspended in glycerine and starch every three hours.

March 20th.—Patient vomited less; in other respects no perceptible change.

March 21st.—Vomiting has ceased, and whatever food or medicine is given is tolerated.

March 22d.—About 1 A.M., several ounces of urine was passed, the first for thirteen days. This was repeated several times before 1 saw him at 8 A.M. The quantity could not be well estimated, being mostly passed in bed, the attendants receiving no warning. Some was saved, however, of which I found the reaction slightly acid; sp. gr. 1014; no albumen. The microscope showed some epithelium and amorphous urates, but no blood, pus, or casts. During the remainder of the day patient urinated three or four times. The last time about 8 P.M.

March 23d.—No urine passed to-day. Patient failing fast. Pulse, though weak, is slow and regular; skin moist; muttering delirium, though he can be roused to answer intelligently. Same medication continued.

March 24th.—Patient died about 2 P.M. Autopsy twenty-two hours after death, in the presence of Drs. Wright and Fish. The blood-vessels of the peritoneum were slightly injected. Its cavity contained about three pints of clear urine similar in composition to that passed the 22d, save that it contained some albumen. There was no trace of a right kidney. The left was in normal position, and including the supra-renal capsule was eight and one-half inches in length. The capsule congested, and presenting dark livid spots at its upper and anterior part, through one of which was a small perforation whence the urine had passed into the peritoneal cavity. The cortical substance, save some congestion, appeared healthy. The pelvis showed marks of having been greatly distended, and then contained three or four ounces of urine. Besides an ureter passing to the bladder normally, there was a rudimentary one passing from the upper part of the pelvis and, crossing the vertebral column, was joined at the proper place to the bladder. A fine probe could be passed in its lower section. In the upper, owing to pathological changes, it was not possible to decide whether it had been pervious. The left ureter was closed just above its junction with the bladder by a little ovoid mass about one-quarter of an inch in its long, and one-sixth of an inch in its short diameter, containing, within a firm fibrous capsule, two calculi of uric acid, each about the size of a hemp seed. This was held within the ureter by a ligament which permitted some mobility, and had been doubtless the cause of the repeated attacks of suppression. Just why it should have acted as a complete obturator to the ureter only occasionally, and sometimes with long intervening periods of complete immunity, I am unable to say.

Probably, perforation of the pelvis renis took place

after the last act of micturition, March 22d, at 8 P.M., and was due, of course, to the great and long-continued pressure of the pent-up urine; and, although that pressure had been partially or wholly removed by the natural flow of the urine, yet the injury of tissue was so great at one point as to result in destruction and perforation.

One of the peculiar features of the case was the absence of grave uræmic symptoms after a complete suppression of six days; and in the last attack, when suppression had lasted thirteen days, the gravity of the symptoms were not what might have been expected.

CASE OF CYSTITIS RESULTING FROM STRICTURE, AND CURED BY CYSTOTOMY AND THE APPLICATION OF THE ACTUAL CAUTERY OVER THE PUBES.

By ALFRED C. POST, M.D., LL.D.,

NEW YORK.

Read before the New York Surgical Society, May 11, 1880.

ROBERT GLASSFORD, carpenter; born in New York; ætat 33; unmarried; admitted into the Presbyterian Hospital on the 4th Sept., 1879.

Previous History.—The patient had always enjoyed good health, until he contracted a gonorrhœa, eight years before his admission. This was followed, after six months, by a stricture, in consequence of which the stream of urine became small and twisted. He was examined by a physician, who found a stricture deep in the urethra. He has had repeated attacks of gonorrhœa since the occurrence of the stricture. The last attack was about three years ago. During the year before his admission he had a gleety discharge, but no pain on micturition.

Sept. 6th.—I examined him under ether, and found several strictures. A bulbous sound of 30 mm. in circumference was arrested at the depth of an inch and a half. After slightly incising the meatus, I passed Otis's urethrotome into the stricture, dilated it up to 32, and then cut the stricture. The bulbous sound No. 30 was then passed without difficulty. Another stricture at four and a half inches was then divided in the same manner. At five and a half inches from the orifice I encountered a third stricture, through which I could not succeed in passing any instrument, even a filiform. The patient was put to bed, and ten grains of sulph. quiniæ was given to him with one-third of a grain of sulph. morphiæ.

7.30 P.M.—Patient a little chilly. He had a slight rise of temperature. An additional dose of ten grains of sulph. quiniæ was given to him.

Sept. 7th.—Patient is very easy this morning. As he had some difficulty in passing his urine, hot cloths were applied over his bladder.

Sept. 9th.—Urine dribbles, but does not pass in a stream. Sounds Nos. 30 and 32 were passed as far as he had been cut. A filiform bougie was passed into the bladder.

Sept. 11th.—Nos. 30 and 32 were passed as before, but the filiform instrument could not be passed into the bladder.

Sept. 15th.—Another unsuccessful attempt was made to pass the filiform bougie.

Sept. 16th.—I performed external urethrotomy. The patient being etherized, I introduced a staff 22 mm. in circumference to the depth of five inches, where it was arrested by the stricture. I then made an incision into the groove of the staff, half an inch in front of its distal extremity, and exposed the urethra in front of the stricture. Curved needles armed with ligatures were then introduced on each side through the lips of the urethral wound, and traction made in opposite directions, so as to expose fully the mucous membrane of the superior wall of the canal. The incision was then made three quarters of an inch further along the canal, and curved needles armed with ligatures were introduced through the extended wound. On making tractions upon the ligatures in opposite directions, the urethra appeared to terminate in a blind pouch, at the end of which no continuation of the canal could be seen, or detected by a probe. The external incision was then carried backward nearly to the verge of the anus, and the index finger of the left hand being introduced into the rectum, and that of the right hand through the wound, the ends of the two fingers were brought nearly together opposite to the triangular ligament. The incision was carefully extended into the vicinity of the triangular ligament, and a finger again introduced into the deepest part of the wound, when a gush of turbid urine took place, the finger having penetrated the dilated pouch of the urethra behind the stricture. A silver catheter was then passed through the whole length of the urethra, and the urine drawn off, after which the bladder was thoroughly washed out with an irrigator. A steel sound, No. 33, was then passed through the whole length of the urethra into the bladder. As soon as the patient recovered from the ether he took ten grains of sulph. quiniæ with one-third of a grain of sulph. morphiæ.

Sept. 17th.—Patient very comfortable. Urine dribbles through the perineal incision. In the afternoon he suffered from colic, with flatulence; relief was afforded by a dose of turpentine.

Sept. 19th.—Sounds, 27 and 30, were passed into the bladder without difficulty, guided by a finger introduced into the wound.

Sept. 21st.—Sounds 27, 30, and 33, were passed. A portion of the urine escapes through the meatus.

Sept. 30th.—Wound granulating well; washed with carbolic acid, 1 to 40, two or three times a day.

Oct. 14th.—Sounds 28, 30, and 31, passed every other day. Urine continues to pass partly through perineal wound and partly through meatus.

Oct. 15th.—Examination of urine. Sp. gravity, 1010. Reaction, alkaline. Color, light straw. Odor foul. Sediment, copious and white. Phosphates. Flat epithelium. Pus. No considerable amount of albumen. The external wound is lightly touched every other day with the following solution:

℞. Argenti nitrat..... ℈ i.
Aquæ..... ℥ ss.
M.

Oct. 25th.—Injected bladder with nitric acid diluted with water, sixteen minims to a pint. On passing the catheter, the bladder did not empty itself, but on making pressure, five ounces of residual urine were expelled. This was ammoniacal, and contained a large quantity of mucus and pus.

Nov. 13th.—The bladder has been daily washed out with the acid solution. But the bladder has not recovered from its atony, and the residual urine continues to be loaded with mucus and pus. To-day I performed cystotomy, as advised by Prof. Willard Parker. The patient being etherized, and a large staff having been introduced into the bladder through the urethra, I made an incision on the left side of the perineum, extending from the fistula left by the former operation, down to a point midway between the anus and the tuberosity of the ischium. The

point of a scalpel was introduced into the groove of the staff, and pushed on to the neck of the bladder, dividing the prostate gland as in lateral lithotomy. Sims's rectal dilator was then introduced through the wound into the bladder, and the screw was turned so as to expand the blades to the extent of nearly two inches. This expansion of the neck of the bladder caused a pretty copious discharge of urine loaded with pus. The cavity of the bladder was washed out with an irrigator. Two fingers could be readily introduced through the enlarged opening into the bladder. A drainage-tube was introduced through the wound into the bladder, and direction given to wash out daily with the acidulated lotion previously used. As an additional means of overcoming the cystitis from which the patient was suffering, an actual cautery, half an inch in diameter, was heated to a red heat, and applied to two points in the hypogastric region, so as to destroy the whole thickness of the skin at these two points. The burned surfaces were covered with a paste of soda bi-carb. moistened with water. After the patient was put to bed, ten grains of sulph. quinia were administered.

Nov. 14th.—Patient rested well during the night. This morning the bladder was washed out with the acidulated lotion. The drainage-tube gives free exit to the urine.

Nov. 16th.—Drainage-tube removed, cleaned, and reintroduced, and the bladder washed out. General condition good. Temperature lower than it has been since admission.

Nov. 20th.—Sound No. 30 introduced through urethra. Bladder washed out through wound.

Nov. 24th. — Drainage-tube left out. Bladder washed out through silver catheter introduced through whole length of urethra. Sound No. 31 introduced.

Dec. 5th.—Patient can hold his water for an hour, and then expel it with a good degree of force. Bladder washed out as before. Ordered ferri dialysat. gtt. xv. ter in die.

Dec. 15th.—Bladder washed out every other day with nitric acid solution (℥j. to ℥j) after a sound No. 30 has been passed. The ulcers from the actual cautery are healing. Urine flows freely through the opening in the perineum.

Dec. 30th.—Patient has complete control of evacuations from bladder. Cauterized opening of fistula with arg. nit.

Jan. 16th.—Etherized patient and applied actual cautery to fistula.

Jan. 30th.—Fistula diminished, but still a considerable portion of urine flows through it.

Feb. 18th.—As urine has continued to flow through the fistula, I performed the following operation for the purpose of closing the artificial opening: The patient being etherized, I dissected up a semi-elliptical flap about an inch and a half in length and half an inch in breadth on each side of the fistula. The two broad surfaces of the flaps were brought in contact and supported by perforated felt splints, through which two rows of silver-wire sutures were passed, so as to elevate the two flaps into a prominent crest. The edges of the flaps were united by fine silk sutures.

Feb. 19th.—The flaps remain in close contact.

Feb. 24th.—The splints and sutures were removed. Union is complete, except at the two extremities of the flaps, where there are small openings through which a portion of the urine escapes.

Feb. 29th.—The posterior opening has closed.

March 4th.—The anterior opening is contracting, but some urine still escapes through it.

March 8th.—As there was some difficulty in passing a sound through the urethra, Otis's urethrotome was passed through the contracted portion of the canal, and after it had been stretched to 33 millimeters, the point of obstruction was divided on the dorsal surface, after which the instrument was passed with ease.

March 15th.—The fistulous opening in the perineum is entirely closed. The bladder continues to be washed out every second day with the nitric acid solution.

March 31st.—As there was still some difficulty in passing a catheter, apparently due to an obstruction at the meatus, this portion of the canal was enlarged with a straight probe-pointed bistoury, after which the catheter passed more easily into the bladder.

April 8th.—A bulbous sound, No. 34, was arrested at three and a half inches from the meatus. Otis's urethrotome was employed to remove the constriction, after which conical sounds Nos. 28, 30, 33 and 34 were passed with ease into the bladder.

April 15th.—The patient left the hospital in perfect health, passing his urine in a full stream, and with a good degree of force.

The urine was clear and deposited no sediment, all traces of inflammation having subsided.

The following are the points of special interest in the case which has just been detailed.

1st. The complete cure of a series of strictures of long standing, one of which was very close and resisting. The means of cure were external and internal urethrotomy and persistent dilatation.

2d. The cure of an obstinate cystitis, indicated by an almost complete atony of the bladder, and by a very copious deposit of pus and mucus in the urine. The means by which this desirable result was obtained, were, the cure of the stricture, the free division and dilatation of the neck of the bladder, the powerful revulsion occasioned by the actual cautery, and the thorough irrigation of the vesical cavity with an acidulated lotion. I do not think that the results could have been secured without a combination of all these remedial measures.

3d. The cure of a perineal fistula, resulting from the external urethrotomy, and showing a remarkable indisposition to heal. As a general rule, the incision made in external urethrotomy is disposed to heal within a few weeks. The persistence of the fistula in this case was probably due to the cystitis, with its unhealthy secretions, and the atony of the bladder, causing a continuous dribbling through the perineal opening. Before the cystitis was cured, the fistula had become confirmed, and had lost its tendency to heal. The application of the actual cautery had occasioned some contraction of the fistula, but had failed to close it. The means by which the fistula was finally healed, consisted in the performance of the plastic operation originally suggested by Dieffenbach, viz., dissecting two flaps, one on each side of the fistula, and uniting their two broad surfaces, so as to form a crest projecting beyond the surface of the surrounding parts.

A Medical Novelist.—Dr. T. C. Minor, late health officer of Cincinnati, has been found out at last. He is the author of "Her Ladyship," an exceedingly popular novel recently published. It depicts Southern life after the war, and its descriptions are said to be very finely drawn.

Progress of Medical Science.

TREATMENT OF PHTHISIS BY INHALATIONS OF BORAX AND SALICYLIC ACID.—Dr. Müller, a Berlin chemist, lays claim to the priority in the employment of antiseptic inhalations in the treatment of phthisis. He states that he recommended inhalations of borax and salicylic acid in a case of phthisis in 1876, and that his suggestion was carried into effect by Dr. Sachse, of Berlin, with remarkable success. He was led to make this suggestion by the theory, that in pulmonary phthisis a portion of the lungs is in a state of decomposition, or of alkaline fermentation, and as similar processes in open wounds are controlled by antiseptics, so the inhalation of antiseptics might be expected to exert an inhibitory action on the morbid process in the lungs, and thus effect a cure. He recommended for this purpose salicylic acid, which was made easily soluble by the addition of borax. This combination is quite as powerfully antiseptic as the benzoate of soda, and is, he believes, preferable to it, because it acts more energetically on the alkaline fermentation in the lungs, and produces no deleterious effects. The solution he recommended was 750 parts water, 25 parts salicylic acid, and 19½ parts borax.

Dr. Sachse, in an open letter, confirms the claims of Dr. Müller, and states that he has since employed the borax salicylic acid inhalations in a number of cases, of which he gives brief accounts, with, on the whole, very satisfactory results. He uses a solution of two parts borax, 2½ parts salicylic acid, and 100 to 150 parts hot water, and orders the inhalations to be practised morning and evening for five or ten minutes, instructing the patients not only to inspire deeply, but particularly to make deep and prolonged expirations. The inhalations often caused, at first, cough and a slight burning sensation in the neck, and some of the patients complained of loss of appetite, due to swallowing a good deal of the fluid; in such cases the solution was diluted with an equal quantity of hot water, until the patients became accustomed to it. The taste of the solution is bitter and very unpleasant. No hæmoptysis occurred in any of the cases after the inhalations.—*Allg. med. Cent.-Zeit.*, February 18, 1880.

ON THE VALUE OF QUEBRACHO AND OF INHALATIONS OF BENZOATE OF SODA.—Dr. Frommüller, of Furth, reports three cases, one of phthisis, with severe dyspnœa, one of severe asthmatic attacks complicating an extensive burn, and one of dyspnœa due to cirrhosis of the liver, with general dropsy and slight hydrothorax, in which the dyspnœa was greatly relieved by the internal administration of quebracho. He gave a teaspoonful every three hours of a mixture containing one part of the fluid extract of quebracho to two parts of water. In all, he has used quebracho in about forty cases, some of which were cases of essential asthma, and the rest of dyspnœa due to various causes. The results, as was expected, were not uniform. Sometimes the remedy proved useless, and sometimes the patients refused to take it on account of its peculiar taste and of the burning sensation in the throat caused by it. In cases of pneumonia, with pronounced dyspnœa, it sometimes gave great relief.

Dr. Frommüller also reports that he has treated a number of cases of phthisis with inhalations of benzoate of soda, according to Rokitansky's method. Some of the patients seemed to be benefited slightly at first, but the amelioration proved very transitory; the inhalations soon became very onerous and painful, and finally had to be discontinued entirely. He has now discarded this method of treatment, as he found it useless, troublesome, and expensive.—*Allg. med. Cent. Zeit.*, February 18, 1880.

RECENT INVESTIGATIONS ON THE BLOOD.—It has, up to the present time, been believed that hæmoglobin, which exists in the blood of all vertebrate animals, is not crystallizable in all of them. M. Blanchard, however, states that the hæmoglobin of the blood of any animal will always be found in crystallized form, after the blood has remained for some time in the stomach of a leech. To obtain the crystals, it is only necessary to make a leech suck the blood of an animal and subsequently disgorge it. If the crystals be exposed to the vapor of a concentrated solution of carbolic acid, they become insoluble in glycerine, and can be preserved for an indefinite period. The form in which iron exists in hæmoglobin is still a matter of dispute. Mr. Joly insists that it is always in the state of a phosphate. The blood of the octopus vulgaris, according to Frédéricq, contains no hæmoglobine, but in place of it a unique albuminoid substance, which he calls *hæmocyanine*, because, in its chemical constitution, copper takes the place of the iron in hæmoglobin. The venous blood of the octopus is colorless, the arterial blood a pronounced blue. M. Paul Bert, several years ago, discovered this same substance in the cuttle-fish, but did not give it a name. Frédéricq has also found it in the lobster. Hæmoglobin is frequently found in the leucocytes, and Prof. Kühne, of Heidelberg, states, though on rather insufficient grounds, that he has also found it in the voluntary muscles. The quantity of hæmoglobin present in the blood of a man of ordinary size is estimated at about 125 grammes. The quantity is relatively larger at birth than at any other period of life; it is least between the ages of six months and five years, and then increases, gradually attaining its second highest point between the ages of twenty-five and forty-five years, after which it again decreases slightly. The quantity of hæmoglobin does not diminish appreciably during the course of acute febrile diseases, but it does during a prolonged convalescence, and in chronic diseases.—*Le Progrès Médical*, Jan. 17, 1880.

ON THE TREATMENT OF ENDOMETRITIS.—The indiscriminate cauterization of the uterus has been so often resorted to without a careful consideration of the etiology and pathology of the diseases to be treated, that in many instances more harm than good has resulted. In the treatment of endometritis, Dr. J. Hickinbotham, of Birmingham, England, suggests that the physician should take a careful survey of each case before proceeding to the treatment. He tests the nervous system, as in his experience the disease is often occasioned by overwork and mental anxiety; excessive sexual intercourse, and other causes of an exhausting nature, should also be considered. To remedy the first condition he gives phosphorus and iron, or strychnine, and when the patient is peculiarly nervous, bromide of ammonium and potassium. For topical use, morphia and belladonna are highly extolled. The extract of belladonna may be applied directly to the cavity of the uterus by means of a probe. If morphia is employed, one-third or half a grain is made use of in the same way. If there is great thickening of the womb, a glycerine tampon may be introduced and the parts scarified.

A belladonna plaster is often placed over the sacrum to alleviate the pain. Opiate suppositories also are useful. After the subsidence of acute symptoms, if the pain still continues, counter-irritation may be resorted to, as by blisters to the sacrum, or weak liniments of croton oil. Rest, together with the complete abstinence from sexual intercourse, is specially enjoined.—*Birmingham Med. Review.*

Some New Observations upon the Anatomy and Functions of the Ankle and Tibio-fibular Joints.—Dr. Nancrede, of Philadelphia, describes the arrangement of the ligamentous fibres entering into ankle and tibio-fibular articulations as follows: "The fibres have an oblique direction downward from the tibia to the fibula, the upper tibio-fibular joint being a loose one, and more movable. As there is a tendency for the body to be propelled forward when the foot is placed, thus causing dislocation, the ligaments should be inelastic and inextensible. As a further precaution against luxation, the ligament should be tight, which would prevent free flexion. To obviate this, according to Dr. Nancrede's observations, the astragalus is wedge-shaped with the base in front, and as the bones of the leg move forward, their articular surfaces and those of the astragalus are pressed together. To admit of free flexion, which is necessary in walking, an adaptable socket is provided by having one of the bones of the leg—the fibula—movable. In flexion the wide or anterior portion of the astragalus presses up between the narrow part of the tibio-fibular articulation, and the fibula glides upward. In extension, the narrow portion of the tarsal bone is carried forward, the bones of the leg are approximated, and the fibula moves downward."—*Phila. Med. Times*, March 27, 1880.

Remarks on Lipæmia Retinalis Occurring in a Case of Diabetes Mellitus.—In the July number of the *Edinburgh Medical Journal* for 1879, Prof. Sanders and Dr. Hamilton contributed a paper on the "Lipæmia and Fat Embolism in the Fatal Dyspnœa and Coma of Diabetes," in which the results of the post-mortem examination of two patients dying from the above cause are given, and in whom the blood presented a milky stratum on top and contained oil-globules and granular matter in great abundance. Dr. A. G. Heyl, of Philadelphia, describes a somewhat similar case occurring in a man, the eyes in this instance being also affected. The fundus of the eye presented the following appearances on ophthalmoscopic examination: the arterial and venous blood-vessels were of a very light color, approaching that of the fundus, and on that account could not be traced to any distance, although a vessel was seen in its upper half which stopped at the edge of what appeared to be an excavation, and was probably a branch of the artery. The veins were enlarged, but not tortuous. Blood from the finger of the patient presented a milky-red color, and on microscopic examination fat-globes were found. The red globules were counted, but the patient was found not to be leucocythæmic. The peculiar condition of the blood-vessels of the fundus of the eye was thought to be due to the presence of fat in the blood.—*Phila. Med. Times*, March 27, 1880.

Congenital Dislocation of the Wrists.—Congenital dislocations occur so infrequently that many writers of systematic treatises on surgery dismiss the subject with merely a cursory mention. Some authors do not believe that this form of dislocation ever occurs at the wrist unless accompanied by fracture. Dupuytren, among others, held this opinion. Thus far, but ten cases of congenital dislocation of the radio-carpal joint have been placed on record, to which Dr. J. H. Pooley, of Columbus, Ohio, adds another. The patient, a married woman, thirty-three years of age, has remarkably short forearms, being both of the same length, and measuring eight and one-quarter inches from the olecranon to the styloid process of the ulna, being about one and a half inches shorter than the average; the radius measures seven and a half inches in length, and the hand six and a quarter. The appearance presented is that of dislocation forward of the wrist. On the posterior surface of the joint there is a projection of the ulna and radius to the extent of three-quarters of an inch. The carpal bones are pushed forward in the opposite direction. The joints admit of greater flexion than would be the case were there no deformity, whilst extension is performed with difficulty and limited to a line parallel with the forearm. The patient has always enjoyed good health, never having received any injury of the parts involved, nor have they been the seat of disease at any time. She can use her hands with freedom in the performance of her household duties, and can sew with ease. The main points in favor of its being a congenital dislocation are the history of the case, and the examination, together with the presence of the deformity on both sides.—*Am. Practitioner*, April, 1880.

Homœopathic Springs for Fever and Ague.—In Westphalia there is a spring which, after flowing for twenty-four hours, entirely ceases for six, then returns with a very loud noise, and in a stream large enough to turn three mills. The well at Torbay ebbs and flows sixteen times in an hour. The Giggleswick well in Yorkshire rises and falls every ten minutes. St. Anthony's well, near Edinburgh, has a similar regular intermittent movement. In Savoy there is a spring which is very uncertain and irregular in its rises and falls; this water has been suggested for the irregular chills of pyæmia, while sea-water, which rises and falls regularly with tides, is said by Dr. Max Greubler to rival natrum muriaticum in the cure of intermittent fevers. He also hints that the other waters may be tried in obstinate cases of fever and ague. The waters from the intermittent geyser springs in Iceland have not yet been suggested by Dr. Greubler for the worst cases, but he points, with pride and pleasure, to the numerous cases of malarial disease which have been cured at the springs, called the *Puits de Vaisse* at Vichy, which have a perfectly regular and curious *intermittent* action, preceded by a subterranean noise, followed by a violent eruption of mud, water, and gas, strongly impregnated with the hydrosulphureous odor, which occurs at intervals more or less regular, six or eight times every twenty-four hours. Dr. G. prides himself very much upon a homœopathic inspiration which led him to give these waters, especially in cases attended with flatulence and more or less violent explosions of gas and scybalæ. In some cases he was obliged to use what he calls the ascending rectal douche, or injections of the water, which is highly impregnated with gas. Thus all the indications were fulfilled, the water, gas, and fæces were forced first to ascend, and then to descend; and were finally expelled from the patient's body, to his great relief and comfort.

Quarantine at Baltimore was established May 1st. All vessels, except from United States ports north of Cape Henry, will have to be examined before entering the port.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, May 20, 1880.

THE AMERICAN MEDICAL ASSOCIATION.

THE coming week will witness the meeting, in this city, of a large number of representative medical men from all parts of the country. The occasion will be a favorable one for the discussion of many subjects of great interest, and for the expression of opinions upon many topics of much importance. It is hardly a matter of doubt as to the general character of the meeting, and the influence for good which it will exert upon the profession at large. But the circumstances of the meeting, the attendance of so many eminent men, the presence of experts in every branch of medicine, and the earnestness with which most of these men do their work, suggest the possibility of even a wider range of usefulness for the Association than that which would pertain to the medical profession proper. In other words, the opportunity will be an excellent one for creating that better understanding between the physician and the people which is so necessary for the benefit of both. The daily press will be ready with its powerful influence for good to inform the public of the work done in the different sessions, and more than the ordinary interest will be manifested in medical matters in general.

The responsibility, always a great one, of conducting the meeting properly, will be doubly so in the coming session, not only on account of the goodly number of delegates and members who will be present, but on account of the large audiences outside. It is safe to assume that the profession of the country will be well represented by the delegates who attend the meeting, and that the general business of the Association will be conducted in that spirit of harmony which has so notably characterized its proceedings for the last few years. The only possible chance of there being anything to the contrary may be the introduction of the question of teaching homœopathic students. We have alluded, on a previous occasion, to the true merits of this question, and take occasion now to say that neither the Association nor the profession can afford to discuss it in anything but the most liberal spirit. The cause of legitimate medicine will not suffer if the proposed amendment to the by-law is still kept upon the table. Certain it is that the adoption of the proposition would destroy much of the real influence of the Association for good, and would be very prejudicial against many of its best directed efforts to elevate medicine to the true dignity of a broad and progressive science.

As to the purely scientific work of the Association there will doubtless be a good showing. The selection and arrangement of subjects are in good hands, and the time will be well spent in their presentation and discussion. In the scientific, as well as the purely business part of the meeting, it would be well for the members to consider that they have the responsibility of representing their profession to the public, and that they should do and act accordingly. Working with such an understanding and actuated by such a principle, it is impossible to say what influence for good the Association may not exert upon the public mind. We have repeatedly said that the vocation of the physician is something more than a mere prescriber for the sick. His influence should extend beyond the precincts of the sick chamber or the hospital ward. The profession which he represents should rise to the higher privileges of educating the public, and should claim requisite respect for its opinion and advice. Such a representative body as the American Medical Association can do a great deal to such an end in speaking for the profession as a whole, and in placing it in its proper relation to the people and to the State.

It will be conceded by the majority of the members that little can be done to perfect the organization of the Association. It is true that its machinery is quite perfect and works very smoothly. Instead of being an arena for the ventilation of local quarrels for the settlement of disputes concerning ethical questions or for the discussion of purely personal matters, it has become a dignified scientific body, which disposes of all its detail work in the committee-room, and which devotes its time and energies to the cultivation of strictly scientific medicine. But it strikes us that some necessary improvements are still wanting in its management. Among the changes which can be made for the better are those which relate to the publication of the transactions of the Association.

We believe that the majority of the members agree with us that the yearly volume, as now published, does not meet the real wants of the Association. By a rule of the Association, no papers read at the meeting can appear in full except in the yearly volume. It is not difficult to prove that the appearance of such papers is very tardy, and their circulation

among the profession very small. It is hardly fair, for the mere sake of making the yearly volume a success in its small way, that the authors of papers therein should be denied the right of appealing to that large class of medical readers which can only be reached through the columns of the various medical journals of the country. The policy is suicidal for all parties, and some new one should take its place. The exclusiveness of publication as now carried on is unworthy the liberal design of the Association, and should be discontinued. Permission should be given to authors to publish their papers in any medical periodical they may think proper, with the privilege afterward of having them appear in the yearly Transactions. If the papers are valuable, so much the better reputation will they give for the volume when it appears. Again, authors knowing that such a privilege is granted them, will gladly come forward and contribute to the success of the meeting, which they would not think of doing under other circumstances.

Some influential members of the profession, who are interested in the success of the Association, have advised that the publication of the Transactions in book form be entirely suspended. In view of the fact that as yet there is nothing to take its place, this proposition is hardly practical. As an offset to this, however, it has been suggested that the Association have a journal of its own, which shall be the medium for all its publications. It is hardly possible that it will be able to carry out such a plan. To start a new medical periodical for the sole purpose of being an organ of the Association would be exceedingly difficult, and its circulation would hardly be much more than the present volume of Transactions. There would be no guarantee that it would be taken by the members merely because of the official transactions of the Association which it might contain. Except for that feature it would have no other claim upon the members than any ordinary medical journal. It would be quite impossible to select any established journal as the official organ of the Association, inasmuch as no such periodical would be ready and willing to sacrifice its independence for the mere privileges of publishing an official report, or for the opportunity of using the different papers read at the meeting. These papers and transactions, at least such as any conscientious editor would admit to his pages, would occupy but a few numbers, and the right of their publication would not weigh against the disadvantages of being under the control of a publication committee as to time and space. The safer and better way would appear to be to leave the choice of journals to the authors of the papers, and the publication of the transactions to such periodicals as chose to report them. This is a perfectly natural and easy way out of the difficulty, and one which will hardly fail to give general satisfaction.

THE GUY'S HOSPITAL CONTROVERSY.

We referred in our last issue to the appearance of an article in *The Nineteenth Century*, by Miss Lonsdale, defending the new system of nursing in general, and that attempted at Guy's Hospital in particular. In the succeeding number of the above journal three replies have appeared, written by Sir Wm. Gull, Dr. S. O. Habershon, and Dr. Arthur Henriques, respectively. Dr. Wm. Moxam has also written a fourth reply, which appears in *The Contemporary Review*. Altogether, the young lady must feel herself very much answered. These answers show, on the whole, only what we asserted last week, that the article by Miss Lonsdale was exaggerated, and, in most respects, unjust. Any special analysis of them would hardly prove interesting. Sir Wm. Gull discusses the question from a general point of view, and is as severe as he can be, with courtesy, toward his lady opponent. Dr. Habershon and Dr. Moxam go more into details, and specifically deny most of the points made by Miss Lonsdale. Dr. Henriques defends the London hospitals against certain aspersions in regard to the character of its nursing.

The articles are all of them forcibly written and make interesting reading for the doctors, and probably for Miss Lonsdale. They should not create the opinion, however, that the advocates of the new system of nursing are entirely in the wrong and have no justice on their side. Physicians on this side of the water know pretty well what the old style of hospital nurse was, and also what an addition to our hospitals the training-schools for nurses are. The opposition, though partial and qualified, which the present controversy in England has developed against the trained and educated nurse, is, on the whole, likely to produce a bad effect on the cause of good nursing, and is to be deplored on that account. But, however the question ends, it is to be hoped that it will be settled before long. Periodical literature has now had quite enough of the squabbles of a hospital and medical school, neither of which are of very serious significance either to humanity or medicine.

TRICHINOSIS IN BROOKLYN.

A suit was recently tried in Brooklyn involving the subject of trichinosis. A Mrs. Griefeldt, the plaintiff, was desirous of obtaining damages for the loss of her husband by that disease. The facts brought out were to the effect that on January 29, 1880, Mrs. Griefeldt, her husband, and two other members of the family, ate smoked and boiled ham, bought of a certain pork-packing establishment. On February 3d the members of the family began to be sick, complaining of abdominal pains and digestive disturbance. The symptoms were particularly severe in Mr. Griefeldt's case. In the course of a week muscular pains, cramps, swelling of the face and legs,

and a high fever set in. Shortly after this he died and trichinæ were found in his muscles at the autopsy. The number was not so great as in the other cases. Dr. Jos. H. Raymond found seven in a piece of muscle the size of a pea. The other members of the family were more or less severely sick.

The trial brought out a good deal of expert testimony. There were, however, no very notable contributions to the natural history of the disease, and the case has its chief interest in the legal question that was raised, as to who was responsible for the death of Mr. Cruickshilt, and in the question of the prophylaxis of the disease, trichinosis.

It was claimed by the plaintiff that the defendants were responsible for Mr. Cruickshilt's death, because they sold smoked ham which was diseased, and that such ham, if properly selected or cured, would have been harmless; it was claimed also that the court should take judicial notice of the latest discoveries in science; that raw, fresh animal food, free from parasites, is perfectly wholesome; that ordinary culinary operations will not destroy trichinæ, that eating trichinosed meat, even when the parasites are dead, is not safe; and that meats sold for domestic purposes are presumed to be sound and wholesome. In reference to this indictment we may say that some of the points are not true, while those that are true are not applicable to the case in question. It would be impossible to take a position upon such questions which would make pork-packers and pork-sellers, under present laws, responsible for the presence of trichinæ in the meat they sell. This fact the jury recognized, and returned a verdict for the defendants. There is but one sure and practicable way at present to lessen the danger of trichinosis, and that is to inform the people thoroughly in regard to it, and how pork should be treated to kill the dreaded parasite. We must teach the people; we cannot punish the pork-packer.

As regards further prophylaxis, the use of microscopes in pork-packing establishments is undoubtedly of value, but it cannot insure perfect freedom from the trichinæ, and is liable to beget a false security. It is probable that we may gain some protection when we know just how the trichinæ enter the swine originally. Here is a point where little has been done, because little is known. The evidence at the recent trial was purely negative, two experts testifying that they did not believe in the current theory that the trichinæ entered pigs through the latter eating rats and mice.

The present case comes in opportunely with those which have been recently discovered to have occurred on the school-ship *Cornwall*. The lesson from them both is, to beware of pork; danger lurks in it in increasing proportion according as it is boiled, roasted, broiled, smoked, or raw.

A MINISTER OF HEALTH FOR GREAT BRITAIN.

The medical profession of Great Britain has reason to congratulate itself upon the attainment of an object which it has long desired. The new Government, under Mr. Gladstone, has made the President of the Local Government Board a member of his Cabinet, thus creating a Department of Public Health. For this Local Government Board is the central authority which supervises all matters of public health and public charity throughout the kingdom. Vital statistics, compulsory vaccination, medical relief of paupers, and all public hygienic measures come under its administration. There has been heretofore much difficulty and embarrassment in the work of the central board, owing to the fact that its chief officer was only the head of a bureau and had but little real authority. The elevation to the rank of a cabinet officer will add dignity and authority to the new department. It cannot fail to draw more attention to questions of State medicine, and increase the importance attached to the work and recommendations of the medical profession in that direction.

Reviews and Notices of Books.

THE VENEREAL DISEASES, INCLUDING STRICTURE OF THE MALE URETHRA. By E. L. KEYES, A.M., M.D., Professor of Dermatology and adjunct Professor of Surgery in the Bellevue Hospital Medical College; one of the Surgeons to Bellevue Hospital, etc. New York: William Wood & Co., 27 Great Jones Street. 1880. Pp. 318.

This volume is the first number of Wood's Library of Standard Medical Authors, for 1880, and, if it is a "sample brick," speaks well for the value of the series for this year. The volume is divided into three parts, namely: I. Chancroid; II. Syphilis; III. Gonorrhœa and its complications. The first section, that on chancroids, takes up the first 52 pages. The second, occupying 200 pages, gives the history, modes of transmission, the diagnosis and treatment of syphilis. This subject is treated more in detail than any of the others, and our author's aim evidently has been to make this section as full and perfect as his space would allow. The use of mercury is advocated in "tonic doses" throughout the whole course of treatment. He expresses his preference for the proto-iodide given in the following manner: he commences with a standard dose of one-sixth of a grain (granular), one after each meal for two or three days. On the fourth day one extra standard dose is added at the mid-day meal. This is continued for three days, and on the fourth succeeding day another standard dose is added, and on the following fourth day another. In this way the amount of mercury is gradually increased until some of its physiological effects are produced. This he considers a "full dose." If this is continued, the patient will soon suffer both in the stomach and in the quality of his blood, while his strength will fail. The "full dose" is only to be used in case of necessity. A "tonic dose" is one half or even one-third of a "full dose," and on this the patient should be kept

during the whole course of treatment, except that it may be increased to a "full dose" when the occasion requires. The illustrations in this portion of the book, from photographs of skin lesions in syphilis, furnished by Dr. Geo. H. Fox, add much to the value of the book, although more care in the plates would not have detracted from their value. The views of the author on the treatment of stricture are so well known that they require but brief mention. His rule seems to be that, for non-resilient strictures of large calibre, that is, those that will admit a No. X. English sound in the pendulous urethra dilatation should be employed; and for resilient internal urethrotomy should be resorted to. For strictures in the deep portion of the urethra, gradual dilatation "should be the rule, all operative measures the exception." Perhaps this is rather too general a statement, and will be criticised by some; yet, if it be an error, it is on the safe side.

To appreciate the amount of labor that has been expended on this volume, and the practical and thorough manner in which the whole subject of venereal diseases has been treated, it must be read. And in closing this short notice we can but congratulate both the author on his success, and the publishers in having issued so valuable a work as the first volume of Wood's Library of Standard Medical Authors for 1880.

A Treatise on Foreign Bodies in Surgical Practice. By Alfred Poulet, M.D, Adjutant Surgeon-Major, Inspector of the School for Military Medicine at Val-de-Grâce. Two volumes. New York: William Wood & Co., 27 Great Jones Street. 1880.

The author states in his preface that "no surgeon has hitherto thought of collecting in one book all the material scattered throughout the annals of science, concerning the question of foreign bodies, and yet there are few subjects which are more worthy of attracting the serious attention of practitioners. He has collected from the many treatises and journals, both old and recent, all cases in which foreign bodies have been found in the different organs of the body. These have been analyzed, and only such have been introduced into the text as from their rarity are of interest, or that illustrate the topic under consideration. It is not a book that one can review; we can only point out its arrangement, and refer to the amount of matter that these two volumes contain. After some general remarks on "Foreign Bodies in General," in which they are defined and classified, he lays down the general rule of treatment. He then takes up foreign bodies in the pharynx, œsophagus, stomach, intestines, and rectum: these occupy the first volume.

The second volume begins with those in the air-passages, and is followed by sections on those in the genito-urinary organs, both male and female, in the ear, nasal fossæ, in the glandular canal, and Wharton's duct. Under each head the different substances that may be found are enumerated—their behavior, symptoms, general and special, the danger to which they give rise, and their treatment. It is perhaps unnecessary to say that our author covers the ground very completely, and that his work contains all that is known on foreign bodies in surgery. It is an exhaustive work, and will no doubt add much to the value of Wood's Library of Standard Authors, of which these form the second and third volumes.

A Handbook of Physical Diagnosis, comprising the Throat, Thorax, and Abdomen. By Dr. Paul Guttman, Privat Docent in Medicine, University of Berlin. Translated from the third German edition, by Alex. Napier, M.D., Fel. Fac. Phys. and Surg., Glasgow. With a colored plate, and eighty-nine fine wood engravings. New York: William Wood & Co., 27 Great Jones Street. 1880. Pp. 344.

This, the third volume of Wood's Library, has been well received, not only in Germany, but it has been translated into Italian, Russian, Spanish, and French. It has evidently been found to fill a want in Continental Europe, and a careful perusal of its pages will demonstrate its value as a handbook of physical diagnosis.

Under each topic the different modes of examination are given, and the conditions met with in health and disease fully and clearly described. The article on Examination of the Lungs takes up the greater portion of the work. As the work does not aim at being theoretical, only such descriptions are given as are of universal acceptation, so there is but little to criticise. The volume contains quite a number of illustrations of different instruments that are used as aids to diagnosis, and some anatomical plates.

The Essentials of Anatomy: designed as a Text-Book for Students. By William Darling, M.D., F.R.C.S., and Ambrose L. Ranney, A.M., M.D. New York: G. P. Putnam's Sons. 1880. 8vo, pp. 629.

To the student and practitioner this work has a taking title. Its aim is to hold a middle place between the smaller manuals and the more elaborate treatises on anatomy. While it may seem somewhat discouraging to the novice to know that a volume of over six hundred pages is required to give what may be considered the mere essentials of anatomy, the work is none too large for its purpose. It is difficult to give an adequate idea of the scope of the work, so different is it from others on the subject. The arrangement of the subjects, their detailed treatment, and the methods of memorizing different points, are peculiar to the authors, and are the results of long experience in the teaching of students. There is, in fact, an individuality about the work, which gives it a peculiar value to the student and practitioner. Prof. Darling's forte in teaching is his power of memorizing by associations, and in view of the end at which he aims, it is pardonable if he occasionally overreaches the mark. Thus, it must be allowed that in some instances it is more difficult to recollect the associations upon which the memorizing is founded, than to trust to abstract memory itself. Still it gives the student an idea as to the means which can be taken by him to recollect the relations of parts by associations which he can make for himself.

As a collateral aid to this method of memorizing, several diagrammatic representations are introduced. Some of these are very good, but others will prove somewhat confusing to the student who has no other illustrations of the subject. Especially is this true when it is taken into account that these diagrams are the only illustrations to be found throughout the work. We cannot help feeling that this is a great detriment to the work as a whole, in so far that in such a respect the book lacks the necessary completeness of a work of its kind. In teaching anatomy, illustration is everything. No memorizing, nor analysis, no diagrammatic representations can take its place. We say thus much of the defect of the work, more in the way of regret than fault-finding, inasmuch as with the addition of the requisite number of illustrations it would rank as a leading text-book,

and would, in the widest acceptation of the term, be one containing the essentials of anatomy.

The work, as a whole, is so thoroughly original in its arrangement, that we have studied it with much interest and pleasure. The authors have a remarkable faculty of bringing out the salient points of their subject of arranging the different sections in such a natural manner as to invite a thorough and complete analysis of their different divisions. In fact, in perusing the book, we study the science of anatomy from a new standpoint, and what would otherwise be dry and uninteresting, is made inviting and profitable.

The volume is divided into five parts, viz.: osteology, arthrology, myology, angiology, neurology, and splanchnology. Each of these divisions is treated as a whole, and is, as far as the purposes of the book will allow, complete in itself.

The work is tersely written, the style, for the most part, is simple and perspicuous, and the descriptions clear and intelligible.

Reports of Societies.

THE NEW YORK STATE PHARMACEUTICAL ASSOCIATION.

Second Annual Meeting, held in the City of Syracuse, May 19 and 20, 1880.

(Special Report for THE MEDICAL RECORD.)

WEDNESDAY, MAY 19TH—FIRST DAY—MORNING SESSION.

THE Association met in Chase's Musical Hall, and was called to order at 11 A.M., by the President, PROF. P. W. BEDFORD, of New York, with congratulatory remarks.

On motion by MR. C. K. BROWN, of Deposit, the reading of the minutes was omitted.

THE PRESIDENT then introduced HON. FRANCIS HENDRICKS, mayor of the city, who extended a welcome to the members of the Association.

DR. H. D. DIDAMA, of Syracuse, was then introduced, and, in behalf of the medical fraternity of the city, welcomed the members of the Association, *first*, because they were the members of an ancient and honorable fraternity; *second*, because at one time pharmaceutists belonged to the tribe of doctors; and *third*, because, whatever their forefathers and innumerable grandfathers did, they were no longer mere venders of nostrums and drugs of whose composition and nature they knew nothing.

MR. CHARLES HUBBARD, of Syracuse, in behalf of the drug fraternity, then gave the Association a most hearty welcome, after which the President responded to the address by the Mayor. Dr. A. B. Huested, of Albany, responded to the address by Dr. Didama, and closed with the following resolution, which was unanimously adopted:

Resolved, That this Association extends a cordial invitation to the physicians of Syracuse and vicinity, to the Professors of the Syracuse University, and to Prof. H. A. Englehardt, of the Salt Works, to attend the second annual meeting, and that they receive the full courtesies of the floor.

MR. W. P. DE FOREST, of Brooklyn, then responded to the address of welcome made by Mr. Hubbard.

THE PRESIDENT then announced several invitations to visit places of interest, which were accepted by the Association, with thanks.

THE PRESIDENT then delivered his Annual Report, in which he reviewed the history of the Association, and referred to the prosperity of like organizations in other States. He then referred to the proceedings of the last National Convention for the revision of the United States Pharmacopœia; urged the members of the New York State Pharmaceutical Association to become members of the American Pharmaceutical Association; and then spoke of the desirability of a pharmacy law for the State of New York; first, of its necessity; second, of its [illegible] and third, of its absolute separation from political [illegible]. Some changes in the by-laws were recommended, and the propriety of sending delegates to the American Pharmaceutical Association was suggested.

He then announced the death of two members: Dr David John Hollis Chubbuck, of Binghamton; and Mr Hermann Hugo Metz, of New York.

On motion by DR. A. B. HUESTED, of Albany, the thanks of the Association were extended to the President for his comprehensive address, a copy requested for publication, and a committee of three appointed to report upon the suggestions it contained.

The committee consisted of Dr A. B. Huested of Albany; Mr W. H. Battelle, of Rochester; and Mr. J. G. Miller, of Gloversville.

On motion by MR. F. K. SWEET, of Lockport, telegrams of congratulations were sent to Pharmaceutical Associations in session in Kentucky, Ohio, and New Jersey.

MR. L. E. NICOT, Chairman of the Executive Committee, then read the names of the applicants for membership, ninety-two in number.

Several reports were then read by title, after which the Association adjourned to meet at 2 P.M.

FIRST DAY—AFTERNOON SESSION.

The Association was called to order at 2.30 P.M., by the President.

The minutes of the morning session were read by the Assistant Secretary, MR. CLAY W. HOLMES, of Elmira, and adopted.

The Secretary then read the names of those recommended by the Executive Committee for membership, and they were unanimously elected.

The Chairman of the Executive Committee then read the names of twenty-two additional applicants for membership.

The Secretary, MR. CHARLES H. GAUS, of Albany, read his report, which showed that two hundred and seventeen members were admitted during the last year, and that certificates of membership had been issued to one hundred and thirty-eight members. The report was adopted.

MR L. E. NICOT, of Brooklyn, read the report of the Executive Committee, which was accepted and adopted.

REPORT OF COMMITTEE ON TRADE INTERESTS.

MR. A. J. INLOES, of Binghamton, presented the report of the committee, in which special reference was made to the use of *printed prescription blanks* by druggists. The tenor of the report was strongly against such practice, and in favor of *plain paper*, without a letter of print indicating what the name of the druggist was by whom it was furnished, or the physician who used it. Although the report contained no special recommendation, its sentiment was

approved of by the Association without dissenting vote, and the report of the committee was unanimously adopted.

Mr. William Blakie, of Utica, presented his report as delegate to the twenty-seventh annual meeting of the American Pharmaceutical Association, held in Indianapolis, September 9, 1879. The report was adopted.

Mr. W. P. De Forest, of Brooklyn, read the report of the Committee on Pharmacy and Queries, which was received and adopted.

The President announced the receipt of a congratulatory telegram from the New Jersey Pharmaceutical Association, in session at Jersey City.

The following

OFFICERS FOR THE ENSUING YEAR

were then elected:

President, Prof. P. W. Bedford of New York; 1st Vice-President, Dr. G. M. Baker of Brooklyn; 2d Vice-President, Mr. Frank Hamilton of Syracuse; 3d Vice-President, Mr. H. B. Napier of Owego; Secretary, Mr. Clay W. Holmes of Elmira; Treasurer, William Blakie of Utica. Executive Committee: Mr. W. L. Brown of Syracuse, Chairman; Mr. C. Z. Otis of Binghamton, and Mr. F. L. Norton of Delhi.

The President announced the receipt of a congratulatory telegram from Dr. J. E. Judge, President of the Ohio State Pharmaceutical Association, in which it was stated, that 145 applications for membership in that Association had already been made.

The Chairman of the Executive Committee announced three additional applications for membership.

The President, on motion, appointed as Committee on Exhibit:

Mr. C. J. Powers of Syracuse, Mr. J. M. Cool of Palmyra, and Mr. E. C. Billings of Smyrna.

Owing to the absence of Mr. J. G. Miller, Mr. C. H. Haskins was substituted on the Committee on the President's Address.

The Association then adjourned to meet at 7.30 P.M.

First Day—Evening Session.

The Association was called to order at 7.30 P.M. by the President, and the minutes of the afternoon session were read and approved.

The Association then elected the following gentlemen as

DELEGATES TO THE AMERICAN PHARMACEUTICAL ASSOCIATION.

Mr. L. E. Nicot of Brooklyn, Mr. C. J. Powers and Mr. W. L. Brown of Syracuse, Mr. A. J. Inloes of Binghamton, and Mr. C. H. Gaus of Albany.

Mr. R. W. Gardner, of New York, offered as an

AMENDMENT TO THE CONSTITUTION

that the Annual Meeting be held on the *fourth* Wednesday and Thursday of May. Laid over for one year under the rule.

The Chairman of the Committee on the President's Address, reported amendments to the Constitution and By-Laws, such as would, if adopted, make them accord with the suggestions offered by the President in his Annual Report. They were laid over under the rule.

Mr. J. T. Watson, of Clinton, brought up the question of

THE CUTTING OF PRICES,

and spoke of the causes, the results, and the means of prevention.

The subject gave rise to considerable remark, but no action was taken by the Association.

Dr. G. M. Baker, of Brooklyn, asked for an interpretation of the words "practice of pharmacy," as found in Sec. 2, of Art. III. of the Constitution.

There was a free interchange of opinion without definite result being reached. After which the Association adjourned to meet at 9 A.M. on Thursday.

Thursday, May 20th—Second Day—Morning Session.

The Association was called to order at 9.20 A.M. by the President, and the minutes of the last session were read and approved.

The Chairman of the Executive Committee reported the names of fifty-two candidates and recommended them for election to membership. All were elected.

THE PROPOSED PHARMACY LAW

being the special order of business, Mr. H. B. Napier, of Owego, of the Committee on Pharmacy Law, read the proposed law, and after some amendments, it was adopted by the Association.

[The law has seventeen sections and two schedules.]

The President announced the following committees:

Committee on Trade Interests: Mr. G. H. Arnold of Cortland, Mr. J. W. Howarth of Utica, and Mr. H. A. Bourne of Poughkeepsie.

Committee on Pharmacy and Queries: Mr. R. K. Smithers of Buffalo, Mr. G. H. Haas of Rochester, and Mr. Louis Hunt of Auburn.

Committee on Pharmacy Law: Mr. Henry B. Napier of Owego, Mr. Julius Rieffenstahl of Buffalo, Mr. B. F. Ray of Utica, Dr. G. M. Baker of Brooklyn, and Mr. W. L. Brown of Syracuse.

The Executive Committee reported in favor of holding the next *Annual Meeting* in the city of Buffalo.

The report was adopted.

On motion, the Association elected by ballot Mr. R. K. Smithers, of Buffalo, as Assistant Secretary.

The following

AMENDMENTS TO THE BY-LAWS

were then brought up by Dr. Huested, of Albany, and adopted by the Association.

In place of Article XV., the following: "The Association invites manufacturers and others to exhibit at the annual meeting, crude drugs, chemicals, pharmaceutical preparations, chemical and pharmaceutical apparatuses, and such objects as possess a general scientific or special pharmaceutical interest; proprietary and patented medicines and medicinal preparations, the complete working formula for which is withheld, and such preparations as are offered under other than their proper scientifically recognized names, will not be received.

For Article XVI. the following as the order of business:

1. Reading of the Minutes; 2. Address of the President; 3, Application for Membership; 4. Election of Members; 5. Reports of Officers and Committees; 6. Miscellaneous Business; 7. Reading of Communications; 8. Election of Officers.

The Association then adjourned to meet at 5 P.M.

SECOND DAY—AFTERNOON SESSION.

The Association met and was called to order at 2.20 P.M. by Mr. RIEFFENSTAHL, of Buffalo.

On motion, Mr. DE FOREST, of Brooklyn, was elected President, *pro tem.*

The minutes of the last session were read, corrected, and adopted.

On motion, Mr. Rieffenstahl and Mr. Gardner were appointed as a Committee to conduct the newly elected officers to the platform.

The By-laws were then suspended, and Mr. Reuben A. Defendorf, of Phœnix, was elected a member of the Association.

Mr. DE FOREST made a supplementary report from the Committee on Pharmacy and Queries.

Mr. F. K. SWEET, of Lockport, then read a paper

ON THE PROPER RELATIONS BETWEEN PRESCRIBER AND THE DISPENSER OF DRUGS AND MEDICINE.

The position taken by the author was that the dispenser was not a prescriber, and that he could not do so without violating the courtesy due the medical profession.

The position of the pharmaceutist was that of a co-worker in the labor of saving human life, and alleviating human suffering, and a help to a superior profession.

Mr. E. G. BISSELL, of Waterville, read a paper

ON THE METHOD OF PREPARING SYRUP OF IPECAC.

The process recommended was to mix the fluid extract with water, and allow the mixture to stand until all the portion insoluble in water has subsided. Then filter, washing the precipitate in the filter with hot water; then dissolve the requisite amount of sugar in the aqueous solution.

Mr. C. W. HOLMES, of Elmira, referred to a process which had given him a perfect product, and which he gave in a paper read before the American Pharmaceutical Association, in 1874. The difference between it and that offered by Mr. Bissell was that the latter stage of the process was done by percolation. Place the sugar in a funnel, the apex of which is closely stopped with a sponge, and, having filtered the solution of ipecac, pour it upon the sugar and allow it to percolate.

The By-laws were suspended, and Mr Charles W. Spingler, of Weedsport, was elected a member of the Association.

The Report of the Committee on Exhibits was then presented by M. C. J. Powers, of Syracuse, after which several resolutions were adopted, extending the thanks of the Association to all who had given it greeting and hospitality during its stay in Syracuse.

The secretary announced that 120 new members had been elected during the present meeting, and on motion, the Association was declared, by the President, adjourned, to meet in the city of Buffalo on the third Wednesday and Thursday of May, 1881.

THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Thirty-First Annual Meeting held at Altoona, Penn., May 19, 20, and 21, 1880.

DR. ANDREW NEBINGER, OF PHILADELPHIA, PRESIDENT, IN THE CHAIR.

(Special report for THE MEDICAL RECORD.)

THE thirty-first annual meeting of this Society was held in Altoona on May 19th, 20th, and 21st, with ANDREW NEBINGER, M.D., of Philadelphia, President, or WM. B. ULRICH, of Chester, First Vice President, occupying the chair during the sessions.

The proceedings consisted of general business relating to matters of interest to the Society; reports of various officers and committees; annual addresses on obstetrics, surgery, mental disorders, and hygiene; and voluntary papers on scientific subjects relating to medical science. The usual excursions and receptions were extended to the members of the Society by the Blair County Medical Society.

GENERAL BUSINESS.

The address of welcome was delivered by DR. ROWAN CLARK, after which the Committee on Credentials and the Corresponding Secretary presented their reports. The reports of the various county medical societies were referred to the Publication Committee without being read. DR. W. B. ATKINSON, Chairman of the Committee on State Board of Health, reported progress, and the committee was continued. The report on Medical Legislation was read by DR. R. L. SIMMETT, chairman, and stated many well known facts in regard to the sale of medical diplomas; but the report, though very lengthy, did not solve the problem which has been handled so unsuccessfully by previous committees. DR. JOHN CURWEN then presented the Report on Epilepsy and Insanity, which was received and ordered to be recorded. The remainder of the general business concerned amendments to the constitution, regulations respecting the preliminary examination of prospective students of medicine by committees appointed by the county societies, and regulations regarding the status of members.

ANNUAL ADDRESSES.

The Address on Medicine was omitted on account of the absence of DR. THOS. SHAW, the appointee. The address of DR. JOHN T. CARPENTER, of Pottsville, entitled "History of the Rise and Progress of the Obstetric Art in Pennsylvania," showed the disfavor in which obstetrics was held by the profession of the last century, and how the efforts of Bond, Duffield, James, Dewees, Meigs, Hodge, and Atlee established it as one of the recognized essential branches in the college curriculum. The author expressed the hope that the time was near when gynecology would almost cease to exist as a department of medicine, because of the perfection to which the obstetric art would reach.

DR. JOHN H. PACKARD'S address on Surgery gave a review of the progress of surgery during the year; considering the subject under these heads: Anæsthetics, Ophthalmic Surgery and Therapeutics, Surgical Appliances, Surgical Pathology, Surgical Achievements, and Antiseptic Surgery. The address on Mental Disorders was a lengthy, statistical paper, showing careful investigation by DR. ISAAC N. KERLIN, of Media. DR. BENJAMIN LEE'S address on Hygiene treated of the importance of having an official inspector of drainage and plumbing in all cities where underground drainage was employed, and suggested a bill to be presented to the State Legislature looking toward the adoption of some such law to protect the lives of citizens of the commonwealth. The PRESIDENT'S address discussed the well-worn subject of Medical Education, and informed the public of Altoona how ignorant many of the graduates of the medical schools may be, though possessing a legitimate diploma.

Unfortunately, these annual addresses allow their authors little opportunity for preventing original scientific matter, and consequently contain but little

novelty. In fact, year after year, the authors are compelled to write extremely long papers in order to accomplish the introduction of a sufficient number of facts to interest the Society.

There were presented sixteen voluntary papers, but owing to the time occupied by the general business, and the annual addresses, these were for the most part read in abstracts.

New Remedies in the Local Treatment of Skin Diseases,

was the title of a paper by Dr. J. V. Shoemaker. The two remedies discussed were oleic iodoform and oil of ergot. The former is made by dissolving iodoform in oleic acid (gr. xxiv. ad. f ʒ i.), and is better than iodoform dissolved in its ordinary solvents, because it has less disagreeable odor. This preparation does not become rancid, is economical, does not stain the clothing, and enhances the therapeutic value of the iodoform. It should be applied with a brush, and acts as a stimulant, astringent, and disinfectant. It has been used with advantage in scrofulous diseases of the skin, fetid ulcers, carbuncles, psoriasis of the scalp, and in functional diseases of the sweat-glands. It may be combined with the oleate of mercury, and is then of benefit in syphilitic affections, especially of the mucous membranes, and may be employed as a parasiticide in favus, pityriasis, and kindred affections.

Oil of ergot is a refuse material left after the manufacture of the ergot preparations; and probably has not been used previously as a topical remedy. Its action is soothing and astringent, and is therefore adapted to cases of acute eczema, cracked nipples, herpes of the genitals, and seborrhœa of the scalp. It has also been employed advantageously in nasal catarrh, leucorrhœa, and gonorrhœa.

Specimens Illustrating Results after Excision of Joints, with Remarks on the Treatment of Joint-Diseases.

Dr. William H. Pancoast, presented a paper with the above title. The specimens were obtained from patients who, months previously, had been subjected to excision for disease of the articular extremities of the bones. One was a hip, the other a shoulder-joint, and both established the fact that a sort of capsule may be developed around the false joint. These results encourage the surgeon in operating upon such cases.

Reference was made to the fact that, though extension gives rest to diseased joints, it may do harm by reflex irritation when too much weight is added to the limb.

Improved Urethrotome.

Dr. Pancoast also exhibited an improved urethrotome, modelled on the principle of Syme's staff for perineal section. The staff is tunnelled, and also contains a blade for cutting the stricture. It is used by passing a filiform bougie through the contracted urethra, the staff is then slipped over this, when the blade is projected and the urethra incised.

Clinical Observations on the Radical Treatment of Fibroid Tumors of the Uterus.

Dr. William Gooddell presented a paper on this subject. After mentioning the treatment by ergot, hypodermically or by the mouth, and that by a combination of ergot and chloride of ammonium—which should always be the therapeutic means first employed—the author referred to the surgical treatment.

The tumor may at times be seized with fenestrated forceps, which are better than the volsella forceps, and removed by the wire écraseur. This is the process of evulsion. When the os is dilatable the surgeon may enucleate if the tumor is in a favorable locality for manipulation.

These operations should not be attempted immediately preceding menstruation. If hemorrhage occur during the operative procedure, it may be arrested by vinegar, or even by sulphate of iron—though this last is to be avoided when possible. When the tumor is high up and deeply imbedded, the capsule should be incised with Adam's subcutaneous osteotomy saw, and ergot given to cause extrusion. If sloughing occurs, the surgeon must use disinfectant solutions to prevent septicæmia. In a few cases laparotomy is required to give access to the growths, and to give the patient a chance of recovery.

Hyperdistention of the Air-Cells as a Therapeutic Measure,

was a subject reported on by Dr. J. Solis Cohen. By means of an ordinary rubber bulb and tube, with a valve, air is forced into the lungs of the patient by himself. He first takes a deep inspiration, and then holds his nostrils with one hand while he pumps air through the mouth into the trachea and lungs with the other. This inspiration of compressed air, as it may be called, gives greater distention of the cells than can be obtained by voluntary respiratory efforts; but is contraindicated in atheroma, tendency to hemorrhage, etc. It is employed with advantage in incipient phthisis, asthma, chronic bronchitis, and hypostatic pneumonia, and acts as a mechanical expectorant by getting a sufficient volume of air behind the muco-purulent masses to effect dislodgment on slight coughing. Care should be observed not to exert too great pressure, which may, however, be accurately measured if a complicated inspiratory pump be employed. In using the simple apparatus, the judgment of the patient must be depended upon.

Practical Remarks on the Treatment of Asthma.

This paper, by Dr. Wm. Pepper, as well as the two previous ones, was only partially read because of the want of time Stress was laid upon the necessity of recognizing the cause of the asthmatic symptoms, and upon making a distinction between the treatment of the paroxysm and that of the condition. In general the patients come under one of two heads—the plethoric or the anæmic.

It is necessary to restore the tone of the cutaneous and muscular systems by bathing, friction, inunction, and light gymnastics. To relieve the congestion of the liver, if there be any, and to improve the condition of the digestion by regulation of diet, are essentials of treatment.

Blue mass or other laxatives may be required in those of plethoric habit, while quinine, strychnia, and muriatic acid may be indicated in the anæmic. Dry cups may at times do good services. An attempt must be made to prevent the occurrence of bronchitic congestion, for which purpose iodide of potassium and alkalies should be given in certain selected cases. Strychnia has a beneficial influence upon the bronchial tubes.

Alterative expectorants may be of service, and the bromides will relieve perhaps the tendency to spasm, though they depress and should be given only occasionally. At times inhalations are to be employed.

The Construction and Advantage of a New Mechanical Appliance for the Treatment of Diseases of the Spine.

Dr. E. H. Coovers, the author of this paper, showed

the method of preparing a spinal jacket similar to Sayre's, but in which the hardening material is not that of ordinary plaster of Paris. The appliances shown were very light, and evidently well adapted for the purposes intended.

Conservative Surgery,

by Dr. S. M. Ross, was the next paper. Two patients who had been subjected to double amputation of the lower limbs were exhibited, and remarks were made as to the condition at the time of injury.

Anæsthesia in Labor, with the Exhibition of a New Inhaler,

was presented by Dr. D. M. Barr. The use of anæsthetics was advocated during parturition, and an inhaler, consisting of a collapsing funnel-like an umbrella, with a diaphragm of Canton flannel, was recommended.

The Bromide of Ethyl as an Anæsthetic in Practical Surgery.

This paper, by Dr. John B. Roberts, of Philadelphia, presented the various views in regard to the new anæsthetic, but recorded nothing new except the use of the agent in a case of severe angina pectoris, where either only seemed to excite the patient to violent struggling. The cause of death in the well-known case of Dr. J. Marion Sims was attributed to a brown, offensive distillate, now known to have existed in the earlier specimens of ethyl bromide manufactured.

Cinchona Alkaloids.

Dr. Benj. Lee read a paper on Cinchona Alkaloids. The great number of alkaloids derived from cinchona (eighteen primary and seven secondary) perhaps explains the reason that effects can sometimes be obtained from bark that do not follow the use of quinine. Some of the alkaloids now in use are, as a rule, recombinations of already separated principles; for example, hospital quinines, cincho-quinine, dextro-quinine. Other alkaloids are single in composition, while quin-quinia contains a number of alkaloids in varying proportions, though it is not an artificial compound. The value of these drugs has, in certain districts, been great, and they deserve consideration.

Some Points in Relation to Puerperal Septicæmia

was the title of a paper by Dr. W. H. Parish. Preference is given to the above name rather than to puerperal fever, because less likely to frighten the patient, and because giving some idea of the pathology of the condition. The relation of the poison to erysipelas, to surgical septicæmia, and to diphtheria was ably discussed. As to treatment, importance was attached to prophylaxis. The obstetrician was warned against carrying forceps for years in the same woollen bag.

The hot-water douche with carbolic acid was recommended as a uterine injection after labor. The temperature should be 112° F. This removes clots, and prevents post-partum hemorrhage. Abstraction of blood may be beneficial in the very incipiency of the disease, by relieving pelvic engorgement, but if done later it is liable to promote absorption of septic matter generated by decomposing clots.

Dr. J. L. Ziegler read a paper on

Carbuncular Inflammation of the Arms from Contact with the Liquor Amnii of a Dead Fœtus.

In a case of placenta previa the membranes were ruptured, and the liquor amnii gushed out, wetting the arms of the obstetrician. The child was dead and decomposed. Carbuncular inflammation, limited to the parts of the arms wetted, soon occurred, and was accompanied by chills and phenomena of septic poisoning. There were no abrasions of the arms. At the present time, six weeks from the inoculation, the ulcerated surfaces have not entirely cicatrized.

A Report of the Removal of a Large Sebaceous Tumor from the Breast,

by Dr. S. T. Dana, was read by title. Some remarks on the axis of the human foot, showing it to be a curved line, and demonstrating that the ordinary shoe is an orthopedic instrument, were made by Dr. B. Lee.

The following officers were elected for 1881:

President, Dr. J. P. Carpenter, of Schuylkill County. *Vice-Presidents*, Thomas Lyon, Lycoming; William Varner Crawford, C. A. Ralston, Dauphin; W. R. Cowden, Butler. *Secretary*, William B. Atkinson, Philadelphia. *Recording Secretary*, Alexander Craig, of Columbia. *Corresponding Secretary*, O. H. Allis, of Philadelphia. *Treasurer*, Benjamin Lee, of Philadelphia.

The delegates to represent the Society at the meeting of the American Medical Association are:

H. H. Smith, Philadelphia; A. B. Shaeffer, Mifflin; James Oglesby, Montour; F. Ross, Clarion; L. G. Mayer, Mercer; L. H. Gibbs, Lackawanna; P. B. Barnes, Northampton; J. P. Burchfield, Clearfield; T. H. Hobby, Lycoming; J. McMichael, Butler; L. De B. Kuhn, Berks.

The annual addresses of next year are to be delivered as follows:

Address in Medicine, Dr. J. S. Cohen, of Philadelphia. *Address in Surgery*, Dr. S. M. Ross, of Altoona. *Address in Obstetrics*, Dr. S. C. Davis, of Lancaster. *Address in Hygiene*, Dr. Benjamin Lee, of Philadelphia. *Address in Mental Disorders*, Dr. S. S. Schultz, of Danville.

The Society adjourned to meet in Lancaster, in May, 1881.

THE STATE MEDICAL SOCIETY OF WISCONSIN.

Annual Meeting, held at Milwaukee, May 4 and 5, 1880.

(Special report for The Medical Record.)

The Thirty-fourth Annual Session of the State Medical Society of Wisconsin was held at Milwaukee, commencing May 4th.

the president's address.

Dr. J. G. Meachem, Sen., delivered the annual address, on "Honor to Medical Men."

The profession has always held a prominent place in all beneficent and charitable works. Hospitals, asylums, etc., owe their existence in many cases, their continued usefulness in almost every case, to the labor, often unappreciated and unrewarded, of medical men. To them is due in great part the increased longevity of the race, so often remarked upon within the last century. The heroism with which physicians face imminent danger and inevitable death has been proven again and again; while such courage is accepted by the public at large as a matter of course, is unnoticed and unrecompensed, honors and wealth without stint are heaped upon a successful pedestrian. The address favored a more frequent interchange of thought among physicians, more and closer association for such interchange, and a greater elevation of the standard of education both among members of the profession and among those who

aspired to become students, and the exclusion of all illiterate and unqualified pretenders.

ANTISEPTIC SURGERY—THE SPRAY-PRODUCER CONDEMNED.

Dr. Marks, from the Committee on Surgery, read a paper on Antiseptic Surgery, in which he discussed Lister's theory of the revitalization of carbolized animal tissues when used as ligatures. Dr. M. believes that Lister's methods constitute a marked advance in surgical practice, and that statistics show a greater proportion of recoveries since the introduction of those methods, though there may be room for doubt as to whether this increase is due wholly to them or to the better style of dressing which has followed them. While giving all due merit to the antiseptic spray in such operations as ovariotomy, the writer thought that, in amputations of the thigh for example, much better results would be obtained if care was exercised in the subsequent dressing, even without the use of the atomizer, than could be looked for if the atomizer were employed and the after-care dispensed with. Dr. Marks had employed carbolized deer-tendons in over one hundred operations, the largest vessel tied being the femoral artery, and had never known them to fail.

ANTISEPTIC LIGATURES.

Some discussion followed the reading of the above report, chiefly upon the question of revitalization of animal tissues, the majority of the speakers inclining to think that no such thing could occur; that the value of the ligatures in question consisted in the power of the surrounding tissues to absorb them and dispose of them without irritation.

FRACTURE OF THE RIM OF THE ACETABULUM.

Dr. Senn read an able and exhaustive paper on Fracture of the Rim of the Acetabulum, based on the reports of twenty-seven cases and on experiments on the cadaver.

The conclusion reached by the author was that fractures were of more frequent occurrence through the floor of the acetabulum than simple fractures of the rim, and that the mortality is chiefly due to accompanying visceral lesions.

Dr. Pritchard read an interesting paper on Fracture of the Superior Maxillary.

Profs. Jenks, Fitch, and Jones, of Chicago, were introduced to the Society at this point of the proceedings, and invited to participate therein.

THE PROPHYLACTIC TREATMENT OF DIPHTHERIA.

Dr. Griffin read a paper on Diphtheria, in the course of which he urged upon the Society the eminent propriety of impressing upon the minds of the laity the intensely contagious character of the disease. He illustrated this by recounting some facts obtained during an investigation made at the city of New London, Wis., where contagion was traced from case to case in so many instances as to set the matter beyond all possible doubt. Dr. G. suggested the propriety of greater attention to prophylaxis, arguing that remedies which were known to be powerful in treating the disease upon its appearance ought to have some power in preventing it from getting a foothold; he believed that very much might be done in this direction, and advised that the attempt should be made. He himself had adopted the plan of giving those exposed to diphtheria chlorate of potash and tinct. ferri chlorid. three times daily, and believed that he had prevented outbreaks in this way. Whether he was right or not, it was only by careful and conscientious experiments of this kind, and not by denouncing theories as "bosh and nonsense," that truth could be ascertained. His treatment of the disease resolved itself into quinine, iron, chlorate of potash, and alcoholic stimulants.

Dr. Hall urged the importance of using alcoholic stimulants early and freely in the disease, and illustrated his position by detailing cases thus treated with success.

Dr. Vivian indorsed the idea of prophylaxis put forward by Dr. Griffin; he believed that he had prevented the spread of the disease by the employment of chlorate potass., iron, and quinine, in very many cases.

Dr Butler gave an account of an epidemic of diphtheria which occurred in the town of Lima thirty-six years ago. A schoolhouse was located in a rich farming district, its site being high and dry and the building well ventilated. Diphtheria broke out, no one knew how, and in three weeks carried off sixty-one out of sixty three of the scholars in attendance. Such frightful mortality attracted attention, and every crack was searched for a cause, but without success. Other cases were narrated in which the malady seemed to set all logic and all reason at defiance. With regard to prophylaxis, the speaker thought that anything which strengthens the physical system—fresh air, suitable exercise, proper diet, etc.—might be called prophylactic; while anything which lowered the general tone predisposed to diphtheria, or any other disease which happened to be prevalent. He doubted that we knew very much about diphtheria—it seemed to refuse hitherto to be corralled—but thought Dr. Griffin's idea worth taking up and following out carefully. He believed, moreover, that a point worthy of the closest attention was the influence of one poison in neutralizing or exalting the action of another, and instanced, in illustration, cases in which membranous poison had seemed to act as a preventive of malarious croup, and where sewer-gas had greatly increased the malignancy of cholera.

Dr. Griffin desired to add to what he had already said, that where diphtheria made its appearance among the better class of people, it would often be found that, while the front of the house was kept scrupulously clean, the backyard was very often far from being so; that even tolerably intelligent people were as ignorant of the danger arising from decomposing vegetable and other matter in the backyard and cellar as are the most poverty stricken and uneducated; that, in investigating the cause of the disease where everything looked fair and cleanly in front of the house, critical and exhaustive examination of the cellar and backyard was needful, and would often reveal a wholly unsuspected and surprising state of affairs sufficient to account for diphtheria or any other malignant form of disease. Did the gentleman who reported the fearful mortality of sixty-one cases out of sixty-three think that such a calamity could fall upon any community without there being some active local cause therefor?

Dr. Butler replied that he was too young, when the case in question occurred, to take part in the investigation, having been but just admitted to practice; but he believed that the investigation had been honestly and thoroughly made, with all the light obtainable from a case occurring but a short time before, in which the death of an eminent citizen had been clearly shown to be due to such an accumulation of filth in the cellar as Dr. Griffin had referred

to. He could truly say that no local cause was discovered. Parents who rose on Monday morning surrounded by their seven children, went to bed childless on the following Saturday night.

Dr. Manley wanted to say that some of the younger members of the profession might have the misfortune to fight diphtheria in epidemic form in the future. To any such he would make one suggestion: sporadic cases of the disease were generally easily managed but when an epidemic comes and the young practitioner finds his usual remedies failing him, and his patients dying off as though some poisonous serpent had bitten them, he is apt to become demoralized, to drop his safe practice, and look around for some new means of treatment, too often in vain. My advice is, don't do it; stand to your business and keep on with your quinine, iron, and whiskey, and you will do better than in any other way known as yet. With whiskey I have had but little experience; I have found quinine answer my purpose well; I begin with 20 grs for an adult, and give little beside, except chlorate potass. and iron.

Dr. Reynolds desired to hear from some one who favored local treatment in diphtheria. He himself had formerly been inclined to depend upon it, but had gradually changed his views and come to regard the constitutional treatment as the only one to be relied upon. Since Ziemssen's Cyclopedia has been introduced into this country there has been a revival of the idea of local treatment to some extent, and we have chlorinated soda and a hundred other things, all fanciful, as I believe, urged upon the attention of the profession. I want to hear this local treatment discussed.

Other members followed, generally favoring constitutional treatment. Dr. Griffin desired to enforce the idea that unsanitary surroundings were important factors in the production of the disease. Dr. Vivian, while not undervaluing sanitary precautions, was unable to conclude that they had much effect on the disease, or that their neglect did much toward producing it.

Dr. Hall gave an account of an outbreak which originated in a house apparently clean and well situated, but where the timbers were in a state of decay and the whole building water-soaked. From this case the disease spread through the medium of the district school, and took on a malignant form in several cases. He had found the best and most successful treatment to be the exhibition of calomel in tolerably large doses, aided, if necessary, by castor-oil. When the bowels had been thoroughly moved he used stimulants and tonics. If sanitary conditions had no effect whatever in preventing the disease, it was a curious coincidence, to say the least, that it should so often occur where these were bad.

THE MANAGEMENT OF UNNATURAL LABORS.

At the afternoon session, the discussion of obstetrics being in order, Profs. Fitch and Jenks, of Chicago, were specially invited, as experts in that branch, to take part.

Dr. Hunt presented a paper on Uterine Hemorrhage. There is no branch of practice of greater importance than that of obstetrics, and few cases give the young practitioner more anxiety than those connected therewith. Many a young man has labored under disadvantages which have acted against him for years, springing originally from lack of skill in conducting his first half-dozen obstetric cases. All females are liable to abort to a greater or less extent during the child-bearing period, and the general practitioner is frequently called upon to manage cases of this character. Death from this cause is comparatively infrequent, nature, in a large proportion of cases, without aid from art, stops the flow of blood and saves the patient's life. But cases do occur in which the powers of nature prove insufficient for the work, and the resources of art must be called upon to save life. When called upon in such an emergency our first question must be, Is the fœtus living or dead, and if living can the flow be arrested and the pregnancy carried on to its full term with safety to the mother? This question is not easily answered during the earlier part of gestation, but later on the viability of the fœtus can be ascertained with a great degree of certainty; where, however, any doubt remains we are bound to proceed on the more favorable assumption, and direct our efforts toward the salvation of both lives. Our sheet-anchor is absolute rest and treatment by opiates in large doses. The patient should be at once put to bed, and opiates administered freely from the outset, otherwise valuable time will be lost. In addition to rest and opiates, cold applications to the abdomen and even within the vagina are powerful adjuvants in arresting the flow of blood.

Retention of the placenta at full term may cause hemorrhage, and occasion the death of the mother. No patient can be considered safe while the placenta remains in the uterus after the birth of the child, and the man would be guilty of gross negligence who should allow it to remain longer than an hour or an hour and a half; for all experience has shown that after that time the unaided power of nature will not suffice for its expulsion.

An adherent placenta is a common cause of hemorrhage. Under these circumstances it is our duty to administer a powerful stimulant at once if there has been profuse hemorrhage, or if the patient shows any sign of weakness; with one hand grasp the abdominal walls, or make firm pressure over the uterus, and with the other, passed into the womb up by the side of the placenta, break up any adhesions that may exist between it and the uterine walls.

HEMORRHAGE FROM PLACENTA PRÆVIA.

The time at which we may expect bleeding in this case varies with the position of the placenta; the higher up it is placed on the uterine walls the later in gestation will the uterine flow take place. We possess no means of making a correct diagnosis in these cases, and the patient remains ignorant of her great danger until warned of it by a sudden gush of blood. When convinced of the nature of the case with which we have to deal we should endeavor to save both mother and child, but the life of the mother should be our first consideration. We must enjoin absolute rest of both body and mind, calm the fears of our patient, administer a large opiate, and apply cold and even iced water to the abdomen and even within the vagina. Should the flow not be arrested by these means, the vagina must be thoroughly and completely packed with cotton wool, or similar material, saturated with alum water or some other powerful astringent. After the first attack we should keep our patient as quiet as possible, and inform her or her friends that there will be probably similar attacks before delivery. Having stayed the flow for the time being, when the moment of delivery arrives we must face the danger boldly or retire from the field.

In accidental hemorrhage the fœtus is in the nor-

mal position, and the placenta in its proper place, but, owing to some accident, some injury, the placenta becomes detached from the uterine walls, and hemorrhage follows. In treating this form several things must be considered. If pregnancy be not too far advanced, we should endeavor to stop the flow, while, on the other hand, if our patient be in the eighth or ninth month, it will be good practice to administer ergot. Should the flow continue in quantity to endanger life, we must rupture the membranes and deliver as speedily as possible.

UTERINE HEMORRHAGE.

Prof. Fitch said: With regard to the principal part of the treatment laid down, I don't know that I have any criticism to make. I think, however, that the writer does not go far enough. He does not mention some of the most important means for relieving the hemorrhage occurring in abortion. Opium is often not well borne; it creates nausea and vomiting, and thus causes a pressure which has a tendency to dilate the os, thereby favoring the expulsion of the ovum. When abortion is inevitable, the question arises, What is the best means of conducting it? When the flow has been great, and the life of the mother is in danger, the use of the tampon is one of the most important measures to be employed. Usually I employ dry cotton batting, which I allow to remain in position about twelve hours, the patient meanwhile remaining recumbent with the head low and the hips elevated. Of course, this tamponing should never be done unless we are satisfied that the loss of the ovum is inevitable. I know that the use of ice is recommended, both externally and internally, but I must offer my evidence against the practice. I believe the exposure of the patient to this degree of cold and dampness cannot be other than injurious, and that the reaction may render her final recovery doubtful. I believe in keeping the patient as dry as possible, and have little confidence in the use of ice in any way. I would rather trust to the gradual dilatation of the os uteri by the use of the tampon, or by the pressure exerted upon it by the oozing of the blood. I make it a point, when the os is sufficiently dilated, to introduce the placental forceps and deliver the placenta, or the ovum, or whatever may be there, as rapidly as possible, and give at the same time ergot sufficient to produce strong contractions. I have used ergot for many years, and, where I have used a good preparation, I have never had unfavorable results.

I do not believe in the propriety of allowing the placenta to remain in the womb long after delivery. I think it bad practice. I never allow it, and I have not had a case of hour glass contraction for twenty years, and very few excessive or dangerous hemorrhages. I give my undivided attention to the uterus until after the placenta is delivered, and never leave the patient for a moment until this is effected. Waiting five or ten minutes after the birth of the child, in order to allow the uterus some rest after its hard labor, I stimulate it to contraction by pressure upon it through the abdominal walls, making traction upon the cord at the same time. I know that this is dangerous doctrine to preach to young men who are without experience. They may tear off the cord, and thus have no guide to the placenta itself; but I do not remember that I have ever torn a cord, and it need never be done when one has gained a little experience, and considerable force may be exerted too. I have tested to see how much traction I have been in the habit of making, and have found it to be about six pounds. I have used traction to the degree of six pounds many times without injury to the cord or without tearing it off. This traction should never be made, however, during the relaxation of the uterus—only at such times as it is firmly contracting; and if, moreover, any depression of the fundus is perceived, which may readily be done by means of the little finger which rests upon it, all traction should cease at once.

Papers upon Infantile Paralysis, The Use of the Forceps in Pelvic Contraction, The Presentation of the Funis, and On Hemorrhoids, were read.

A CURIOUS FRACTURE OF SKULL AND FACE.

Dr. Palmer gave a verbal description of the Burr Robbins case as follows: Mr. Robbins's injuries were received Jan. 17, 1880, by coming into collision with a bridge while standing upon a small steamboat which was moving very rapidly. His head was caught between the timbers of the bridge and the flange of the boiler, which was an upright one. The bones of the skull were crushed in; the frontal bone was separated along the course of the sutures, longitudinally and transversely, and raised out in front as far as the tissues would permit; without being torn they were put upon the stretch so that the bone could be raised and lowered like the lid of a box over a space of about two inches. The temporal bone was depressed—crushed in, about an inch and a half back of the eye, and the bone forming the upper part of the orbit of both eyes crushed into fragments, as were also the nasal bones. The temporal bone was so badly crushed that a large portion was removed, with the bone at the outer angle of the eye, the upper floor of the orbit, the partition between the eyes, and the nasal bone on one side. The bones on the opposite side were adjusted as accurately as possible. There was a fracture of the malar bone extending down toward the throat, and the upper jaw was broken loose, and knocked over toward the left side about one-quarter of an inch, so that the whole jaw might be moved to and fro laterally to that extent. There was also a fracture at the back of the head and a scalp wound of about three and one-half inches in extent. The amount of bone removed was about three and one-half square inches in area. The brain was lifted out of its resting place about half an inch, and one of the internal temporal arteries was torn across. Of course, it seemed as though such injuries must prove fatal almost instantly. Although the patient was a man of remarkable vitality and power, he was at the point of dying about half an hour after the accident. The marked peculiarity of the case was the retention of consciousness by the sufferer. While his wounds were being dressed he gave directions about his business, made his will, and adjusted all his affairs as if nothing were the matter. The only loss of consciousness occurred while a sponge wet with cold water was applied to the surface of the brain. When the pressure was made he would cease talking, and the instant it was removed he would resume at the point where he left off. He has suffered more from the injury to the upper jaw than from the damage to the brain. At present he can use either eye separately, but there is a loss of co-ordinating power which prevents the use of both together. He is in very good physical condition and fair mental power; says that he can attend to his business and give general directions, but tires quickly.

Dr. Vivian also gave details of an interesting case in which the skull of a child had been crushed in by the kick of a horse, and in which there was no loss of

consciousness at any time except when under the influence of chloroform for the removal of the lens.

Several interesting pathological specimens were presented to the Society. The subject of annual banquets was discussed, some members favoring them, others deeming them injurious to the welfare of the Society.

Dr Mackie, of Markesan, was elected President for the ensuing year, and Dr J. T. Reeve, of Appleton, Secretary and Treasurer, Vice-Presidents, Drs Reynolds and Marston.

The Committee on Medical Legislation reported that an attempt had been made to secure the passage through the legislature of a bill for regulating the Practice of Medicine during the preceding winter, but that the effort had resulted in entire failure.

The Society adjourned to meet at Milwaukee in 1881.

Correspondence.

THE ALLEGED CURE OF CATARACT BY ELECTRICITY.

To the Editor of The Medical Record.

SIR:—We have read Dr. Neftel's communication in your issue of May 22d. The discrepancies between the doctor's statements and ours are due to his relying too much upon subjective symptoms. The diagnosis of cataract can only be made by the medical observer *looking into* the patient's eyes. To accept the statements of patients in regard to their maladies, or as to what other physicians have said or done, without subjecting them to the ordeal of logical analysis, would make an end of all progress and safety in the practice of medicine.

The facts of the case are given in our communication printed in the Record of May 15th, page 552. For the benefit of those whom it may concern, we here reiterate them.

The patient was examined at our office on July 24, 1878. We found that she had incipient cataract in both eyes, more advanced in the left than in the right. We found that her vision for distant objects, without glasses, was, in each eye, only one-tenth the normal. On correcting her error of refraction with glasses of the proper strength, her vision was as good as that of the average normal eye. She was able to read fine print with each eye, with the proper spectacles. Two days later, according to Dr. Neftel's statement, she placed herself under his care and received galvanic treatment, extending through some weeks.

On October 22d she came to our office again and was examined, and the note was made in our record: "no apparent change since last visit." This, of course, could only mean that there were still opacities in her crystalline lenses, probably of a non-progressive character. Her eyes were examined a third time on April 15, 1880, less than two years later, and lenticular opacities were found still to persist, though the acuteness of vision did not seem to have become impaired.

This proves to our minds, most conclusively, that her cataract had not been cured.

C. R. Agnew, M.D.
D. Webster, M.D.

To the Editor of The Medical Record.

SIR:—In answer to Dr. Knapp's letter in the last issue of the Medical Record, concerning the case of Mrs H. B. W., I gave the following particulars:

I saw the patient for the first time June 9, 1879. The improvement of her vision commenced about two years previously, and at the time she came to me she complained of being unable to distinguish any features, or even to see distinctly her own fingers. In the course of a few weeks, under the galvanic treatment, she became able to read even small print and see objects quite distinctly. At the end of the treatment the patient said: "Tell me candidly if I ever had cataract, or was there a mistake in the diagnosis, as I can see everything as well at present." I wrote down these words, of which the lady has a recollection. This result obtained under the galvanic treatment is certainly remarkable, especially as the same has been obtained in other patients. If this case appeared "with so much *eclat* in the *Church-man*," it is because the patient gave to the editor of that journal a glowing account of her condition after the galvanic treatment.

However I decline the details of the method in *Virchow's Archiv*, and will patiently wait until other investigators obtain the same results. Brenner's classical researches on the effects of the galvanic current upon the auditory apparatus were also met with great scepticism, and at first were flatly contradicted by authorities in otology, some even alleging to have repeated his experiments with perfectly negative results. Nevertheless, at present, Brenner's views are accepted by the profession, and I hope the same will ultimately be the case with my researches upon the optic apparatus.

Wm. B. Neftel, M.D.

New York, May 22, 1880.

THE USE OF CHLOROFORM.

To the Editor of The Medical Record.

SIR:—In the Record of May 8th I notice a suggestion of Dr. C. W. Robbins that the National Medical Association pass resolutions condemning the use of *chloroform as an anæsthetic*. While not believing that such a proposition would for a moment be entertained, I beg to raise my voice against the action of many of our profession in decrying the most valuable anæsthetic we yet have, as producing unfavorable impressions on the minds of the people, and often deterring us from the use of an invaluable agent. But a few days since, I had a comminuted fracture of the lower maxilla in a child brought to me, which previously two physicians had unsuccessfully attempted to put up without an anæsthetic, as they had discovered "heart affection that precluded its use." Their failure to obtain apposition was due entirely, I believe, to the exquisite pain produced in manipulation and the struggles of the child. With seventeen years' experience with chloroform, and in many hundred cases, I have yet to see my first accident from it, and I have pretty much ceased to regard heart or functional troubles as contraindicating its use. In cases where prolonged anæsthesia is necessary, I usually introduce *ether* at intervals, with happy effects on the circulation and respiration, returning to chloroform when I find the patient regaining sensibility. This has been a much more satisfactory method than administering mixtures of chloroform and ether, and if there is a danger of paralysis occurring from over saturation with chloroform, it can in this way be avoided. The sad expe-

rience of Sir A. Cooper, from hemorrhage after pulling that *tooth* (*vide* works on surgery), has perhaps deterred some from the indiscriminate use of the forceps, but, as a class, we still extract molars when they ache,' and so I hope we may be permitted to use chloroform till some other more safe and efficacious anæsthetic is discovered.

I remain yours very truly,

M. F. Leary, M.D.

Gaylord, Kansas.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from May 16 to May 22, 1880.

Surgeons J. B. Brown, J. H. Bill, C. H. Alden, and J. S. Billings, to represent the Med. Dept. of the Army at annual meeting of Amer. Med. Assoc., N. Y. City, June 1, 1880. S. O. 107, A. G. O., May 14, 1880.

Vollum, E. P., Major and Surgeon. When relieved to report in person to Comd'g Gen'l, Dept. of the East, for assignment to duty. S. O. 107, A. G. O., May 14, 1880.

Byrne, C. C., Major and Surgeon. Relieved from duty in Dept. of Dakota and to report in person to Comd'g Gen'l, Div. Pacific and Dept. Cal., for assignment to duty in Dept. of California. S. O. 107, C. S., A. G. O.

Happersett, J. C. G., Major and Surgeon. Relieved from duty in Dept. of the East and to report to Comd'g Gen'l, Dept. of Texas, for assignment to duty. S. O. 107, C. S., A. G. O.

De Hanne, J. V., Capt. and Asst. Surgeon. Relieved from duty in Dept. of Texas, and to report by letter to Surg. Gen'l. S. O., 107, C. S , A. G. O.

McElderry, H., Capt. and Asst. Surgeon. Upon withdrawal of troops from camp on White River, Col., to accompany them to R. R. and then repair to Ft. D. A. Russell, Wyo. T., and report for temporary duty at that post. S. O. 42, Dept. of the Platte, May 12, 1880.

Lauderdale, J. V., Capt. and Asst. Surgeon. Granted leave of absence for four months with permission to go beyond sea. S. O. 111, A. G. O., May 19, 1880.

Matthews, W., Capt. and Asst. Surgeon. Relieved from duty in Dept. of California to proceed to N. Y. City, and report arrival to Surg. Gen'l. S. O. 107, C. S., A. G. O.

Byrne, C. B., Capt. and Asst. Surgeon. To report in person May 30, 1880, to Comd'g Gen'l, Dept. of the South, for assignment to duty. S. O. 107, C. S., A. G. O.

Hall, W. R., 1st Lieut. and Asst. Surgeon. To report in person to Comd'g Gen'l, Dept. of the Missouri, for assignment to duty. S. O. 107, C. S., A. G. O.

Tesson, L. S., 1st Lieut. and Asst. Surgeon. Assigned to temporary duty at Cavalry Depot, Jefferson B'ks, Mo., relieving Surgeon E. P. Vollum. S. O. 107, C. S., A. G. O.

Randolph, Jno. F., Major and Surgeon. Died at Philadelphia, Pa., May 14, 1880.

Yeomans, Aug. A., Capt. and Asst. Surgeon. Died at Toronto, Canada, May 19, 1880.

Floating Hospital for Memphis.—A marine hospital is wanted at Memphis, and needed there as well. We have a suggestion to make on this subject, to this effect: let the hospital authorities have constructed a floating hospital, built on an iron scow, say 300 feet long and 60 feet beam, and from 8 to 10 feet depth of hold. On this structure can be built a strong, substantial, hospital building, two stories in height. The advantages of this floating hospital, which would be moored to the river bank, would be that it would cost less to construct and keep in repair than a shore hospital, and no land need be purchased on which to place a hospital. It could be removed, in case of a yellow fever epidemic, to a less exposed place, and in the event of a great public emergency, could be made available for a general hospital.—*Nautical Gazette.*

A bill has passed the House of Representatives, appropriating $30,000 to construct a hospital at Memphis.

Beer as a Remedial Agent.—Dr. Jesse Ewell, Jr., in the *Monthly Review of Medicine and Pharmacy*, describes, with much fervor, the good effects of beer in hæmaturia from renal calculi. He had been a sufferer from this himself for several years, and had tried all kinds of medicines without getting any benefit. He was subject to attacks of pain over the left kidney, occasionally amounting to genuine colic; once he had passed a small stone. There was blood in the urine when the attacks came on. At the suggestion of Prof. J. E. Lindsay, who had known beer to act favorably in other similar cases, he tried that beverage; the relief was very prompt and complete. Now, if he has any attacks of pain, a glass or two of beer will relieve it in five minutes.

Aspiration of the Knee-Joint, by Henry O. Marcy, A.M., M.D. Reprinted from Transactions of the American Medical Association, 1879. We have here presented the results of the study of seventy cases of aspiration of the knee-joint, together with the opinions of a large number of surgeons to whom Dr. Marcy directed circulars of inquiry. The conclusions are quite contrary to those usually received, for it is shown that the best results of aspiration follow in acute inflammatory and traumatic cases. In these cases the teaching should be to aspirate and reaspirate as often as the fluid accumulates, aiding by rest, compression and fixation of the joint.

Adulterations in a New Sugar.—The manufacture of a new kind of sugar by a secret process has excited much attention again to the question of the adulterations of this article. The City Board of

Health is now engaged in examining various kinds and grades of sugars for the purpose of obtaining exact knowledge on the subject, and it will doubtless furnish facts that will be decisive as to how much harmful adulteration there really is. Meanwhile, there is a good deal of talk and protest concerning the deceitfulness of the so-called "new process sugar." This sugar is made by mixing very carefully refined grape-sugar with various grades of ordinary cane-sugar. As the grape-sugar is perfectly white, it of course gives a finer appearance to the dark sugars with which it is mixed, and, as it costs only four or five cents a pound, considerable profit can be made. The grape-sugar is made out of corn, sulphuric acid being used in the process. As prepared by the "new process," it is white, dry, very finely grained, and not so sweet as cane-sugar. The only objection that can be made against it is that sulphuric acid and gypsum are liable to become mixed with it in its manufacture. Such adulteration, however, if it exists, is in too small amount to be of any harm. The same may be said of the alleged adulterations of other sugars. It is very doubtful if the Board of Health finds anything to alarm housekeepers as the result of their investigations.

THE NEW STATE BOARD OF HEALTH.—The bill creating a State Board of Health has become a law, and the members are already appointed. These are Dr. Elisha Harris, John S. Delavan, and Erastus Brooks. As representatives of City Boards already existing, the Governor has appointed Dr. Charles F. Chandler, of New York, Dr. James G. Hunt, of Utica, and Dr Edward M Moore, of Rochester. The other three members are the Attorney-General, the Superintendent of the State Survey, and the Health Officer of the Port of New York.

THE DIPPER-SHAPED EAR-TRUMPET.—Dr. Knapp writes that the dipper-shaped ear-trumpet, with the invention of which our reviewer had credited him (MEDICAL RECORD, May 15th), is an old instrument, and that its inventor is unknown.

AMERICAN ACADEMY OF MEDICINE.—There will be a meeting of the council of the American Academy of Medicine at 33 West Thirty-second Street, May 31st, at 8 P.M., when applications for fellowship will be in order.

THE LATE DR. F. J. BUMSTEAD.—In our last report of the New York Academy of Medicine, it should have been stated that an obituary notice of the late Dr. Freeman J. Bumstead was read by Dr. George A. Peters.

DEATH RETURNS up to June 1st, are expected of physicians by the census office.

LEMON MERINGUE PIE has again caused a number of cases of sickness, the symptoms being vomiting, diarrhœa, and intestinal pains. The material was cooked in a copper kettle, and citrate and acetates of copper were formed. This is the second case that has occurred in this city within a few months.

A COMMISSION TO INVESTIGATE THE STATE INSANE ASYLUMS has been appointed by the State Legislature. It consists of Senators Woodin, Baker, and Fowler.

THE SECOND ANNUAL MEETING OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION will be held at Delmonico's, New York City, on Monday, May 31st, Tuesday, June 1st, and Wednesday, June 2d, 1880, morning session from 10 to 1; afternoon session from 3 to 5.

THE RHODE ISLAND MEDICAL SOCIETY.—The annual meeting of the Rhode Island Medical Society will be held June 9, 1880.

EXTENT OF THE LUNG PLAGUE.—The report of Dr C. P. Lyman, recently made to the Connecticut Commissioner of Agriculture, shows that contagious pleuro-pneumonia now exists in one county of Connecticut, five counties of New York, fourteen counties of New Jersey, ten counties of Pennsylvania, four counties in Maryland. There are cases, also, in the District of Columbia and in Virginia.

TRACHEOTOMY HOOKS.—Dr. J. T. Crow, of Carrollton, Ill. sends us a model of a useful device for keeping patent the opening made by tracheotomy, without the use of a tube. It consists simply of a pair of hooks made of silver wire, and bent so as to grasp the two sides of the orifice. There are two cross-pieces to which elastic tapes are attached. These tapes pass around the neck, and, by tying them behind the opening into the trachea, can be made to gape as much as is desired.

RUSH MEDICAL COLLEGE.—A concours for the position of "Clinical Adjunct to the Chair of Diseases of Children" will be held in Rush Medical College, commencing May 27, 1880. The duties of the gentleman filling the position will be to deliver one clinical lecture per week throughout the year, on the diseases of children. Application should be made to the undersigned, who will assign subjects. —JAMES H. ETHERIDGE, M.D., Secretary.

DEATH OF DR. S. B. BRINKERHOFF, OF SANTA BARBARA, CALIFORNIA.—Dr. S. B. Brinkerhoff, of Santa Barbara, died suddenly, March 25th, of apoplexy. He was born in Auburn, New York, and was a graduate of the Buffalo Medical University. He afterward removed to Mansfield, Ohio, where he practised his profession, devoting himself faithfully to his calling, and winning for himself a place in the foremost ranks of his medical associates. He has a brother, General Brinkerhoff, who is still a resident of Mansfield, and who did good service for his country in the late war, while his uncle, Judge Brinkerhoff, of Ohio, is a man who is well known throughout the country for his learning, integrity, and knowledge of the law. Dr. Brinkerhoff went to Santa Barbara in 1852, and was one of the first physicians in his county.

DR. ROTHE'S TRACHEAL DILATOR.—The name of the author of the letter in a recent issue (No. 15) describing a tracheal dilator, should be *Rothe* instead of *Rolhe*.

BROMIDE OF ETHYL IN OBSTETRIC PRACTICE.—Dr. H. L. Getz, of Marshalltown, Ia., writes that he has used bromide of ethyl with very satisfactory results, in obstetric practice.

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, June 5, 1880.

THE AMERICAN MEDICAL ASSOCIATION.

The thirty-first annual meeting of the American Medical Association was held in this city, commencing June 1, 1880. By a reference to the full report to which the present enlarged number is devoted, the amount and character of the work done during the different sessions can be estimated. The number of delegates and members was larger than any other similar meeting since the war, and was fairly representative of every part of the United States. The Committee of Arrangements, through Drs. T. G. Thomas, M. A. Pallen, Walter R. Gillette, and others, was very successful in its efforts to systematize the workings of the general session and of the various sections, and proved what could be done when the real wants of the Association as to business management are properly understood. The prompt publication each day of an elaborate programme was an entirely new feature, and establishes a worthy precedent for similar committees in future.

The Reception Committee did everything that could have been expected of it in providing entertainment for the large number present at the meeting. The affair at the Academy of Medicine was managed with a taste and skill which reflected the highest credit upon the Chairman of the Committee, Dr. Pardee, as well as upon his numerous associates. The entertainment at Booth's Theatre was also a success, although a larger number of tickets were issued than the actual capacity of the house would warrant. The receptions on Thursday evening were also duly appreciated by the guests, while the grand excursion on Friday afternoon, given by Messrs. William Wood & Co., brought the purely social element of the sessions to a fitting climax.

Having said thus much of the success of one element of the meeting, we are perhaps the better prepared in all charity to criticize the really scientific value of the proceedings. Notwithstanding the large number present, the full attendance at all the general sessions, and at the meetings of the various sections, the actual work of the Association was much below the usual standard. The various addresses delivered by the chairmen of the sections fell far short of what they should have been. Instead of giving a comprehensive review of the progress made in the different departments of medicine during the past year, the orators contented themselves by treating of one or two subjects merely. The only real merit of these addresses was their comparative brevity.

The papers before the various sections were, with a few notable exceptions, much below the par of usual society material. The redeeming features of their presentation were the discussions which they invited. In several instances papers were presented which had been read and re-read before different medical societies in this city, and elsewhere. These, like everything else in the way of communications, were formally referred to the Committee of Publication, with the understanding that they are to appear in the volume of the Transactions. We admit that it is quite necessary that there should be a suitable receptacle for such material.

The establishment of a new section, that on diseases of children, was a bright spot in the doings of the Association. The good work which this new organization has done has already proved the necessity of its establishment. The change in the by-laws affecting prize essays was properly made, as also that referring to the representation of the Marine Hospital Service.

The President showed in his annual address his appreciation of the real aim of the Association, and made some very practical suggestions as to increasing its usefulness and extending its good influences. The idea of establishing a journal for the Association, although not a new one, was very forcibly put. The necessity for abolishing the volume of Transactions, and substituting therefor a weekly organ, was so clearly demonstrated that few of those who have an interest in the success of the Association will have any doubt on the subject. In fact, there is such a strong feeling in its favor that the establishment of such a periodical must be only a question of time. There is no disguising the fact that there is a great deal of dissatisfaction regarding the present method of publishing the volume, and that some change will soon be made in that direction, even if the Association is not prepared to adopt at once the suggestion of Dr. Sayre.

We believe that the Medical Record has demonstrated what an official journal of the Association could do by the prompt and full publication of the proceedings, not only of the general sessions, but of the different sections. During the meeting we were enabled to issue daily editions of the Medical Record

containing the complete reports of all the meetings held the day previous. How thoroughly this work was done can be appreciated by a reference to such reports collected from the different daily issues and published in the present number. This number gives the complete report of everything that was done. Not only is every paper which was read before the section daily considered, but there is a full and correct of all the different discussions held.

It is, perhaps, safe to say that never before in the history of medicine has the daily issue of a medical journal been made to cover before each succeeding and exhaustive scientific reports been published in any daily periodical. In this connection it is with the greatest pleasure that we take occasion to acknowledge the valuable services of the following members of our staff, who have labored day and night to make the daily edition a success. Although it may not be in good taste to praise the members of one's family, we feel warranted in saying that there is no medical journal in the country that can bring together so much talent and so much capacity for efficient work than such as are found on the staff of the RECORD. If the work in the present number does not prove this, we are ready to continue our argument. It is, perhaps, unnecessary to do more in this connection than to mention those members of the staff who have so successfully labored to prove the possibilities of medical journalism. Dr Wesley M. Carpenter reported the meetings of the general session, while the reports of the different sections were made as follows: The Section on Practical Medicine by Dr. Chas. L. Dana; the Section on Surgery by Dr. E. C. Wendt; the Section on Obstetrics by Dr. P. Brynberg Porter; the Section on Ophthalmology by Dr. E. S. Peck; the Section on State Medicine by Dr. Robert Campbell. We also tender our acknowledgments to Dr. Frank Woodbury, of Philadelphia, who, as Secretary of the Section on Diseases of Children, furnished the report of that body.

THE DAILY EDITIONS OF THE MEDICAL RECORD.

THE publication of daily issues of the MEDICAL RECORD, during the meeting of the Association, and the necessity of waiting until the last moment for the final proceedings of that body, have caused a slight delay in the publication of the present weekly issue. In view, however, of the fact that this number contains a complete report of the doings of the Association, and, in fact, gives a full abstract of the forthcoming volume of the Transactions, we have reason to believe that the end will justify the means.

THE PROGRESS OF SANITARY ORGANIZATION.

IN a statistical table published in the *Bulletin of the National Board of Health*, the present condition of sanitary organization throughout the country is very fully shown. An examination of this table shows there are at present twenty-three State and two hundred and thirty-two Local Health Boards besides the National Board. A comparison of the dates upon which these various Boards were organized reveals a very rapid yearly increase since 1870, and indicates that sanitary organizations are everywhere becoming a part of our institutions. We give the following table:

Years	State Health Boards	Local Health Boards
1874	1	2
1877	4	6
1878	4	21
1879	2	27
1880	2	89
Total since 1870, inclusive.	14	145

It will thus be seen that half of our State Boards of Health and nearly two-thirds of the Local Boards have been organized within the last three years. The number of local organizations is also rapidly increasing each year. We are not half through the year 1880, and already there are eighty-nine of these new Boards. It should be noted, however, that seventy-four of them are in the counties of Mississippi. Indeed, local organization has been most active among the Southern States during the past two years, while previously to that, this activity was chiefly in New England and the Middle States. Mississippi is now the most completely organized as regards sanitation of any State. Next to this, in the number of Health Boards, comes New York, which has nineteen, then Massachusetts, which has fifteen, then California with eleven, Illinois and Pennsylvania with ten, and Tennessee with nine.

Of the fourteen States which are still without any Health Board only three are on the Southern coast. These are Virginia, Florida, and Georgia. The last named State has an organization, but its legislature refuses, through some unaccountable stupidity, to appropriate any money for its support. Equally remarkable is the fact that Louisiana has but one Local Health Board, while its neighbor, Mississippi, has seventy-four. These coast States have about one hundred Local Boards in all, which is no more than their share, and not nearly so many as need to be established.

The statistics, however, give on the whole a very favorable showing. We can certainly expect much in the future, although health organizations are still comparatively few.

DOCTORS IN PARLIAMENT.—At the recent Parliamentary elections, Dr. Lyons was elected from Dublin, Dr. Cameron from Glasgow, and Dr. R. Farquharson from West Aberdeenshire.

American Medical Association.

THIRTY-FIRST ANNUAL MEETING,

Held in the City of New York, N. Y., June 1, 2, 3, and 4, 1880.

Tuesday, June 1—First Day.

The Association met in Association Hall, and was called to order at 11 A.M., by the President, Lewis A. Sayre, M.D., of New York, N. Y.

Prayer was offered by Rev. W. F. Morgan, D.D.

ADDRESS OF WELCOME.

Dr. T. Gaillard Thomas then welcomed the Members and Delegates of the Association to New York, and offered to them the hospitality of our homes. Sixteen years had passed since the Association last honored the city with a visit, and for a moment a pause was made to consider what those years had borne upon their wings. The struggle which at that time convulsed our land had given way to peace, and unity and concord had made glad the blessed land which we proudly called our home. Within the sixteen years many changes had taken place in the great metropolis, but none more evident than in that department upon which their affections, their best wishes, and their highest ambition were fixed. It would be the pleasure of the profession to exhibit to them, not the palaces in which New York bankers conducted the finances of the world, nor those in which her merchant princes carried on traffic which knew no limits but those of the earth, but it would be to show how those men housed and clothed the sick and needy, and to lead the Fellows until a pleasant fatigue overtook them through miles of well-appointed hospital wards, whose hygienic appointment would put to blush those of the stateliest palaces of European Kings, and convince, by incontestable evidence, how true, how loyal, and how sincere an appreciation of the science and art of medicine the representative city of America had acquired. It should, to-day, be known as the "city of noble charities," the home of healthy and vigorous science.

Dr. Thomas then spoke of the great progress which had been made, through the instrumentality of the printing press, the railroad, and the telegraph, which and which alone were what had rendered our civilization superior to that of any which had preceded the nineteenth century. Another grand result which these agencies had accomplished, was the general elevation of the professional tone throughout the world, and the medical profession represented by the American Medical Association might truthfully declare to the young men about to enter it, that the shibboleth of success was merit.

The end and object that brought the Association together was to emit and absorb thought, to give one another friendly greeting, and the hand-shake, and the kindly interchange of expression, and to advance the interests of a profession which most closely allied man to his Maker. Let it be hoped that the work done in the Association would lead those who tread in our steps to say, they met those who, like Ben-Adhem, loved their fellow-men, and strove earnestly in their cause. "In the name of the united profession of the city of New York and with outstretched hand and a glowing heart, I bid you welcome, thrice welcome to our home."

The Secretary, Dr. W. B. Atkinson, of Philadelphia, then read the list of names registered, 372 in number, and on motion by Dr. J. M. Toner, of Washington, they were confirmed.

Protests were entered with reference to registration of delegates from the United States Navy, and also against the registration of certain delegates from Allen County Medical Society, Indiana, both of which were referred to the Judicial Council.

THE PRESIDENT'S ADDRESS.

The President then delivered his address, of which the following is an abstract.

"*Gentlemen of the American Medical Association:*—Before entering upon the duties of the high office to which you have elected me, I wish to return you my sincere thanks for the distinguished honor thus conferred, and to pledge you that I will endeavor to discharge its duties to the best of my ability.

"No one can feel more keenly than I do my own incapacity properly to fill the distinguished position to which you have elected me, or more sincerely regret that some other member, more competent and more worthy of the honor, had not been elected in my place. But as your too partial friendship has thus elevated me to this position, I must appeal to your generosity to overlook all shortcomings, and shall rely upon your mutual aid to assist me in the discharge of the important duties thus imposed. Who can properly appreciate the immense value which this Association has already been to the medical profession throughout our whole country? Contemplate for a moment the difference in the *morale*, the devotion to scientific investigation, the mutual respect and good feeling between its members at the present time, and its condition when the Association was organized. At that time there were often envyings, jealousies and heart-burnings, fault-finding, and traduction; those who had achieved distinction were frequently slandered and abused by those who had not been so fortunate; the slightest imperfection of a professional brother was magnified into such undue proportions as completely to obscure any really good qualities or attainments which he might possess, and thus the whole profession was injured in the estimation of the public by the rivalries, bickerings, and jealousies that existed among its members. Now, each one seems so engaged in endeavoring to improve himself and elevate his own position in the profession, that he has no time to devote to studying his neighbor's faults, much less to accurately scrutinize and publicly herald his seeming defects. The science of medicine has been so much enlarged in all its different departments by the minute research now demanded, and by the great and rapid progress of many of its specialties, as to require that every moment of a man's time be occupied in the closest study if he would keep himself abreast with the daily improvements in our profession, and he who is thus occupied has no time to study the defects of others. By this constant effort to improve ourselves and advance our science, the tone of the whole profession is elevated, and we already see that medical men are more and more respected by the community at large.

"Let us review, briefly, what has been done by the profession in America for the improvement of medical and surgical science and the relief of suffering humanity. Some years ago, Sidney Smith, one of

England's most popular authors, said, in the *Edinburgh Review*, 'The Americans are a brave, industrious, and acute people, but they have hitherto made no approaches to the heroic, either in their morality or their character. During the thirty or forty years of their independence they have done absolutely nothing for the sciences, for the arts, for literature, or even for the statesmanlike studies of politics and political economy. . . . In the four quarters of the globe, who reads an American book? or goes to an American play? or looks upon an American picture or statue? What does the world yet owe to American physicians or surgeons? What new substances have their chemists discovered, or what old ones have they analysed? What new constellations have been discovered by the telescopes of Americans? What have they done in mathematics?' Who drinks out of American glasses or eats from American plates, or wears American coats or gowns, or sleeps in American blankets?'

"It seems to me that the Declaration of Independence, and the willingness of Americans to sacrifice their lives to obtain it, were acts of heroism equal to any recorded in history.

"The organization of government under constitutional law, which has yielded such results as were never before obtained, is an evidence of statesmanship, and of knowledge in political economy which has been seldom equalled and never surpassed.

"As to the question of American manufactures and the nations that use them, we can safely refer to the reports of our Chamber of Commerce, for a satisfactory answer. American science has no need to be ashamed of its Henry and its Morse, its Bache, Peirce, Newcomb, Draper, Dana, Marsh, Gray, Hall, and its adopted Agassiz. Nor, has the *American Journal of Science* anything to fear by comparison with its European contemporaries.

"But to the question, 'What does the world yet owe to American physicians and surgeons?' we will venture a more extended reply, although time permits us to refer only to a few of our professional achievements.

"First among the greatest boons ever conferred upon suffering humanity stands 'anæsthesia,' an American suggestion, and one that immortalizes the name of Morton. Who can ever estimate the value of this discovery? When we consider the fact that at every moment of time in some part of the civilized world hundreds, if not thousands, are receiving the benefits of this great discovery, the mind becomes overawed at the magnitude of the blessing, and even imagination fails to comprehend fully its benefits.

"Ovariotomy, another American contribution by the medical profession, has done probably as much toward saving life as any other surgical discovery in the nineteenth century. It was first practised in 1809 on Mrs. Crawford, in Danville, Kentucky, by Dr. Ephraim McDowell. At the present time it is acknowledged as a proper operation, and Dr. Peaslee said that 'in the United States and Great Britain alone ovariotomy has within the last thirty years directly contributed more than thirty thousand years of active life to woman, all of which would have been lost had ovariotomy never been performed.'

"In gynæcology the whole professional world cheerfully and gratefully acknowledges the original and valuable contributions of Sims, Thomas, Emmet, Peaslee, Atlee, Kimball, Taylor, Pallen, Dunlap, Minor, and others in this department.

"The new operation of litholapaxy, as performed and described by Dr. Bigelow, of Boston, is one of the greatest triumphs of modern surgery, and of which any American surgeon may justly feel proud.

"In conservative surgery we certainly compare most favorably with any other nation. In the mechanical treatment of diseases of the joints alone we are able to exhibit triumphs in surgery of which the American profession may well be proud.

"In the *Lancet* of February 14, 1880, Mr. Roderick Maclaren, M.D., Surgeon to the Cumberland Infirmary, in his presidential address to one of the branches of the British Medical Association, on 'The Advances in Surgery during the past Twenty Years,' says 'No account of the recent progress in surgery can justly omit the application of the principle of absolute rest to diseases of the vertebræ. . . . It is done by enclosing the body in a plaster of Paris jacket. Though only introduced into this country about two years ago, it has established itself as an *incontrovertible success*.' This is another triumph for American surgery, and is justly admitted, not only in England, but in all parts of the civilized world, and we feel that American surgery has a right to congratulate herself that she has contributed this great boon for the relief of human suffering.

"In laryngology we can certainly claim Green as a pioneer, and the facts he established are now acknowledged by the entire scientific world. The improvements made in this department of surgery by Cohen, Cutter, Bosworth, Elsberg, Lincoln, Lefferts, Robinson, and many others in this country, entitle us to favorable rank with other nations.

I believe I have enumerated enough to justify the statement that if the distinguished author before referred to were to write now, he would express sentiments very different from those contained in the above quotation. Not content, however, with what we have already achieved, let us still press onward, and, accepting the motto of this great State, constantly cry 'Excelsior.'"

The President then referred to the claims which the metric system had upon the Association and the profession, and then passed to the question of the

PUBLICATION OF TRANSACTIONS,

and presented the merits of two plans, the volume and the journal form. As an example of the journal form, reference was made to the *British Medical Journal* and the British Medical Association.

"The similarity of the two associations, in many respects, both in their organization and in their objects, is so great, that we may possibly learn something to our advantage by carefully studying the history of the older association, and profit by her experience, and, if necessary, by her example. The importance of the subject must be my excuse for bringing to your attention many details which otherwise might possibly be regarded as superfluous. . . .

"These details are of importance to the American Medical Association, for they include the germs of an organization peculiarly adapted to American ideas. It is essentially democratic and entirely representative. It is dependent for its success on the intelligence, union, and good-will of the members. It is decentralizing, inasmuch as it tends to the formation and the strengthening everywhere of the local societies, which have thus throughout the year the means of making themselves heard in metropolitan centres, and of communicating with each other. Above all, it is a most successful and influential means of increasing the membership, and enlarging the power and widening the basis of the Associa-

tion, and of making it a living organization during the intervals between the annual meetings.

"Finally, it has the great advantage of securing the largest amount of value to each and all of the members, for the smallest possible subscription. The *Journal* becomes, in fact, a co-operative enterprise in which *the profits resulting from their subscriptions go into their own pockets*, instead of those of any individual proprietor. They *own their own paper*. They are able to get the advantage of a powerful organization and of a first-class medical paper at the same annual subscription as that of a medical paper by itself, and with the surplus they find funds for the promotion of public and scientific objects, and the creation of a reserve fund for future public uses.

"There seems no reason why an experiment so essentially in accord with American instincts and traditions, and one which has succeeded so well in England, should not have at least as great, if not a greater, success in America.

"One point, however, that is specially worthy of note is, that the success of the *British Medical Journal* has been largely dependent upon the manner in which it has been conducted. The weekly *Journal* did little for the Association until it fell into the hands of an experienced editor, whose ability is so generally recognized that there is no need to dwell upon it, and to whom a large and unfettered responsibility is left, although he remains, of course, personally responsible to the executive body of the Association for the right use of the power entrusted to him, as every editor does to those who appoint him. It will be necessary to find for any organ which this Association may publish an editor of recognized position, whom the Association would accept as its worthy officer and representative in so responsible a post —a man of literary skill, scientific knowledge, and journalistic experience, or, at least, journalistic instincts and tact. He should be paid liberally; he should be treated with respect, and from him ought to be expected a serious determination to use the powers entrusted to him with courtesy and fairness, and with one sole object, the elevation of the standard of professional knowledge and interests, the maintenance of a high order of professional dignity and mutual courtesy.

"It is impossible to doubt that such a man can be found. Possibly, there may be many, and the question is one which appears to be well worthy of thorough examination by the council and members of this Association, because it seems tolerably certain that if, for the present bulky, tardy, little-read, and unproductive volume of transactions, there could be substituted an active, vigorous weekly journal, read everywhere, and with a large income such as would naturally come to it from its advertising sheet, there would be in such a change the earnest of a rapid and important growth in the numbers, influence, and usefulness of the American Medical Association."

On motion, by Dr. Wm. Brodie, of Michigan, a vote of thanks was tendered to the President for his able address, a copy requested for publication, and the recommendations which it contained were referred to a Committee of five to report upon during the present meeting.

MEMBERS BY INVITATION.

The following were elected as members by invitation: John L. Campbell, J. C. Thomas, Robert Newman, Charles Heitzman, S. A. Raborg, A. S. Church, Chas. Bliss, E. H. Janes, Y. W. Stromach, Geo. G. Wheelock, of New York, G. B. Bayles, Orange, N. J., David Magie, F. Lange, J. C. Jay, F. E. Hyde, G. Langman, Wm. H. Chamberlain, S. H. Dessau, C. A. Kinch, A. M. Jacobus, J. H. Fruightnight, C. S. Wood, P. C. Cole, John H. Nesbitt, Wm. J. Fields, Wm. H. Katzenbach, Richard T. Bang, Wm. M. McLaury, E. C. Harwood, A. W. Maynard, of New York, Geo. W. Wells, Brooklyn, J. Baxton Upham, Boston, F. Gundrum, Michigan, Robert Taylor, Henry F. Walker, Louis H. Sayre, J. Williston Wright, W. C. Gilliam, J. H. Anderson, F. R. Sturgis, A. McLane Hamilton, H. Goldthwaite, C. H. Van Ramdohr, H. F. Norris, C. S. Ward, T. H. Burchard, B. McE. Emmet, H. D. Nicol, E. D. Loring, R. A. Witthaus, A. E. Macdonald, B. F. Dawson, F. A. Castle, A. H. Buck, Wm. H. Hall, C. C. Lee, D. Phillips, C. J. Sharretts, R. W. Taylor, F. H. Bosworth, M. Clymer and C. Wagner of New York, J. S. Coleman, Augusta, D. D. Bramble, Cincinnati, J. B. A. Risk, Covington, W. W. Welch, Norfolk, Conn., J. W. Welch, West Winston, Conn., W. H. Welch and L. Pitkin of New York, H. L. Sims, San Francisco, J. Mackenzie Gordon, Australia, J. W. Rosedrigh, Hamilton, Canada, A. H. David, Montreal, Canada, M. L. Dixon, Montreal, Canada, J. L. Axtelle, Mr. Joseph Hutchinson, Liverpool, Eng., Jos. Trenholme, Montreal, Canada, T. H. Nott, Texas, W. H. Nash, New York, John H. Janeway, U. S. A., W. H. Hingston, Montreal, Canada, David Clark, Toronto, Canada, I. McFadin Campenos, Gaston, Brazil, W. R. Birdsall, New York, C. D. Alton, Hartford, Conn., J. Solon Briggs, Newark, N. J., Mrs. J. S. Briggs, Newark, N. J., E. Cogeswell, Cambridge, Mass., Talbot Jones, St. Paul, Minn., H. C. Palmer, Rome, N. Y., Mr. Jonathan Hutchinson, London, Eng., G. S. Ryerson, Toronto, Canada, G. A. Coburn, Cambridge, Mass., L. V. Cortelyou, Ponghkeepsie, T. A. McParlin, U. S. A., F. S. Dennis, New York, T. Mitchell Prudden, New York, G. E. Sussdorf, New York, W. Miner, Ware, Mass.

SECTION ON DISEASES OF CHILDREN.

Dr. Pallen, of the Committee of Arrangements, announced that provision had been made for a temporary section on Diseases of Children.

RESOLUTION OF CONDOLENCE.

Dr. S. D. Gross, of Philadelphia, moved, with appropriate remarks, that the Association tender to their President, and, through him, to the family, their warmest sympathy in their sad bereavement by the death of Dr. Charles H. H. Sayre. The motion was adopted by a rising vote.

THE REPORT OF THE FOREIGN DELEGATION ON THE PROGRESS OF MEDICAL INTERNATIONAL UNIFORMITY

was presented by Dr. E. Seguin, of New York, Secretary, which on motion by Dr. Brodie, of Detroit, was ordered to be printed and laid on the desks of the members to-morrow morning.

COMMUNICATIONS FROM ABSENTEES.

On motion, the order of business was suspended, and a letter read from Dr. B. A. Pope, of New Orleans, Chairman of the Section on Ophthalmology, etc., announcing his inability to be present. Entered upon the minutes.

It was also announced that Dr. A. H. Smith, of Philadelphia, Chairman of the section of Obstetrics, etc., is in Europe on account of ill-health, and therefore unable to be present. Entered upon the minutes.

REPORT OF COMMITTEE ON PRIZE ESSAY.

The Committee on Prize Essays, through its Chairman, Dr. ALFRED LEWIS, reported that they did not find any material to award a prize to the single essay presented. Accepted and adopted.

The reports of other committees were announced, and received and filed for reference.

On motion, the Chairman of the Committee of Arrangements was instructed to have announced in the Sections that to-morrow morning, at 9:30, the several delegations will meet in the general hall for the purpose of selecting a representative to serve on the Committee on Nominations.

The Association then adjourned to meet on Wednesday morning at 10 o'clock.

SECTION ON PRACTICE OF MEDICINE.

J. S. LAYCOCK, M.D., Chairman.

W. C. GLAZEBROOK, M.D., Secretary.

The first paper,

ON THE CLASSIFICATION OF REMEDIES,

was read by DR. WM. H. THOMSON, of New York.

Dr. Thomson referred to the many classifications of remedies already in vogue, and the objections which can be found against each.

The weakness of the classification on symptomatological grounds, for instance, is illustrated by the properties given to "hoarhound" in our dispensatory. Here it is stated to be laxative, diuretic, diaphoretic, expectorant, and a general deobstruent.

A better principle to go on is that of taking as the character of the drug, on the one hand, the effect it produces in a certain time in one large dose, and, on the other hand, the effect that is produced by a gradual administration of it. Illustrations of the one class are cantharides and opium; of the other, are mercury, iron, and arsenic. The difference between these two classes is marked. Thus, the *immediate remedies* produce symptoms at once; the *remote* do not act so, or, if they do, it may be considered that they are not acting remedially. Another difference is that the immediate remedies produce their symptoms in the healthy as much as in the sick; the remote remedies do not act so. Iron does not enrich the blood of the healthy.

Again, the first class is given to remove symptoms, the second class, to cure disease. Opium, on the one hand, and iodide of potassium on the other, illustrate this.

We may lay it down as a rule that when the first class, or symptom-remedies, do not produce symptoms, we have not given enough. On the other hand, when the second class produces symptoms, we have given too much. The first class, or symptom-medicines, again affect functions; the second class, or disease-medicines, affect organs. This difference is shown in the effects of iron and digitalis. The latter is a neurotic, and affects the function of the heart. Iron, however, affects the tissue of the organ, and may prevent its fatty degeneration.

In the treatment of acute affections, fevers, etc., the disease-medicines are almost always useless; and in the treatment of chronic diseases, the symptom-medicines are generally useless. This is because acute diseases, as a rule, are due to accidental functional derangement, while chronic diseases are due to organic changes. Here it is that the physician cures, if anywhere, and here he will gain the greatest triumphs.

The classification proposed, therefore, is as follows:

CLASS I.—SYMPTOM-MEDICINES.

Class I.—Restoratives, which are natural to the system.

Class II.—Alteratives, which are unnatural or foreign to the body. These medicines cease to act remedially when they begin to produce symptoms. It is well to give the restoratives with the alteratives, as it will put off or prevent the development of symptoms.

CLASS II.—SYMPTOM-MEDICINES.

Class I.—Neurotics, which affect nerve functions.

(*a*) Those which are both stimulants and sedatives, as opium.

(*b*) Stimulants, as arnica.

(*c*) Sedatives, as aconite.

Class II.—Glandular medicines.

Class III.—Astringents.

The advantages of this classification are that it helps the student in studying the action of remedies, and the practitioner in administering them intelligently.

The paper of Dr. Thomson being open for discussion,

DR. ROBERTS BARTHOLOW spoke of the interest which the paper had been to him. He said, however, that certain fundamental objections occurred to him, as to the classification into disease- and symptom-medicines. Opium would be an illustration. Thus, opium, in small doses, had an entirely different effect from it when given in large doses, and any classification based upon dosage could not be established. Again, there were drugs which, though symptom-medicines, did sometimes cure disease; thus, digitalis will cure dilatation of the heart. Again, certain symptom-medicines will produce structural changes; thus, opium, if given continually, will produce anæmia.

Dr. Bartholow was of opinion that no correct classification of remedies could be made at present, as our knowledge is insufficient.

DR. THOMSON said in reply that he thought Dr. Bartholow misunderstood his position. Thus, in regard to the classification by dosage, his point was that one dose of symptom-medicines, whether great or small, must act at once. The symptoms may vary, but the time is immediate.

In regard to symptom-medicines not curing disease, he had never seen digitalis do what Dr. Bartholow asserted it could, *i. e.*, cure dilatation of the heart.

In regard to the use of the word alterative, Dr. T. had used it with reluctance, and did not use it at all with his students; but it was a convenient and familiar term.

DR. PUTNAM-JACOBI called attention to the fact that the ultimate action of all medicines was necessarily molecular. That Nothnagel endorsed the conclusions based on our experiments, that alkaloids acted by diminishing the oxidations in nerve tissue—that is, affected the first step in the process of elementary respiration, whereby the atom of carbon was liberated from its albuminous molecule and given up to the oxygen of the blood. Thus, we may suppose that opium, for instance, diminishes the activity of the intra-molecular oscillation of atoms. While mercury, on the contrary, accelerates this intra-molecular os-

cillation, and favors the breaking up of the albuminous molecule saturated with a specific poison.

Again, although small doses of morphine produced only perceptible effects on the molecules of the nerve-tissues, poisonous doses were seen to extend these very same effects to *all* tissues. Thus, in opium coma, the elementary respiration *is everywhere arrested*, oxidation of all tissues deficient, hence the secondary paralysis of capillaries, which is a prominent feature of opium-poisoning.

In such a conception of molecular action we are able to have a comprehensive view of the entire action of the drug; also a proof that an influence called "functional," when confined to nerve-centres, becomes structural when with increasing doses it extends beyond them.

Dr. Roberts Bartholow objected further to Dr. Thomson's paper. He instanced several examples of symptom-remedies which did cure disease.

Dr. Thomson said that the anæmia produced, as stated by Dr. Bartholow, was not due to the direct effect of the drug, but to the anorexia which the drug produced. So of other remedies of this class—they might produce structural changes, but not as a direct result of their use.

With reference to Dr. Jacobi's remarks that, even in functional, remedies there are molecular and therefore really structural changes, he admitted this, but said that we are so very far away from ever knowing what these changes are, that they need not be taken into account. He did not believe in the value of the German theories in regard to the precipitation of albumen by various drugs.

At the close of the discussion the paper was referred to the Committee on Publication, and ordered to be printed.

The next paper was entitled

A CASE OF OCCLUSION OF ONE OR MORE OF THE CEREBRAL SINUSES,

by Dr. M. O'Hara, of Philadelphia. Dr. O'Hara related a case of a girl whom he was called to see some months before. The patient suffered from intense headache, œdema of the face, slight strabismus, and ecchymosis of the conjunctiva. There was slight anæsthesia of the left side and hyperæsthesia of the right; slight dulness of hearing on the left side. There was evidence of some paralysis on the left side of the body. Her mind was clear. She was treated at first with mercury and iodide of potash; purgatives also were given with good effect. She gradually improved, and in three weeks was quite well. The chief points in her symptoms were the œdema, neuralgic pains, conjunctival ecchymosis, ocular protrusion, and paralysis of the right sixth nerve. It seemed probable that there was a thrombosis of the right cavernous sinus which extended through the circular sinus to the left cavernous sinus.

The cause of this thrombosis was not very evident. It was not brought on by any trauma, erysipelas, or inflammation of the middle ear. The writer went through all the possible causes of the symptoms in the present case and rejected all but phlebitis. He then referred to the lack of information upon cerebral thrombosis in American text-books, and to the varying opinions as to where the lesion lies when there is œdema and ocular protrusion due to venous stasis. It had been asserted that many cases of ocular protrusion, supposed to be due to aneurism, are really due to venous obstruction. The statement was also quoted from Dr. Harland that orbital aneurism is very rare, if it ever occurs.

The paper being open for discussion,

Dr. Bennett, of Cleveland, asked the reader the explanation of the recovery, if there was a thrombosis.

Dr. O'Hara replied that he was inclined to think that the cause of the trouble was a specific one. The patient recovered rapidly under large doses of biniodide of mercury.

SECTION ON SURGERY AND ANATOMY.

W. T. Briggs, M.D., Nashville, Tenn., Chairman.
C. Powell Adams, M.D., Hastings, Minn., Secretary.

In the absence of the permanent secretary, Dr. Cummings, of Arkansas, was elected temporary secretary. Dr. Adams, however, came later, and took his seat as secretary of the section.

SPINAL EXTENSION—ITS MODES, MEANS, AND MOTIVES.

Dr. Benj. Lee, of Philadelphia, read a paper on spinal extension, illustrated by numerous diagrams and accompanied by the demonstration of the author's apparatus. Vertical, inclined, and horizontal extension were successively discussed. Dr. Lee showed his apparatus for self-suspension, which he considered an important modification of existing appliances. Its mode of employment placed the extending force in the patient's own hands, robbed the operation of all its terrors, converting it in fact into a pleasant amusement.

The author then exhibited an improved "surgical table," manufactured by W. H. Johnstone, of Philadelphia, and described the method of its employment. It was thought to be the most perfect piece of mechanism ever constructed for the purpose of producing horizontal extension of the spine. The entire absence of all jerk or jar in its action enabled us to make extension to a very considerable degree, almost without consciousness on the part of the patient.

The indirect or mediate object of spinal extension was always the overcoming or redressing of a curvature, and the concomitant deformity of the trunk for a brief space of time, during which a fixed dressing could be applied, or a cast taken from which a removable jacket could be made. With the former of these plans, namely, the application of the plaster-of-Paris jacket, the name of the distinguished president of the society was associated the world over.

PHIMOSIS AS A CAUSE OF NERVOUS SYMPTOMS, WITH RESULTS OF OPERATIONS.

Dr. Geo. M. Beard, of New York, read a paper on phimosis as a cause of nervous symptoms, and gave the results of operative treatment in several of his cases. He stated that Lallemand had first brought this subject to professional notice, and to this author also belonged the credit of having organized this department of surgery and neurology. Dr. Beard then reviewed the literature of the subject, and finally formulated his conclusions as follows:

First.—There were a large number of neurasthenic symptoms in addition to those previously referred to by writers. These might be caused or aggravated by phimosis, or the presence of this condition might interfere with their cure. Adherent and redundant prepuce might act in the same way. Among these symptoms Dr. Beard mentioned:

1, Morbid fears of various kinds, as fear of society, of places (topophobia), of being alone (monophobia), etc.; 2, dilated pupils and congestion of the con-

practice; 4, sleeplessness and persistent thinking; 4, sweating of the hands; 5, palpitation and cardiac oppression; 6, numbness of muscles, the so-called fibrillar contractions; 7, lumbar and dorsal pain and tenderness; 8, general or local tremor; 9, great hyperesthesia of the urethra; 10, irritable prostate; 11, relaxed sexual power; 12, frequent and difficult micturition.

Second.—There might be a great degree of phimosis and the prepuce might be both redundant and adherent from birth without exciting any nervous symptoms that could be traced to these conditions. In at least one-half of the healthy adults there was either phimosis or redundancy of the prepuce with or without adherence.

Third.—When the nervous symptoms had become depleted of its force, then this local irritation from phimosis or allied conditions might become the excitant or aggravant of nervous symptoms.

Fourth.—The great points in the operation of circumcision in these cases were thoroughness and care in details.

Fifth.—Immediate or startling results were not to be expected.

Sixth.—Long confinement after operations of this kind was not always necessary.

Seventh.—Keeping back the prepuce and stretching it was sufficient in some cases.

Eighth.—It was not well to depend exclusively upon the operation for the cure of the symptoms that were connected with phimosis. Accessory and supplementary treatment might be needed. This was the same as that employed for general neurasthenia, as described in the author's work on that subject.

Illustrative cases were then cited. Out of eighty cases of general and sexual neurasthenia, thirty-one cases, or over one-third, had either phimosis or adherent and redundant prepuce.

In studying this subject in a Russian bath establishment, it was found that at least one-half of the patrons had either phimosis or redundant prepuce.

Dr. Hart, of Plainfield, related a similar case, which he had formerly published. He also instanced other cases, in which an undoubted connection existed between redundant prepuce and various nervous symptoms. Circumcision was thought to be not always necessary. Simple splitting of the prepuce might often suffice.

Dr. Maxwell, of Delaware, remarked on a case which had occurred in his practice. A boy, five years old, who made slow recoveries after attacks of diphtheria and pneumonia. Upon examination orificial contraction was ascertained to be present. The urine also contained saccharine matter. Circumcision was performed, and resulted in an entire removal of nervous symptoms. Anti-diabetic treatment had formerly lessened the amount of sugar in the urine, but after the operation diabetic urine was never passed.

Dr. Weldon, of Ithaca, said there was a physiological side to this subject, and thought the eight centres might be increased indefinitely.

Dr. Lee, of Philadelphia, referred to the probable connection between the disorders of ovulation and the establishment of lateral curvature of the spine in young females.

He also remembered cases of hip disease where redundant prepuce had existed, but he had had no idea of any interrelation between the two.

Dr. Herrick, of Cleveland, mentioned a case and alluded to disturbances resembling those described by Dr. Bond. Let he said this case was not amenable to treatment by circumcision.

Dr. Cheney, of Berlin, also related a case upon which he had operated.

Dr. Hodgen, of Denver, said he had advised the operation of circumcision in cases of mental alienation. This was done merely to make an impression on the patient and had been practised where preputial relief could not exist.

SECTION ON THE INFRA-ORBITAL AND INFERIOR DENTAL NERVE FOR NEURALGIA.

Dr. John T. Hodgen, of St. Louis, read a paper on section of the infra-orbital and inferior dental nerve, for neuralgia. He said that by using a hook, or an elevator after section of the nerve, this might be drawn out of its canal and then clipped off. This was done to preclude the possibility of the reestablishment of union, which would lead to the return of neuralgia.

The details of his methods of operating were then given. The inferior dental nerve was exposed by suitable incision, and then looped up and cut. He had operated on twelve patients, operating in all twenty-four times. Sometimes, when the infra-orbital had been cut, the neuralgia had attacked the inferior maxillary, and vice versa.

In 1 cases 1 operation had been done.
In 3 cases 2 operations had been done.
In 4 cases 3 operations had been done.
In 9 cases 1 nerve was cut.
In 3 cases both nerves were cut.
In 3 cases the infra-orbital only.
In 6 cases the inferior dental only.

In every instance the pain ceased immediately after operation. But in some it returned after a longer or shorter interval. All patients were immensely benefited, some were entirely cured. In others final success had not yet occurred.

Dr. J. R. Wood, of New York, thought the first operation was not a difficult one with the right appliances and plenty of light. His own method of operation differed somewhat from that adopted by Dr. Hodgen. A disk of bone was removed from the anterior wall of the antrum, another disk was then removed by a smaller trephine, the spheno-maxillary fossa and foramen rotundum were reached, and by curved scissors the nerve was cut where it made its exit from the foramen. Meckel's ganglion, he added, should be removed if success was expected to be permanent. But in the majority of cases, although all the nerve was removed, the terrible malady would return. Relief often followed immediately after operation, but this did not permanently continue. Illustrative cases were also instanced by Dr. Wood. Concerning operations on the jaw, he had repeatedly trephined, and the patients had generally been quite cured. Still the pains might come back. On the other hand, the pains were so excruciating that any operation was warranted.

Dr. Pancoast, of Philadelphia, concurred in the views expressed by his predecessors. He said that the portion of nerve removed might include its only diseased portion, and thus lead to a cure. Dr. Pancoast's father was said to have removed a part of the nerve, even beyond the foramen ovale, in four successful cases.

Dr. S. W. Gross, of Philadelphia, referred to his paper on the subject, published some years ago in the *Amer. Jour. of the Med. Sciences*, and then gave his method of operating in such cases.

Dr. J. R. Wood, of New York, reported on the re-

sults of a pathological examination of an affected nerve, made by Dr. Welch, of New York.

Dr. Hart, of Philadelphia, related a case where Meckel's ganglion had not been removed and cure had taken place.

Dr. Campbell, of Georgia, thought that, in cases reported as such, Meckel's ganglion had not always been removed. He believed in the central origin of this affection. Hence, removal of peripheral nerve-portions could not be expected to result in a cure.

NEWLY DEVISED ORTHOPEDIC APPLIANCES, INCLUDING THE SECTOR SPLINT.

Dr Chas. F. Stillman, of Plainfield, N. J., read a paper on some newly devised orthopedic appliances, including the sector splint.

He first spoke of some appliances for the more common abnormalities of the foot, and showed a brace, devised by himself, explaining the method and rationale of its application. Weak ankles were next considered, and a brace shown which fulfilled all the therapeutic requirements. The points for which he claimed originality and excellence were: 1, placing the hinge-joint at the back of the heel; 2, making the brace and shoe distinct. Then followed the subject of inverted feet, which in its more advanced stages constituted the various types of talipes varus. Talipes equinus was also discussed, and a bracket, devised by Dr. Stillman, shown. He also spoke of talipes valgus, and showed his brace for this affection.

The sector splint was fully explained, and its various advantages set forth. This part of the paper was, however, not read to the end, owing to the lateness of the hour.

Dr. Hingston, of Montreal, took exception to the pathology of club-foot as explained by Dr. Stillman. In addition, he said an early tenotomy was always the best remedy. He would, however, not operate if the foot could be easily brought into proper position; and it was in such cases that mechanical appliances should be employed.

CERTAIN METHODS IN SURGERY, AND CONSIDERATIONS OF THE ETIOLOGY AND PATHOLOGY OF WHITE SWELLING OR SYNOVITIS OF JOINTS IN REGARD TO THE PRACTICE OF EXTENSION IN TREATMENT.

Dr. Pancoast, of Philadelphia, read this as the title of his paper, and then spoke on various subjects more or less associated therewith. He first showed samples of black silk for sutures, which he preferred to the ordinary white silk, because the latter commonly contained impurities from lead salts. He then described his method of operating for varicocele, in which he employed a zinc button, and exerted great force in the tying of the ligatures. Here also he used strong black silk. Forty cases of amputation at the metacarpo-phalangeal articulation were then instanced. In these he had, contrary to the method commonly in vogue, employed a volar flap. The success had invariably proved gratifying.

A case of removal of a large steel body from the antrum was next related. The patient recovered. An instrument for cutting strictures was described and the mode of its employment shown. Deep incision was condemned as leading to a large, firm, intractable cicatrix. Twenty-one cases were successfully operated on with this new instrument.

A pathological specimen was exhibited, showing the result of exsection at the shoulder-joint. A new capsule had formed six months after the operation, at which time the patient had died of alcoholism. The articular lesion was a rheumatic arthritis.

Dr. Pancoast also presented a specimen illustrating successful exsection at the hip-joint. In this case, likewise, a new capsule of very perfect nature had been formed after six months.

Another specimen was then demonstrated. It consisted of the femoral condyles which had been removed in a case of telescopic fracture of both inferior extremities. The cartilage had been exposed intra vitam, but it never became inflamed, macerating away gradually.

He next presented a specimen of ostitis of the femur, which showed breaking-down of the bone near the femoral condyles, without involvement of the adjoining articular cartilages.

Various diagrams illustrative of knee-joint lesions were exhibited. Dr. Pancoast emphasized the fact that ligaments would not stretch normally. But when altered by inflammation they readily gave way. Injected specimens of joints were passed around for inspection. These showed the absence of vascular filling in the cartilaginous portions of the articulations. Cartilage, he said, was nourished by the surrounding and adjoining tissues, not by a vascular supply.

An experiment was then performed which illustrated effusion taking place into the hip-joint, and its consequent action.

The great principle in the treatment of articular affections was rest, and not extension. The latter often had bad effects from irritation of the synovial membranes, which were the chief seat of disease.

In the stage of spastic muscular contraction of such cases, tenotomy and myotomy were recommended as tending to relieve the spasm. In the advanced stages exsection alone could be relied upon. Extension would only aggravate the disease in those stages, because the synovial structures would be additionally irritated by the extending force. The hot iron was recommended as the most efficient revulsive in articular affections. Rest, he said, must be enforced, and suitable antiphlogistic treatment combined with this, was far superior to any apparatus for permanent extension.

Dr. Martin, of Massachusetts, observed that Dr. Pancoast's points were well taken. He also stated that a much thickened synovial membrane frequently simulated articular effusion. His mode of enforcing prolonged rest was then described. This, he also, like Dr. Pancoast, considered the most essential factor in the treatment of articular lesions. Several illustrative cases were related.

Dr. Pancoast gave a description of a French method of employing cotton wadding for articular bandaging, which, he said, adapted itself admirably to the natural configuration of the limb.

Dr. Martin finally said that, in his 240 cases of exploratory articular punctures, he had purposely abstained from using antiseptic precautions, and had never found the slightest symptom of inflammatory reaction.

The Society then resolved, on motion of Dr. Pancoast, to resume the discussion of his paper on the following day.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

Albert H. Smith, M.D., Philadelphia, Pa., Chairman.

Robert Battey, M.D., Rome, Ga., Secretary.

In the absence of Dr. Smith, in Europe, on account of ill-health, Dr. G. M. B. Maughs, of St. Louis, was called to the chair.

Dr. J. Marion Sims of New York, read a paper on

BATTEY'S OPERATION IS EPILEPTOID AFFECTIONS.

Battey's operation, he said, like all innovations, had had to fight its way, but he had no doubt, from the favor it had already received, both in this country and in Europe, that the time would soon arrive when it would be recognized as a legitimate operation. He had performed it eleven times, the first four cases occurring before he adopted the antiseptic method, and the last four operations being performed with full antiseptic precautions. As bacteria had rendered the operation of ovariotomy one of the safest in the whole domain of surgery, he saw no reason why it should not do the same for Battey's operation. On this occasion he desired to report the last four cases upon which he had operated. Three of these were cases of epileptoid convulsions associated with the menstrual molimen, and the other was one of hystero-epilepsy of a peculiar and unique character.

The first patient was thirty years of age. Her menses appeared for the first time at 18, and were very painful during the whole of the flow. She would often lie on the floor and writhe in agony, without any relief from remedies ordinarily administered in similar attacks.

The dysmenorrhœa was accompanied with cramps and severe pain in the back, through the pelvis, down the thighs, and in the back of the head. She also had nausea and vomiting every day and hysterical spasms occasionally during the flow.

She was married at 22, and all her symptoms seemed to have been aggravated by marriage.

About six weeks after her marriage she had epileptoid attacks during the menstrual period. At first they were slight, but afterward of great length and severity.

When Dr. Sims first saw her, in April, 1877, she had vaginismus, vaginitis, retroversion of the uterus, hypertrophy of the posterior wall, flexure and stenosis of the cervical canal, and both ovaries were enlarged and exceedingly tender on pressure.

At that time he was satisfied that there was no remedy for her but in Battey's operation; but, as he was on the eve of departure for Europe, he did not see her again for two years and a half.

On January 12, 1880, Battey's operation was performed at St. Elizabeth's Hospital, New York. Both ovaries were removed, and she recovered from the effects of the operation without any untoward accident. She has never had a single convulsion since the operation, and her health has improved in every way. She is now a happy wife and a useful member of society. Before the operation the sexual appetite was very strong, but not morbid.

A good deal of nonsense, the writer said, had been written by men high in the profession on the subject of Battey's operation unsexing the woman.

The second case was also one of hystero-epilepsy. The patient was thirty years old and unmarried. When Dr. Sims first saw her, in October, 1879, she was weak and miserable, and never for one moment free from pain, which radiated from the pelvic organs. She also suffered from severe dysmenorrhœa and the uterus was retroverted. Both ovaries were exquisitely sensitive on pressure, and the pain thus occasioned radiated through the back and hips. Battey's operation was performed December 12, 1879, and she recovered rapidly from it, suffering only from abscess in the track of the sutures closing the abdominal incisions. After the operation she was for the first time in ten years free from pain, and, although still weak, her health bids fair soon to be better than it ever had been.

In the third case, likewise one of hystero-epilepsy, the patient died. Dr. Sims believes from the effects of the anæsthetic employed, the bromide of ethyl, two minutes and a half after the operation. The case had already been made the basis of a paper on this anæsthetic, which he read before the N. Y. Academy of Medicine in March last, and the gentlemen then present had all agreed with him as to the cause of death.

The fourth case was a very peculiar one. The patient was twenty years old and unmarried. During her childhood she was subject to convulsions with every attack of disease from which she suffered, and also when over-excited in any manner. Menstruation appeared at the age of ten and a half years, and with it she always had convulsions until she was fourteen. Under treatment the convulsions then ceased for a short time, except during the menstrual period, when they invariably recurred. This comparative freedom from convulsions continued during a residence of six months in Europe, but on her return to America they came on again with great frequency and severity. She sometimes had a dozen at night and half a dozen during the day. She described the aura as starting from the uterus and radiating toward each ovary, where it often stopped. But if the sensation went beyond to the epigastrium, it always resulted in this terrific convulsive explosion. Menstruation was irregular, scanty, and painful. Pressure over the uterus and ovaries by conjoined manipulation caused the sensation of the aura, but did not actually produce convulsions. One peculiar point about the case was that consciousness was never lost during the seizures. After trying every method of treatment without relief, Battey's operation was performed on the 11th of January, 1880. She soon recovered from the effects of the operation, but the convulsions were not controlled by it.

The latest reports showed that she was improving, however, at the institution of Dr. Mann, at Fort Washington, and hopes were still entertained of her recovery.

All the operations were done antiseptically and by abdominal incision. After some general remarks on the operation, Dr. Sims described his own method of procedure as follows: "I use the simple abdominal incision, as we usually make it for ordinary ovariotomy, midway between the umbilicus and symphysis pubis. The patient lies flatly on the back, with her knees a little flexed, and an incision three inches or three and a half inches long is made between the recti muscles down nearly to the pubic bones. As soon as this is done, and before the peritoneal cavity is opened, the Sims uterine elevator is introduced into the cavity of the uterus (whether in a normal position or otherwise), and it is raised by the instrument locked at right angles, and the fundus is held firmly just above the symphysis pubis by an assistant, who holds the handle of the locked instrument immovably until the operation is completed.

The peritoneum is now opened, and the fundus uteri is found in contact with the lower end of the abdominal incision. The fundus is grasped, the finger passed along the Fallopian tube on one side until the ovary is reached, at the same time that the fundus of the uterus is turned by the elevator to the opposite side from the ovary that we are reaching.

With the fore and middle fingers the ovary is brought to the surface, the pedicle ligated, and the

ovary removed. Then, by rotating the handle of the elevator to the opposite side, the other ovary is elevated correspondingly nearer the external incision, when the fore and middle fingers are passed along the Fallopian tube as a guide until the ovary is found and brought to the surface and treated in the same manner as the first. After we are satisfied that the peritoneal cavity is dry and cleared of all coagula and all oozing blood, we proceed to close the external incision by sutures." Great stress was laid on the importance of perfect antiseptic precautions.

Of the four cases thus detailed, the first two recovered easily from the effects of the operation, and were perfectly cured of epileptoid affections for which the operation was performed. The third died from the effects of the anæsthetic, and the fourth recovered rapidly from the effects of the operation, but the convulsive attacks still continued. In every instance the ovaries were diseased, having undergone cystic degeneration; although the microscopic examination had not yet been completed.

Dr. M. A. Pallen, of New York, then read a paper entitled:

ON THE TRUE IMPORT OF OOPHORECTOMY, OR SPAYING FOR REFLEX DISEASE, MORE PARTICULARLY IN EPILEPSY, HYSTERO-EPILEPSY, OR CATALEPSY.

He commenced by giving the histories of three cases in which he had operated himself. The first one was that of a patient who came to him in St. Louis in May, 1872. She was thirty-two years of age, and had been afflicted with epileptiform dysmenorrhœa for twelve years. Physical exploration revealed the presence in the Douglas pouch of a somewhat elastic and not very tender tumor, about the size of a large walnut, which could without difficulty be returned into the abdominal cavity when the patient was in the knee-chest position, and which he believed to be the detached hypertrophied (cystic?) left ovary. The examination also showed that the right ovary was over-sensitive, and that strong pressure by conjoined manipulation evoked symptoms not unlike epileptic spasm. The menstrual sufferings were excruciating, and she declared that she preferred death to the torture they inflicted. In order to give a trial to other means of relief, however, and for various other reasons, it was not until the following December that Dr. Pallen felt justified in performing the operation of oophorectomy. The incision was made through the abdominal walls, and both ovaries removed. On the ninth day after the operation, which was immediately followed by no unfavorable symptoms whatever, the patient died of general peritonitis.

Dr. Pallen thought at the time that he was the pioneer in this operation; but five days after its performance by him he was surprised by having handed him Dr. Robert Battey's pamphlet on "Normal Ovariotomy," and he found that Battey had made his first operation about the same time that he himself proposed its performance to the patient just mentioned. Battey, however, was not the first to make oöphorectomy, nor himself the first to propose it, since Koeberle, of Strasburg, suggested it as early as 1863, and actually performed it successfully in 1869.

Dr. Pallen's second operation took place in 1878, and was undertaken for the relief of hystero-epilepsy, induced primarily by masturbation when the patient was a girl at boarding-school. In this instance clitorectomy had previously been performed by a French surgeon, but the removal of the clitoris did not in the least diminish the desire for self-abuse. She had most marked hystero-epileptic attacks pending her menstrual flow, and she felt that her mental condition would rapidly degenerate into idiocy if she could not be relieved. On the 18th of May, 1878, with the assistance of the late Prof. John T. Darby and the father of the patient (a physician living in the West), he performed laparotomy and removed both ovaries. In this instance Listerism was thoroughly adopted, no drainage-tract made, and the ligatures of carbolized silk cut short and closed up in the abdominal cavity. It is now two years since the oöphorectomy was made, and she has never had a desire for self-pollution, nor has she had any epileptiform or hystero-epileptic attack; neither has she experienced any menstrual molimen.

Dr. Pallen's third oöphorectomy was performed February 24, 1880. It is, he said, in a measure, already historical, in consequence of malignant misrepresentations on the part of irresponsible employees, who were discharged from the Blackwell's Island Female Lunatic Asylum (of which the patient was an inmate) for drunkenness and lying, and who gave vent to their revenge by retailing their unmitigated falsehoods to some of the sensational public newspapers. The general history of this case, as presented in detail, was copied from the records of the institution by Dr. Wm. M. Leszynsky, and shows that the patient, Mary Ann Mullin, had for three months previous to the operation persistent catalepsy, this being the most marked case of true "waxy flexibility" of the muscles that the writer had ever met with. She had not menstruated for four months, and from the best information that could be obtained it seemed almost positive that she had been amennorrhœic previous to her entrance into the asylum, although this fact could not be made out with absolute certainty. There was no doubt, however, that she had been cataleptic, with grave failing of the strength, for three months, and the prognosis was unfavorable. Examination *per vaginam*, with conjoined manipulation, evidently increased the reflex spasm of the eyelids, and suffused the face with epileptoid flushing whenever the ovaries were palpated.

Dr. Pallen believed that this was a case of pure reflex catalepsy, in consequence of the suspended ovarian cell-action necessary to menstruation, and felt that a neglect to perform oöphorectomy here would have been a palpable neglect of his duty as consulting gynæcologist to an institution of such importance as the Female Lunatic Asylum on Blackwell's Island. To have restored this poor girl to health, he thought, would have been a blessing to herself and a boon to science; and if the fatal septic peritonitis which followed the operation could have been averted, he was firmly of the opinion that she would have been cured of her catalepsy and insanity. The great mistake, he said, was to attempt to operate in a building already filled with septic germs; but we see often a failure what we hoped might not exist prior to an operation. He classed Mary Ann Mullin's case with the curable insanities of women, and trusted to show that this operation came under the head of justifiable spaying for the relief of reflex conditions. The clinical history of the case, he continued, was written by Dr. Leszynsky, and as a record of patient, self-sacrificing duty it stands almost alone, when we bear in mind that he wrote down the condition of the patient every fifteen minutes, as he observed it for three days and twenty-two hours of uninterrupted watching. Yet Dr. Leszynsky was but an unpaid assistant in a pauper

to one's self, working only for the sake of science, humanity and knowledge."

The operation of oöphorectomy or sparing (a castration of the female, as it has been called by Hegar, the writer went on to say, has now been done sufficiently often for us to arrive at something definite as to its true import. He deemed oöphorectomy as a removal of the ovaries, not so much for disease of these organs as for disease produced by change in their action or function. Herein he stated, he differed from Prof. A. Hegar, of Freiburg, who had blended true ovariotomy with oöphorectomy. After alluding to the statistics of the subject, he mentioned that sparing the human female was practised by edict among the Lydians, as Herodotus and Andranystus ordered women to be thus mutilated in order that they might take the place of eunuchs in the harem.

In 1841 Platz proposed the operation in hopes of "repressing the lasciviousness" of certain women; but he met with violent opposition on the part of Riolan and Diemerbroech. From 1871 to 1873, when Koeberle deliberately proposed extirpation of both ovaries simultaneously with ablation of the supra-vaginal portion of the uterus, there are several instances on record of recovery from oöphorectomy accidentally performed. Barnham, of Lowell (in 1854), seemed to have been the first in modern times to have successfully made uterine ablation with oöphorectomy; although he mistook his case for one of ovarian cyst. In 1867 Koeberle put in practice oöphorectomy with uterine ablation, and in 1869 he performed unilateral normal ovariotomy upon a patient who was the subject of hysterical manifestations and affected with vaginismus. She also had retroversion and retroflexion of the uterus; which produced obstinate constipation from intestinal obstruction, with frequent and violent attacks of ileus.

Oöphorectomy was essentially Battey's operation, and it had for its object the production of the menopause, in order to overcome disease developed through the agency of ovarian action. Its scope was quite wide, as had been demonstrated by numerous successful issues; and upon the true pathology of epilepsy, hystero-epilepsy and catalepsy, in so far as they were connected with ovarian cell-genesis, would be the future determination of its true import in the cure of these diseases.

The subject of the papers now being open for discussion, the Chair called on Dr. Robert Battey, of Georgia, who stated that he had nothing more to add to what he had given to the profession in his reported cases and in his argument before the American Gynæcological Association, at the meeting in Boston three years ago. The operation was practically out of his hands now, as in his secluded position he had few opportunities for performing it, and he looked to the distinguished men in the great medical centres to take it up and thoroughly test the questions involved in it.

Dr. Trenholme, of Montreal, stated that when in 1876 he performed normal ovariotomy, he supposed that he was the first operator to undertake it; but when he found out, six weeks afterward, that Dr. Battey was the pioneer in this field, he cheerfully yielded the priority to him; and he was delighted now to see that eminent surgeon reaping the honors which he so justly deserved.

Dr. Marcy, of Massachusetts, thought that Dr. Sims had been inclined to exaggerate the difficulty of removing the ovaries by the vaginal incision.

Both Dr. Battey and himself had practised this method very successfully, and he considered it less dangerous on account of the avoidance of the risk of peritonitis. In one case he had removed the Fallopian tube and a portion of the broad ligament without bad result. In every instance he had followed very carefully the directions of Lister, of whom he was a pupil more than ten years ago.

Dr. W. M. Pyeatt, of Pennsylvania, related a case of his, in which Prof. Goodell, of Philadelphia, had performed Battey's operation, *per vaginam* during the past month. She had been the subject of periodical insanity, and at the time of the operation was violently maniacal. The next morning after it she was perfectly rational, and had remained so ever since. He did not like to report the case cured, however, until it was known how she passed her menstrual period, which would occur about the 10th of June.

In answer to a question as to whether there was not great difficulty in removing the ovaries by the vagina when the adhesions were marked, Dr. Battey stated that he had met most serious obstacles in adhesions of the ovaries and other pelvic organs, and in one or two instances to such an extent that the object of the operation was defeated on this account. As was well known, the object of the operation was to induce the menopause; but he had been astonished to find how small a fragment of the stroma of the ovary would keep up menstruation indefinitely. After relating two or three instances of this, he said that he had become very strongly impressed with the idea that in some, at least, of the instances of continued menstruation after removal of both ovaries reported by Atlee, Peaslee, and many other authorities, some small portion of one of the ovaries had been unintentionally allowed to remain in the body. Dr. Battey then referred to some of his cases in which the ovaries were so firmly imbedded in adherent lymph that the organs actually became disintegrated in the process of removal. In more than one instance he had therefore failed to perfectly enucleate the ovaries, and thus make a complete extirpation. In every one of his cases, however, he had been able to state distinctly, upon leaving the operating-table, whether menstruation would certainly cease, or whether some fragment of the ovary had to be left, and the future result of the case would, therefore, be somewhat uncertain. He was disposed to attach considerable value to the vaginal operation; although Sims, since the application of Listerism in this department, now always performed the abdominal.

In some respects, indeed, it was even better in the vaginal operation, since the vagina acted as a funnel, and thus concentrated the antiseptic spray. It was true that it somewhat obscured the seat of operation; but in this procedure it was much better to depend upon the touch than the sight. To express his views on this question succinctly, he would say that the vaginal operation was always preferable in dexterous hands when we can be sure of the absence of adhesions, and the abdominal in conditions the reverse of this. In his fifteen cases there had been two deaths, and in both of them the vaginal operation had been performed; but he was able to state positively that in neither of them had the method adopted anything to do with the fatal result.

Dr. Parsons, of Detroit, inquired of Dr. Battey, whether in case he found firm adhesions he would not advise to abandon the attempt to remove the ovaries by the vagina and perform the abdominal operation, to which Dr. Battey replied that he was

willing to follow the example of Sims in this respect. With his present lights, he would not undertake the operation by the vagina when there were many adhesions.

Dr. Sims said he should like to be convinced very much that the operation could always be performed as successfully by the vagina as by the abdomen. If there were no adhesions, the vaginal operation required but little skill, while the abdominal one, whether there were adhesions or not, was always difficult. He had made one failure in attempting to remove the ovaries by the vagina, and in this instance the patient was too much exhausted to open the abdomen afterward.

Dr. Thomas had also failed once; but his patient was in such good condition that he afterward made the abdominal incision, and she recovered. He would like to inquire of Dr. Battey, on the other hand, if he had ever failed to remove the ovaries after opening the abdomen.

Dr. Battey stated that he performed the vaginal operation in selected cases because it was less dangerous. The cases selected were those where the vagina was large and the ovaries loose in the pelvis. If these conditions did not exist, it was better to operate through the abdomen. He considered the vaginal operation, in many instances, more difficult than Dr. Sims seemed to think, his latter experience especially convincing him of this point.

The idea of Sims in elevating the uterus, he thought an excellent one, and he had no doubt that it would greatly facilitate the operation. Of his fifteen cases, twelve had been performed *per vaginam*, and three by the abdomen, but he thought it likely that if he had them to do over again, these proportions might be reversed.

Dr. Pallen agreed with Dr. Sims as to the superiority of the abdominal operation. Even Dr. Battey, with all his skill, had failed in the vaginal; and he considered it an utter impossibility, with all of the appliances of modern gynecology at command, to diagnose symmetrical peri-ovarian adhesions before operating.

Dr. Sims: "Dr. Battey has not yet answered my question. Have you ever failed to remove the ovaries by the abdominal incision?"

Dr. Battey: "Never!"

SECTION OF OPHTHALMOLOGY, OTOLOGY, AND LARYNGOLOGY.

Dr. Laurence Turnbull, of Philadelphia, Chairman.

Dr. Eugene Smith, of Detroit, Secretary.

In the absence of Dr. Bolling A. Pope, of New Orleans, Dr. Lawrence Turnbull, of Philadelphia, was made Temporary Chairman.

The session was called to order by the Chairman, and the first paper of the afternoon was read by Dr. W. H. Daly, of Pittsburg, Pa., on

A CASE OF SYPHILITIC STENOSIS OF THE LARYNX WITH FIBROUS ADHESIVE BANDS OF THE TRUE VOCAL CORDS; TRACHEOTOMY; RUPTURE OF BANDS; AND CURE OF THE STENOSIS BY GENERAL AND LOCAL TREATMENT.

This was a case of supposed recurrent asthma. On general examination, the pomum Adami rises and falls 1½ inches externally; inspiration and expiration are in the proportion of 1:3, the latter difficult. A syphiloderm, like linea versicolor, is upon the abdomen; a gummatous node lies in the linea alba 2½ inches below umbilicus, while an irregular ulcer 2½ inches in diameter occupies the left scapular region. Long and high nodes reside upon the upper third of each tibia; clavicular surfaces are irregular, but not tender; patient is emaciated, and has a cachectic look. The difficulty in respiration is evidently due to a valve-like obstruction in the throat; patient stoops forward, and compresses the chest, so as to get a sufficient quantity of air. Laryngoscopic examination reveals an arched, thickened and immovable epiglottis, a rima glottidis of ¼ the length of the vocal cords. The hyperplastic encroachment upon the calibre of the larynx is greatest to the right side of the thyroid box; it obliterates the ventricles and ventricular bands, and pushes against the vocal cords, which are agglutinated in a large part of their extent by a firmly organized plasma. The posterior commissure is obliterated also by the overlapping of the vocal cords; and all the anatomical landmarks of the laryngoscopic field are lost, either by infiltration, degeneration, or displacement. The color of the extra-laryngeal parts is of the leaden hue so well pictured by Türck in his atlas, while that of the intra-laryngeal walls is indian red.

An anti-syphilitic treatment is instituted, and tracheotomy threatened. This is performed three days later, without an anæsthetic, with the loss of less than half an ounce of blood. This is made none too soon, as in three days later the increasing stenosis and perichondritis have made the passage air-tight. From this time there is a gradual recession in the size of the growth, which continues almost without intermission for six weeks. The fibrous bands are ruptured with a laryngeal bougie at repeated sittings, and the vocal cords finally come into view. The patient, after the tracheotomy, is put upon a $\frac{1}{10}$ gr. of bichloride of mercury and iodide of potash, which, after two months' administration, is abandoned. Six months after the operation, in April, 1880, patient is engaged in continued manual labor, breathing through the natural straits. Two photographs, taken before and after the tracheotomy, show the comparative status of the patient.

At 2.30 P.M., Dr. Carl Seiler, of Philadelphia, read a paper entitled,

REMARKS ON THE LESIONS OF THE LARYNX IN PULMONARY PHTHISIS.

He finds that ulcerative processes begin in the glands, and not in the mucous membrane, whence come the serrated edges of the epiglottis. The dépôts or foci of pus contained leucocytes, while giant cells have been found only very rarely. Dr. S. thinks that gastric symptoms are found as often as laryngeal, and that it is an error to attribute to the larynx such pathological changes, as determine its separate location as a phthisical habitat.

No remarks followed this most admirable paper.

At 3 P.M., Dr. H. Knapp made extensive remarks upon

TUMORS OF THE LACHRYMAL GLAND: THEIR PATHOLOGY AND TREATMENT, WITH DEMONSTRATIONS.

Dr. K.'s remarks were based upon lachrymal gland tumors in his practice, the first of which was in a lady 26 years of age, who presented a tumor filling the upper and outer portions of the orbit, and pushing forward the lid. Enucleation found involvement of optic nerve. Case II. was that of a man 36 years of age, whose growth was recurrent, and was first removed by Dr. Williams, of Boston. It reappeared in two months, when Dr. K. found a pro-

tumor forward of 11 mm. The eye was pushed downward and inward. A preliminary diagnostic incision was made, and the tumor was found to consist largely of epithelial cells. For its final removal a semicircular incision under the brow was made; the tumor was found attached to the periosteum. Superior and external recti were divided, as well as the optic nerve. Its removal was slowly but easily accomplished. A silver drainage-tube was introduced, and repair was healthy. In two days an ophthalmoscopic examination was made, which it was found that hemophthalmos existed. The macula lutea was reddened, and the retinal veins were large, the latter finally atrophied and became white tendinous cords.

Case III was that of a young man with a story of exophthalmos for 14 months. The eye was nodular to the touch, and pushed downward and toward the nose. Fundus here, as in Case II, was congested, and there was atrophy of the yellow spot. V. $\frac{2}{3}$. Removal was made this last spring by a semicircular incision along the brow. This was followed by a protrusion of fat; the tumor was found thoroughly encapsulated; sutures were placed in the walls of the incision, and healing was by first intention. Vision improved to $\frac{2}{3}$.

It was stated that very few lachrymal tumors have been removed. These, like those heretofore noted, are adenomatous, yet all parts of these tumors do not show similar properties. All were glandular; there was considerable myxomatous tissue, and epithelial cells were crowded together in a polygonal form. The first tumor, of five years' growth, was adenomatous throughout. The second tumor was glandular. The third was more or less cancerous, with lymphatics leading from the alveoli. There is a very prominent proliferation of epithelial cells. K thinks all began as adenomatous growths; then in some parts there was hypertrophy of tissue, with nodes and knots. This is like alveolar cancer. In all there was much myxomatous tissue, giving the general characters of myxo-adenoma. A recess of ten minutes was taken to examine the three microscopic specimens of lachrymal tumor. Remarks being in order,

Dr. Charles J. Kip, of Newark, N. J., showed two photographs of a woman in advanced years, taken before and after the operation of removal of an orbital tumor of the left side. Exophthalmos was downward and inward nearly one inch. K. made an incision along the supra-orbital wall, and removed the growth; without antiseptic treatment and without subsequent secretion perfect union was obtained. The tumor was an ordinary adenoma, consisting of cartilage cells, epithelial cells, and tubes containing gelatinous masses. This case revealed atrophy of the optic nerve and pigment degeneration in the retina.

Dr. Keyser, of Philadelphia, moved a vote of thanks to Dr. Knapp for the presentation of his remarks and specimens, which was given unanimously.

THE TRAINING OF IDIOTIC EYES

was the title of a paper read by Dr. Edouard Seguin. It was not intended as a monograph, but as a continuation of the paper read by the author in 1879, at Atlanta, Ga., before this Section of the Association. Cases of nystagmus associated with myopia and optic nerve atrophy were detailed. Different forms of motility in nystagmus, as well as the fixed stare of the idiot, were referred to. Under symptomatology, an exaggerated neurasthenia enters largely into such cases, neither [illegible] both the motility of the ocular muscles and the [illegible] of the macula lutea.

The first part in the physiological education of the eyes is to connect with the index finger, bringing them into play according to motion and its rate. It is to be noted, as a curious but constant phenomenon, that an object may be held to follow the finger, which he does with his body and head, but not with the eyes. Whether two hand or the eye is the proper organ to train first is perhaps questionable. In this category fall the training, as in drawing on pencil, chalk, paper, parchment, etc. The paper was very lengthy, and was abridged by the author, who collated a few cases of the education of the eyes of idiots.

No remarks followed its reading, and the Section adjourned at 1.30 P.M. until Wednesday afternoon at two o'clock.

The Reception of the American Medical Association at the Academy of Music in the evening was largely attended, and was very successful in every way. Probably two thousand persons were present during the evening. The profession from all parts of the country was represented, in many prominent medical men from the South and West, from Philadelphia and Boston being on the floor.

The music was excellent, and the supper arrangements were on a scale to meet even the very large demand put upon them. The whole affair reflected much credit upon the profession of the city, and the committee who had the matter in charge.

GENERAL SESSION.

Wednesday, June 2—Second Day.

The Association was called to order at 10 A.M., by the President.

On motion made by Dr. S. D. Gross, of Philadelphia, and seconded by Dr. Brodie, of Detroit, the following gentlemen were elected as

honorary members.

Mr. Jonathan Hutchinson, London, England; Drs. Hingston, Osler, David, Howard, and Trenholme, of Montreal; Dr. G. B. Ercolani, Bologna, Italy; Dr. Emilio L. DeMola No, Lima, Peru; Dr. Dillon, of Dublin; Dr. Rosenbergh, of Hamilton, Canada, and Dr. Clark, of Toronto.

representation from the u. s. navy.

Dr. A. L. Gihon brought up the question of representation from the U. S. Navy, and spoke against the action of the Association at the last session, and a vigorous discussion ensued, which was dissipated by a motion made by Dr. S. D. Gross, that as the Judicial Council stated that no charges preferred against the U. S. Navy had been authenticated, the U. S. Navy be at once admitted to full recognition in the Association.

The motion was unanimously carried.

report of the judicial council.

Dr. Benham, of the Judicial Council, reported concerning the affairs of the Allen County Medical Society, Indiana, referring the questions to the State Medical Society for adjudication.

The following were announced as the

committee on nominations.

W. O. Baldwin, Alabama; E. R. Du Val, Ark.; M. S. Storrs, Conn.; Judson Gilman, Md.; W. S.

Tremaine, Kansas; Marshall Sexton, Indiana; J. B. Book, Mich.; Jos. H. Warren, Mass.; E. M. Moore, N. Y.; Duncan Eve, Tenn.; S. D. Gross, Pa.; J. H. Pope, Texas; J. S. Billings, U. S. A.; J. Rufus Tryon, U. S. N.; J. Eliot, D. C.; T. G. Richardson, Louisiana; Dr. Wakefield, Florida; A. T. Woodward, Vt.; H. B. Ransom, Iowa; G. A. Shurtleff, Cal.; F. D. Cuningham, Va.; S. Baruch, S. C.; C. P. Adams, Minn.; M. Campbell, W. Va.; J. G. Thomas, Ga.; William Marshall, Del.; G. W. Nesbitt, Ill.; A. E. Heighway, Ohio; T. G. Robinson, Mo.; R. E. Howard, Miss.; H. A. Hopper, N. J.; G. P. Conn, N. H.; A. Ballou, R. I.; Walter Kempster, Wis.; W. K. Oaks, Me.; J. A. Octorlony, Ky.

The following were elected

MEMBERS BY INVITATION.

C. I. Pardee, S. Kohn, J. H. Hillyer, and C. H. Nichols, of New York; C. B. White, U. S. A.; J. D. Nelson, Stonington, Conn.; Thos. Goodwillie, Vernon, Vt.; Lewis Fisher, New York; Geo. B. Ferguson, Deer Isle, Me.

Dr. Brodie, Secretary, presented his report from the

DELEGATION TO THE CANADA MEDICAL ASSOCIATION,

which was accepted, and ordered to be entered upon the minutes.

Dr. Pratt, of Michigan, reported from the committee appointed last year to take into consideration the *nine* propositions submitted to the Association by Dr. Chaillé, of New Orleans.

The report was unfavorable to all the propositions except the fourth, which contemplated substituting a periodical medical journal for the present volume of transactions. On that proposition, however, the committee were of the opinion that it was the safer way to wait upon the law of growth rather than to adopt any radical change at present.

The report was accepted and entered upon the minutes.

Dr. Walker, President of the Society of Asylum Superintendents, was invited to a seat on the platform.

REPORT OF THE COMMITTEE ON OZONE.

A letter from Dr. N. S. Davis, of Chicago, was read, which, although not a report, contained the essence of what a formal report would have communicated, and it was to the effect that insurmountable obstacles had been encountered in efforts to obtain records of the condition of the atmosphere, such as men of true science would regard as reliable. He asked for $200 to be expended for instruments, if found advisable.

Dr. Jas. T. White, of Buffalo, who two years ago introduced the resolution that gave origin to the Committee on Ozone, moved that the amount suggested be appropriated, and that the committee be continued. Carried.

Dr. J. S. Lynch, of Baltimore, Chairman of the

SECTION ON THE PRACTICE OF MEDICINE,

then delivered his address, in which he congratulated the profession upon the fact that the general health of the country during the last year had been so exceptionally good, and then turned his attention to the subject of yellow fever. He regarded it as settled that the germs of that disease cannot be destroyed by cold, and reviewed the history of the ship Plymouth as bearing upon that question.

Another peculiarity of the poison was that when first emitted from the subject, it was not in an active or potential condition, but subsequently developed so as to render it capable of imparting the disease; therefore a miasmatic-contagious affection.

A review of several observations was given in substantiation of that doctrine. The doctrine being true, there was an abundance of time to destroy the germs before they could communicate the disease; hence, all danger could be absolutely prevented.

Dr. Lynch then passed to the consideration of the great mortality from consumption, scarlet fever, and diphtheria, and the means to be adopted to reduce such rate. Scarlet fever and diphtheria were preventible diseases, and consumption could be markedly checked in its ravages by means of proper sanitary and hygienic measures.

The next topic was antipyretic treatment, as applied by means of the cinchona alkaloids, salicylic acid, carbolic acid, and aconite.

The Chairman then made a brief allusion to what had been accomplished by the aid of the thermometer, the ophthalmoscope, the microscope, and the hypodermic syringe, and closed with an eloquent reference to the present position occupied by the science and art of medicine.

The address was accepted and referred to the Committee on Publication.

Dr. W. T. Briggs, of Nashville, Tenn., then delivered his address as Chairman of the

SECTION ON SURGERY AND ANATOMY.

He directed attention to a surgical procedure, than which none was older in the history of the science or the art of medicine—*prerentire trephining*. The word trephining Dr. Briggs used in a comprehensive sense, and the operation, by whatever instrument effected, was a means to an end, and that end was the removal of fragments of the skull. He then directed attention to the importance of treating injuries of the head properly, especially such as involved fracture of the skull. After making slight reference to the history of the operation, he spoke of the mutability of opinion concerning many important subjects pertaining to medical science, such as blood-letting and lithotomy, and the same could be said concerning trephining; but at the present time there was a revolution in progress in favor of the procedure. The earliest authentic information concerning the instrument was found in the writings of Hippocrates, although it was known to have been performed as a religious rite in prehistoric times.

There were, according to European authorities, three classes of surgeons holding distinct views with reference to the procedure under consideration: First, Those who absolutely rejected the trephine; second, Those who, while recognizing its great value, regarded it solely as a *curative* agent; and third, and by far the smallest class, Those who accepted the instrument as a valuable prophylactic agent, and urged early resort to it in such cases as, from the nature of the injury, seemed to demand it in order to avert threatening danger.

The position taken by Dr. Briggs was, that trephining was not a dangerous procedure if resorted to before the secondary effects of traumatism were developed, and he then considered the objects to be attained by its performance. In the opinion of most authors it should be restricted to cases in which there is immediate danger from compression caused by pus, extravasated blood, or fragment of bone, and each of these conditions was then discussed some-

what in detail, and the conclusion reached that the surgeon should not wait until the characteristic symptoms of such lesions were well marked before operating, but that the operation should be performed for the purpose of preventing the occurrence of inflammation, and the serious consequences by which it might be followed. Statistics showed that of 106 cases, two thirds were saved by *precoce* trephining. Of the forty two cases whom he had trephined, thirty eight recovered. The deductions from such facts were: 1. Extensive comminuted depressed fractures of the skull were almost invariably fatal without operative measures. 2. Curative operations were but little better than the expectant plan of treatment, and 3, Preventive trephining offered the best chances for a successful operation. Dr. Briggs then discussed the question of the treatment of punctured and simple fractures of the skull, fractures of the external and of the internal table, and stated as the essentials to success: 1, full antiseptic precautions; 2, the use of the conical trephine; 3, entire *removal* of all loose fragments of bone; 4, special attention for the purpose of securing perfect drainage, the open wound treatment being his favorite method.

The address was listened to attentively, and, on motion, was referred to the Committee on Publication.

Communications were then read and received their proper reference, after which the Association adopted the following amendment relating to

PRIZE ESSAYS AND THE COMMITTEE ON PRIZE ESSAYS.

a. There shall be four annual prizes of two hundred and fifty dollars each, which shall be awarded at the close of the second year after announcement, as hereinafter explained, for strictly original contributions to medical and surgical progress.

b. It shall be the duty of the Chairman of each of the following four Sections: 1. Practical Medicine, Materia Medica, and Physiology; 2. Obstetrics and Diseases of Women and Children; 3. Surgery and Anatomy; 4. State Medicine and Public Hygiene, to appoint annually, before the adjournment of the meeting of the Association, three members of ability and good judgment who shall constitute a Committee of Selection, and who shall, within thirty days thereafter, select and publicly announce for competitive investigation and report, a subject belonging to one or other of the branches of medicine included in the title of the Section.

c. It shall also be the duty of the Chairman of each of the Sections mentioned to appoint annually a Committee of Award, consisting of three experts, who shall carefully examine the essays offered for competition, and if any one shall be found worthy of the prize as a substantial contribution to medical knowledge, to recommend the same to the Association.

d. All essays placed by their authors for competition shall be in the hands of the Chairman of the respective Committees of Award on or before the first day of January preceding the meeting of the Association at which the reports of the committee are required to be made.

e. All Prize Essays are considered as the property of the Association.

f. The names of the authors of the competing essays shall be kept secret from the committees by such means as the latter may provide.

g. Membership in either of the two committees shall not debar from membership in the other; nor shall membership in the Committee of Selection exclude a member from the privilege of offering a competitive essay.

The Association then adjourned to meet at 10 A.M., Thursday, June 3d, and the Metric System was made one of the orders for the morning session.

SECTION ON PRACTICE OF MEDICINE, MATERIA MEDICA, AND PHYSIOLOGY

Dr. J. S. Lynch, of Baltimore, Chairman.
Dr. W. C. Glasgow, Secretary.

The first paper was read by Dr. H. R. Hopkins, of Buffalo, N. Y., on

SPHYGMOGRAMS, WITH NOTES OF AUTOPSIES.

The sphygmograph, said the speaker, had been twenty years before the public, but had not yet received any general endorsement. Even experts could not interpret its readings accurately. There are, however, qualities in the pulse which are not perceptible to the touch, and in detecting these the sphygmograph can accomplish very much when more perfectly made and more carefully studied. The speaker then showed some tracings which he had made. These tracings were of cases of locomotor ataxia, cardiac dropsy, endarteritis, Bright's disease, and of normal pulses. The pressure at which the tracings were taken was not given, as it was not thought necessary. The speaker believed that the tracings indicated characteristic peculiarities in the circulatory system of each disease. The tracings were taken by a modification of Pond's sphygmograph. It was asserted that a peculiar trace might be found for many chronic diseases. A description of the post mortem appearances of the several cases whose tracings were shown was given.

The rule was given to mistrust the accuracy of the instrument when it failed to give a sharp angle to the tidal wave. Several other cautions were given, but much hope of attaining valuable results held out by the careful use of a good instrument.

The paper was referred to the Committee on Publication.

The next paper was by Dr. Robert W. Taylor, of New York,

ON THE USE OF CHRYSOPHANIC ACID IN THE TREATMENT OF SKIN DISEASES.

Chrysophanic acid is derived from the Goa powder, and it is as much a cure for some skin diseases as quinine is for malaria. The strength of the ointment should be about gr. x. to ʒi. of simple ointment. The strength may be rarely increased to ʒi. to ʒi. The acid is useful in chronic or subacute skin affections, where there is a superficial infiltration, and in certain scaly diseases. It will not do when the infiltration is deep. Its dangers are, its staining and its irritant properties. The acid has no anti-pruritic properties. It would be good in indurated acne, but for its staining the skin; caution should be used in applying the ointment to the face. In eczema it is useful, but should be combined with oil of cade or some other tarry oil. Two cases of obstinate sycosis had been cured by the acid. Ringworm of the body can also be cured by it.

Lichen, papular and scaling syphilides are also relieved by the same remedy. In psoriasis, however, the acid has achieved its greatest results. The speaker endorsed the high praise that had been given it for its usefulness in this disease.

The paper was referred to the Committee on Publication.

A paper, to be read by Dr. J. Solis Cohen, for Dr. W. T. Gadbury, of Yazoo City, Miss., on

ARTIFICIAL INFLATION AS A REMEDIAL AGENT IN DISEASES OF THE LUNGS,

was read by title and referred.

A paper was then read by Dr. Wm. Pepper, of Philadelphia, on a

FURTHER CONTRIBUTION TO THE LOCAL TREATMENT OF PULMONARY CAVITIES.

The chief indications for the treatment of pulmonary cavities are, cleansing, disinfection, and modifying the walls of the cavity. The use of inhalations, sprays, and direct injections has been employed, but, as regards the first two measures, without much success. There is one form of inhalation by which some good may be accomplished. This is by the continuous inhalation of medicated vapor. An instrument for doing this was shown by the speaker. It consisted of a kind of mask, attached to which is a small box containing sponge on which the medicated fluid is poured. This is tied over the mouth. The best medicines are carbolic acid, iodine, thymol, etc. With an instrument of this kind the bad breath due to putrid cavities, or bronchiectases, can be corrected, and probably good can be done in cases of chronic bronchitis.

It was not likely, however, that much could be done in pulmonary cavities by continual inhalation. The speaker, therefore, called attention to the value of direct injections into the lung cavities.

A number of cases were reported showing the value of this procedure. Lugol's solution, in the proportion of from ℥x., ℥xv. or ʒi. to ℥i. of water was used. In one case related the injections were given forty-eight times in fourteen months. The patient improved, and when he died some time afterward, from Bright's disease, the cavity was found to have been obliterated. Seventeen other cases were related or referred to, in which similar treatment was pursued, 291 injections having been made. Autopsies on some of the cases showed that contraction of the cavities was induced by the injections. Injections into caseous consolidation of the lung, in very bad cases, gave negative results.

The syringe used was like an ordinary hypodermic syringe, but had a larger barrel and longer needle. Lugol's solution and carbolic acid were the only agents suggested. The skin should be first chilled with ice; the injections should be mild at first. There is no danger in such injections, cough and pain being the only symptoms excited.

The paper being open for discussion,

Dr. Bennett, of Ohio, said that there seemed to be a failure in this new form of treatment to secure any general benefit. The healing of cavities was a thing that often took place spontaneously. The cases given by Dr. Pepper only showed that the method was harmless.

Dr. Whitney, of New York, asked if Dr. Pepper would recommend the method to the general practitioner.

Dr. Pepper said that the post-mortem cicatrices in lungs did not often indicate ante-mortem cavities, but rather areas of exudation. In 4,000 cases where there were pulmonary cavities, only 81 seemed to be contracting. Probably not five of these ever finally disappeared. Very few cavities ever healed up, and any method which would promote this healing would be of the greatest value. In the cases related, all other medication was suspended. The patients themselves almost always had great faith in the treatment. In regard to recommending the measure for general adoption, Dr. Pepper felt some hesitation, for he did not think that its value was yet entirely established.

Dr. Whitney said that as the indication for the use of injections was limited he did not think its practical value would be very great.

Dr. Bennett referred to a number of cases in which he had seen pulmonary cavities heal up under constitutional treatment. He thought that such treatment must be always the essential thing.

Dr. E. Cutter, of Boston, referred to some cases in which he had plunged needles into the lung and had seen no harm follow.

Dr. Russell, of Massachusetts, referred to twenty-four cases of gunshot wounds of the chest; twelve of these recovered so far that they could go home. He referred to this as illustrating the capability of the lung of standing severe injuries.

Dr. Wilson, of Ohio, spoke of the fact that phthisis is a constitutional disease and must be treated constitutionally. We may cure one cavity, but another one will appear. The disease cannot be cured by any local treatment.

The paper was referred, with a vote of thanks.

A paper on

THE TREATMENT OF SCROFULOUS DISEASES OF THE SKIN,

by Dr. John V. Shoemaker, of Philadelphia, was read in abstract. The speaker had used all the drugs usually employed in scrofulous diseases of the skin, such as cod-liver oil, iron, iodide of potash, etc., but had met with such poor success that he was led to try chlorate of potash. This had given him the greatest possible satisfaction, and he believed that it often acted almost specifically in the diseases in question.

A number of cases were presented, and one was read in full.

In young children suffering from enlarged and suppurating cervical glands, the best results will be obtained by gr. ii. to gr. iii. four times a day. This drug will increase the appetite, increase the weight, and improve the complexion. Such use of chlorate of potash in phthisis and scrofula was described by Dr. Harken in 1868. Dr. Schoemaker endorsed Dr. H.'s views and believed that it was the only effective remedy in many cases of scrofuloderma. The experience of Dr. Nicholson, who believes that the alkalies should take the place of iron in anæmia, is in consonance with the views of the speaker. Dr. S. believed that physicians should never recommend marriage among the scrofulous.

Dr. Pine, of Poughkeepsie, said that he had been using chlorate of potash considerably of late, among children suffering from slight attacks of scarlatina and from sore throats. He had been much pleased with the drug, and was glad to hear it endorsed as of value in other diseases.

Dr. Garrish, of New York, spoke highly of chlorate of potash in diphtheria, throat affections, and other diseases.

Dr. Ulrich, of Chester, Pa., said Dr. Schoemaker's experience was entirely different from his own. He had great faith in the drug in diphtheria and throat troubles; in scrofulous diseases, however, he had had no good results whatever. He had used it a great deal, and he thought he might just as well have

poured it down a rat hole as down his patient's throat

Dr. R. W. Taylor, of New York, asked what was meant by scrofulous diseases of the skin. He had been accustomed to look upon lupus, for instance, as a scrofulous disease, and he should be astounded to learn that chlorate of potash cured it. Dr. T. had used the chlorate of potash in certain diseases of the skin due to suboxidation, and with success. He would like to know, however, exactly what the skin diseases were that Dr. Shoemaker had cured.

Dr. Shoemaker said that he used the remedy in persons whose lymphatic glands were swollen or broken down, and the skin in a diseased condition over it.

Dr. R. W. Taylor said that the various forms of lupus were generally called the scrofuloderma.

Dr. Smirnow, of Brooklyn, expressed incredulity as to the great efficacy of chlorate of potash.

Further discussion followed by Drs. L. Duncan Bulkley, Whitney, and others. The paper was then referred as usual.

A paper was read by Dr. J. R. Uhler, of Baltimore.

ON RESTORATIVE REMEDIES.

The speaker described a very simple method of determining the amount of nitrogen (and urea) in urine. It consists in taking two bottles, one of which just fits into the other. The smaller bottle is attached by a wire to the cork of the larger one. Into the small bottle is placed urine; in the larger a mixture of liquor sodæ chlorinat., and common salt. The two bottles, one within the other, are first carefully weighed; they are then shaken and their contents mixed together. A decomposition follows, which results in the evolution of nitrogen. This gas is allowed to pass off, and the bottles with their contents are again weighed. The difference between the first weight and the second shows the weight of the nitrogen, from which may be calculated the weight of the urea.

Two or three other processes for determining urea, not quite so simple, but based on the same principle, were also shown.

Dr. Uhler then passed to the subject of foods, and referred to the recent experiments of Dr. Roberts on the digestive ferments, in which he had stated that milk and oysters were the only two foods that should not be eaten cooked. The oyster, he said, was a food which digested itself when taken raw.

The speaker showed a specimen of cod-liver oil, mixed with cheese, which quite effectually disguised its taste. The pungency of the cheese also aided the digestion of the oil. Specimens of cod-liver oil, mixed with bread, were also shown.

The process of the manufacture of extract of malt was described and its value endorsed. Dr. Uhler had proved by several experiments that it changed starch into glucose.

Preparations of pepsine had been tested by the speaker to see how great their value really is. Microscopic examinations showed that the various specimens in the market differed greatly in value. The fresh varieties are the best by far, and many of the others are unreliable.

Dr. Uhler had devised a new process by which he hoped the pepsin could be kept active in powder form. He covered the fresh moist stomach over with gypsum. When this hardened, he pulled it off and ground up the saturated plaster. This he had found was very active, and kept very well.

In conclusion, the uses of iron and digitalis were described. A description of the theory of the action of the heart, and of digitalis upon it was given and illustrated with diagrams.

The paper being concluded, it was voted to make Dr. L. D. Bulkley's paper, which was to follow, the special order for the next day at 2 P.M.

The Section then adjourned at 5.30 P.M.

SECTION ON SURGERY AND ANATOMY.

W. T. Bigger, M.D., Nashville, Tenn., Chairman.
C. Powell Adams, M.D., Hastings, Minn., Secretary.

THE PUNCTURE OF JOINTS.

Dr. Martin, of Massachusetts, renewed the discussion of Dr. Pancoast's paper. There was no question that puncture of joints was regarded by the profession at large as a *dernier ressort*, but in his experience it should be performed early. He added that there was no danger in this procedure. His own investigations on the vascularity of joints tended to confirm Dr. Pancoast's views on this important matter. Sir Benjamin Brodie was cited in support of the view of non-suppuration of cartilage, in inflammatory processes involving joints. Dr. Martin also showed his new adhesive plaster, made of india-rubber, in combination with burgundy pitch and balsam of tolu, and the Section was invited to take samples of it for test examinations. This plaster was devoid of all tendency toward deterioration. U. S. Army Surgeon's Adhesive Plaster was the name by which it was already known to some members of the profession.

Dr. Smith, of Philadelphia, suggested that measures should be taken to bring the plaster to the notice of the authorities of the pharmacopœia.

Dr. Nancrede, of Philadelphia, referred to Dr. Pancoast's paper, and said that already irritated cartilaginous surfaces must be kept apart by extension to facilitate healing.

Dr. A. C. Post, of New York, observed that he had for some time past been in the habit of employing fine sutures of black silk. An illustration was cited.

Dr. Pancoast, of Philadelphia, reiterated that the prime factor in treating articular affections was rest to the synovial membrane and not the removal of pressure from the articular cartilages.

Dr. Hinton, of Canada, thought the sensations of the patient were always the best guide in such instances.

Referring to external and internal urethrotomy, in connection with Dr. Pancoast's urethrotome, he said urethrotomy was too often performed. Very frequently it was a quite superfluous and always a very dangerous operation. Dilation was more satisfactory.

Dr. Pancoast entirely agreed with Dr. Hinton, and explained that his instrument was often used only for superficial nicking, followed by the use of bougies.

Dr. Campbell, of Vermont, asked how long the bougie was allowed to remain in the urethra.

Dr. Pancoast answered "as long as the individual exigencies seem to require."

COMPOUND COMPLICATED HARE-LIP.

Dr. James L. Little, of New York, read a paper on compound complicated hare-lip, illustrated by three cases. The patients were all brothers, aged respectively 22, 18, and 9 years. These youths also

showed cleft palate. No hereditary tendency was ascertained. Besides the boys, there were five girls in the family. These were perfect, while all the boys had the deformity.

One of the latter had died in infancy. The three remaining boys all showed the intermaxillary bone distinct from the superior maxillary and continuous with the nasal septum. It projected beyond the line of the mouth and was covered with a small tag of integument. The hard and soft palates were cleft. An account of the operations performed at St. Luke's Hospital was then given. The final results of the operations were demonstrated by means of photographs and wax-casts.

In the first case it became necessary to operate several successive times before a satisfactory result was obtained. The first operation was for the fissure of the hard and soft palates. Partial success. The next one was for the hare-lip. Perfect result. Some accessory operations were then performed, at varying intervals of time. In the second case, the inter-maxillary bone was first removed. Excellent result. The lip was then operated on with satisfactory result.

The third case resembled the preceding one. The inter-maxillary bone was first removed, and the columna formed in the usual manner. Some secondary operations became necessary, but the final result was a good one. The boy was exhibited to the Section.

Dr. Atlee, of Lancaster, spoke of cases which had occurred in his practice. A family was mentioned which contained seventeen members, afflicted with hare-lip.

Dr. Post, of New York, referred to the late Dr. Gurdon Buck, who had published analogous cases. Photographs of another case were also shown.

Dr. Vanderveer, of Albany, instanced similar cases, which spoke in favor of early operations. It was also stated that Sir William Fergusson always operated twice.

Dr. Atlee, of Lancaster, also strongly advocated early operations.

Dr. Westmoreland, of Georgia, said he had operated on a child only eight days old.

Dr. Sayre, of New York, mentioned a case where he had operated on a child four days old. The best time to operate was before the lips were actively employed for suckling. Dr. Van Buren had assisted at the operation. An anæsthetic was not employed. The exact mode of operation was then described.

Dr. McGuire, of Virginia, only saw one successful case in his practice.

Dr. Hamilton, of Ohio, had operated on a child twelve hours old. Other operations were also cited in support of Dr. Sayre's view concerning the advisability of early operations.

Dr. Goodwillie, of New York, showed casts representing an abnormal condition of the inferior turbinated bones, and described his experiments on erectile tissue in this locality. Wax models were also shown.

Dr. A. C. Post, of New York, read by title a paper on a case of torticollis rapidly and completely cured by open division of the sternal and clavicular origins of the sterno-cleido-mastoid muscle, followed by elastic traction.

A NEW ETHER-INHALER, AND A NEW FORM OF TRANSFUSION APPARATUS,

by Dr. Jos. C Hutchison, of Brooklyn. This paper also was read by title only.

Dr. D. H. Goodwillie, of New York, exhibited an apparatus for the inhalation of nitrous oxide mixed with air, and explained the method of its employment.

HIP-JOINT DISEASE,

by Drs. De Forrest Willard and E. O. Shakespeare, of Philadelphia.

This paper was read by Dr. Willard. It related to a case where death had occurred in the early stage of the disease. The specimen was exhibited and microscopical drawings shown. A microscopical preparation was also demonstrated. The origin and progress of the disease, the pathological appearances after death, and the pathological histology were successively discussed. Many interesting suggestions were made, both as to the pathology and treatment of hip-joint disease. Dr. Willard's splint, used in the treatment of this malady, was finally shown and explained. The splint was made by first taking a plaster cast of the limb in question.

Dr. John B. Roberts, of Philadelphia, read a paper

ON TAPPING OF THE PERICARDIAL SAC.

The operation, it was said, was proposed over two hundred years ago. The pathology, symptoms, and treatment now in vogue were alluded to. The fifth intercostal space about 5 cent. to the left of the median line, was considered to be the best place for the procedure of tapping. Large serous effusions gave the most brilliant results. The operation might be repeated if necessary. The canula could be left *in situ*, and the sac washed out with antiseptic solutions. Forty-two cases were mentioned, with fourteen recoveries and twenty-eight deaths.

Paracentesis of the pericardium would in future have to be performed at an earlier period than heretofore.

Dr. Dowell, of Texas, referred to a peculiar case where effusion was simulated by an entirely different pathological condition. In this instance tapping would probably have led to death

Dr. C. A. Leale, of New York, read a paper on

THORACENTESIS,

in which this operation was warmly advocated. Serous effusions were said to be amenable to treatment by using a trocar. In purulent collections, on the other hand, free incisions were advised. Continuous drainage might become necessary. Restoration of the pleura and lung to their normal condition after thoracentesis, was first considered. The spontaneous cure of empyema by discharge per bronchi was next alluded to. A case of empyema, entirely cured without the operation was mentioned.

The point of election for performing the operation was also referred to. Other points were then set forth, and the following conclusions presented:

Thoracentesis was easily performed, and required no special instruments.

It ranked among the surgical operations most conspicuous for saving of life.

Thoracentesis was justifiable to prevent pain and prolong life, even when an ultimate recovery of the lungs could not be expected.

Complete absorption had followed thoracentesis, when pus, air, or serum had been left in the pleural cavity.

The pleuræ might be restored to health after thoracentesis.

He the fever, the result of unhealthy decomposition, ought to be relieved by a free incision.

The author's recorded illustrations had shown that the operation could be successfully performed on the nursing infant, as well as on the adult. That it could be resorted to when both lungs were diseased, and even in far advanced pulmonary consumption. That relief from a distressing suffocation could be obtained, life prolonged, and painful death averted.

CYSTOTOMY FOR CYSTITIS IN THE MALE.

Dr. Robert F. Weir, of New York, read a paper upon the above subject, which embodied the results of forty-seven cases, in which the operation of cystotomy for cystitis had been resorted to. It opened with a short but interesting historical account of the operation, which was presented to the profession by the venerable Dr. Willard Parker, in 1867, in the "Transactions of the New York State Society." Dr. Parker's claims to priority in this matter were shown to be valid.

Of the 47 cases collected by Dr. Weir 13 died, 10 of which deaths were due to advanced kidney diseases, and only 3 to the operation itself. Of the 34 cases that recovered, 23 were cured by the operation absolutely, or were so much relieved as to be able to return to their vocations, to hold their urine for several hours; 7 were relieved to a moderate extent, and 4 completely failed in affording any benefit. Not all, however, were treated by lateral lithotomy, in only 32 cases was this method used, the bilateral incision five times, and the median ten times. When the median section was resorted to, in six of which a cure resulted, either a supplementary incision (three times) into the prostate was done, or the finger (once) or two fingers (once) were introduced into the bladder, or by a bivalved speculum the vesical orifice was stretched (five times) to the diameter of an inch. Hence, when the median operation was resorted to, incision or laceration of the prostate was of necessity conjoined with it. A permanent fistula was more apt to occur after the median operation. To afford success, not only a free opening into the bladder, preferably by the lateral incision, must be made, but also the wound should be kept open as long as possible by either introducing the finger or a large tube frequently during the first ten days after the operation, and after that time oftentimes a tube can be permanently borne. Dr. Weir also cited a number of cases where, in the performance of lithotomy or cystotomy, the hypertrophied median lobe or other portion of the prostate, had been removed without enhancing the risk of the operation, and advised, after consideration of the subject, that an endeavor should, if possible, be made in the performance of cystotomy in the aged (or past fifty-five) to remove any enlargement of this gland.

Dr. Gouley, of New York, remarked that no patient would get well after cystotomy unless there had been a free division of the urethro-vesical orifice. Rest alone would not effect a cure. Mercier, it was said, had reported about 400 cases of such division of the urethral valvule. The prostatic valvules were also incised by this physician. In some cases, however, even valvular division would not produce the desired result of an effectual cure.

Dr. Dawson, of Cincinnati, concurred in the views expressed by Dr. Gouley, and cited an interesting case which had been intractable to all the methods he had employed.

Dr. Mynter, of Buffalo, also mentioned a similar case. He had performed cystotomy, but after closure of the wound the patient's troubles had returned.

Dr. Hart, of Plainfield, instanced a case where a drainage tube had been placed in the rectum, allowing the residue urine to pass off in that way.

Dr. Hamilton, of Buffalo, said he had given infinite relief to a woman who had suffered intensely for a long time from severe cystitis. An ordinary soft catheter was allowed to remain in the bladder till relief was afforded, and permanent cure followed.

Dr. A. C. Post, of New York, referred to a case which had been commented upon by the author of the paper under discussion. The actual cautery had been applied in this case at two points over the hypogastric region. An absolute cure followed.

After some discussion on publication of papers, it was resolved, on motion of Dr. Dawson, that a committee be appointed to report what alterations, if any, were necessary in the by-laws, to enable members to publish papers read by them either in whole or by abstract, in advance of the publication of the annual volume of the Transactions of the Association, and that Dr. Bronson be made Chairman of the committee.

The President also appointed Drs. Dawson, of Ohio, and Pancoast, of Philadelphia, to act on this committee.

SKIN GRAFTING.

Dr. L. Turnbull, of Philadelphia, read a paper on skin grafting, with illustrative cases. Photographs were also passed around for inspection. This paper had been previously read before the Philadelphia County Medical Society, December 17, 1879, but it had not been published in the Transactions of that Society. After giving the history of the operation, Dr. Turnbull referred to the physiology of skin grafting. Some suggestions in reference to the success of the operation were also given.

Dr. Buchanan, of New York, related a case of great interest in this connection, in which 200 grafts had been taken from an amputated thigh, three hours after its removal, and inserted into an immense ulcerated surface over the breast of a woman. A stimulus had been imparted to the edge of the wound by the implantation of these cutaneous bits. Later on, 500 grafts were placed on the ulcer. The extent of the wound considerably diminished after these procedures. Some practical suggestions concerning the modes of performing these operations were also given. In addition, he said, that to Dr. Van Wagenen belonged all the credit of originality in this matter.

Dr. Mattison, of Brooklyn, referred to some similar case, which had been much benefited by grafting.

On motion it was resolved that Dr. Martin, of Massachusetts, be allowed a half hour to-morrow for the purpose of reading a report on the use of his bandage. It was also resolved to append Dr. Burchard's communication to the reports of the Section.

A paper, by Dr. D. M. Barr, of Philadelphia, on a new inhaler, was read by title only.

Dr. W. A. Byrd, of Quincy, Ill., then read his paper on

LAPAROTOMY AND COLOTOMY, WITH FORMATION OF ARTIFICIAL ANUS FOR INTESTINAL OBSTRUCTION.

The case was that of a farmer, aged 43, who had suffered from enteritis for some months. After de-

scribing the operation in all its details, the following conclusions were reached:

No one should be allowed to die from intestinal obstruction without, at least, an exploratory incision.

If there was much distention of the bowels with gas an aspirator should be used, as intestinal paralysis might be produced from prolonged over-distention.

In occlusion, in cases where abdominal section was contraindicated, an artificial anus should at once be established. Proper rectal alimentation and medication very materially aided the patient's recovery.

A quotation from Mr. T. Bryant closed this paper. It was to the effect that it was not required of the surgeon to diagnosticate the precise cause of the obstruction so long as the diagnosis of its existence could be determined.

Dr. Gouley, of New York, agreed with Dr. Byrd in his condemnation of delay in doubtful cases. Still, he said, time must be given to make sure of the diagnosis. A case was cited where delay had unquestionably led to death. An operation in this instance would doubtless have saved the patient's life. Forty-seven other cases were instanced with only one recovery, and this in a case where an operation had been performed.

Dr. Dawson remarked on the difference in danger between cutting into a previously unirritated peritoneum and one where continual irritation had already established a comparative tolerance of exciting factors. Some cases bearing on the subject under discussion were then adduced. Fluid injections were also recommended preparatory to severer measures. Sometimes Dr. Dawson had found the fluid injected into the rectum escape at the mouth. Spontaneous cure might occur. Cutting into an acutely inflamed peritoneum was too dangerous a practice to justify a universal adoption of laparotomy for acute obstruction of the intestines. The difficulty of diagnosis in many cases of this kind was dwelt upon. He said that laparotomy should remain a last resort after failure of all other methods.

Dr. Jewett, of Massachusetts, stated that he had found no difficulty in introducing rubber tubes into the rectum to the distance of three feet. A case of impacted fæces, illustrating the utility of rectal injections of warm water by means of such rubber tubes was described.

Dr. Hamilton, of Ohio, spoke on the value of the conical elastic bougie in rectal stricture, and cited a case which had occurred in his practice.

Dr. Byrd, of Illinois, mentioned some additional cases.

Dr. Gouley, of New York, said that abdominal section should be practised before peritonitis had set in. He then described a case which had lately come under his observation that clearly showed that the policy of waiting was disastrous. This was an acute case.

In subacute and chronic cases post-peritoneal abscess would gradually develop, and such cases did not indicate abdominal section.

Dr. Weist, of Indiana, suggested that in cases where an operation was not practicable, great efforts would not always be rewarded by success. The let-alone policy had, in his experience at least, sometimes secured the most gratifying results.

Dr. Doyle, of Syracuse, N. Y., showed a new appliance for the treatment of club-foot and other deformities.

The Section then adjourned at 7 P.M.

SECTION OF OBSTETRICS AND DISEASES OF WOMEN.

G. M. B. Maughs, M.D., St. Louis, Mo., Chairman.
Robert Battey, M.D., Rome, Ga., Secretary.

The first paper was read by Dr. Joseph Tabb Johnson, of Washington, D.C., on

MANAGEMENT OF THE THIRD STAGE OF ABORTION, WITH RETENTION OF PLACENTA AND MEMBRANES.

After some general remarks on the subject of abortion and its treatment, he stated that the chief indication in the latter was to completely empty the contents of the uterus as early as possible. This view he regarded as important because, so far as he had been able to determine, a large number of the profession still held the opposite opinion. In support of it he quoted Dr. Angus MacDonald and other authorities.

He then cited a number of cases occurring in his own experience which showed the necessity for prompt action and the danger of leaving the placenta and membranes *in situ*. The majority of these he saw in consultation, after the membranes and placenta had been retained for a considerable time.

Incidentally he alluded to some of the unfavorable effects of ergot in certain instances, occurring in the early months of pregnancy, especially the intense pain to which it gave rise, and the closure of the os by the oxytocic effect of the drug, commencing in the lower segment of the uterus.

The point which he wished to emphasize was, that the patient was not safe until the uterus was completely emptied and firmly contracted, and that, as a rule, the physician should never leave the house until the desired results had been accomplished. After septicæmia had been set up by the retained placenta and membranes, it was often too late to interfere.

Dr. Sherman, of St. Lawrence, said that he commended the paper most heartily. He had been brought up to consider this practice correct, and in the only instance in which he had neglected it, the case had resulted fatally.

Dr. G. W. Christian, of Texas, and Dr. Erich, of Baltimore, spoke in the same strain. The latter related two cases showing the bad results of leaving the placenta *in situ*. In the removal of small fragments of the placenta or membranes he advocated the use of Thomas's short curette, which acted much more efficiently than the unaided finger, and it was also a perfectly harmless instrument.

In both cases mentioned prolonged menorrhagia ensued upon the abortion, and both were completely relieved by the dilatation of the os and the removal of the fragments of the placenta with the curette. In neither instance was there danger of septicæmia, however, as the portions of retained placenta remained living. He advised the use of anæsthetics in all cases of retained placenta, not only for the relief of the pain, but for the more thorough performance of the manipulation requisite.

Dr. Weeks, of Massachusetts, thought that the paper should have been devoted more to the *management* of the third stage, as it was important to know just how and when to carry out active interference.

Dr. Morris, of Baltimore, begged leave to say a word for the men of a past generation, who practised before septicæmia was recognized as it is to-day. He thought that the placenta should be allowed to remain as long as no injurious effect resulted. Na-

ture was quite competent to manage the great majority of cases of abortion occurring in the early stages of pregnancy. This matter of retained placenta he considered a needless bugbear in the eyes of many of the profession. He considered that the bad effect of this teaching was, that it induced the young practitioner to plunge into needless meddlesome midwifery.

Dr. S. T. Hubbard, of New York, advised, like the last speaker, that these cases should be left alone. His practice was to leave a tampon medicated with alum when there was much hemorrhage) in the vagina, and go away without feeling any uneasiness, and he had never seen any bad results from it. He considered that there was great danger of setting up metritis or metro-peritonitis by this active interference in abortion, in the early stages of pregnancy.

Dr. Thomson, of Montreal, also thought that there was little need of operative procedure under ordinary circumstances. When it was necessary to interfere, he thought the finger was better than the curette; especially as many cases of abortion were due to the presence of uterine tumors, and these could not be detached by means of the curette.

Dr. Maury, of Massachusetts, took exception to the views of the last few speakers. If a retained placenta was liable to produce septicæmia, it was our plain duty to remove it as soon as possible. He had known of many instances of death following such conditions, and therefore he considered that this was a most important question. He believed thoroughly in the use of the curette in such instances.

Dr. Weeks considered it very difficult to remove the entire placenta before it had become detached; and thought that great injury often resulted from the attempt to detach it. He advised the use of warm, carbolized water until nature had accomplished the detachment.

Dr. Erich spoke of the importance of examining all the clots passed, in order to find the ovum. His rule was to interfere whenever hemorrhage continued more than a week; which indicated that a portion of the ovum still remained.

Dr. H. T. Hanks, of New York, thought that in all cases where, after abortion in the early stages of pregnancy, a portion of the placenta or membranes remained, there was great danger, and it should by all means be removed. He stated, furthermore, that it was as easy to perform this procedure as to put in a properly adjusted tampon. It ordinarily took but two minutes to dilate the os (with a hard rubber, or other dilator), and two minutes more to remove the retained placenta.

Dr. Isaac E. Taylor, of New York, read a paper entitled

GASTRO-HYSTERECTOMY; BEING REMARKS ON AND EXHIBITION OF A FULL-TERM UTERUS, REMOVED BY LAPAROTOMY.

The writer dwelt for some time on the history of the operation, and then went on to speak of the case referred to in the title. The patient had a kyphotic pelvis, and five years before Dr. Taylor had delivered her by ovariotomy. There were two modifications of the operation of gastro-hysterectomy, Porro's and Müdder's, and he had added a third. Confident that there was a ductile isthmus between the body and the cervix of the uterus, after opening the abdomen and delivering the child by Cæsarian section, he placed two ligatures, almost an inch apart, around the pelvic and cut off the uterus between the two. Unfortunately, however, retraction of the arteries took place, and he found it necessary to put on a ligature with the "cobbler's stitch." The patient did perfectly well for some time after the operation, but on the seventeenth and eighteenth day phlegmasia dolens made its appearance. This subsided before a week but she was still ordered to remain strictly in bed. On the twenty-seventh day, however, she was attacked by cardiac thrombosis, and died in a few hours.

This unfortunate result, he believed, had no connection whatever with the operation performed. In conclusion Dr Taylor spoke of the various advantages of gastro-hysterectomy in deformed pelvis. Out of the fifty cases now reported, twenty-one had recovered. In connection with the paper, Dr Taylor exhibited the uterus removed, which he regarded as affording valuable proof in confirmation of his views as to the structure and action of the tissues of the lower segment and neck of the uterus, prior to and during parturition), and also a number of photographs of the patient and specimen.

At the conclusion of Dr. Taylor's remarks, Dr. Maury, of Massachusetts, exhibited a

NEW UTERINE DILATOR,

which operated by graduated elastic tension, and could also be employed by means of a special attachment for restoring the inverted uterus.

Dr. T. Gaillard Thomas, of New York, then read a paper entitled,

CLINICAL CONTRIBUTIONS TO THE SUBJECT OF REMOVAL OF THE UTERUS, IN WHOLE OR IN PART, BY THE EXTIRPATION OF TUMORS CONNECTED WITH THAT ORGAN.

There were three circumstances, he said, under which complete extirpation of the uterus might now be regarded as a legitimate, and often a very necessary procedure. 1. On account of malignant disease. 2. As an addendum to the Cæsarian section, after the method of Porro, and, 3, in order to render practicable the removal of tumors which took their origin in its tissues, or which arose in the ovaries, and whose attachments were too firm to be broken.

It was with the third class of these indications that the present paper was concerned. After quoting the opinions of Barnes, Emmet, and other authorities, who regard such operations as still *sub judice*, he stated that he was to-day giving evidence in favor of a young and feeble cause. An honest conservatism was the bulwark of scientific surgery; but, at the same time, there was no virtue so likely to run to dangerous extremes. In this connection, he alluded to the splendid triumphs of ovariotomy within the last few years, and said that it was with the desire to put upon record further testimony from which might be drawn reliable deductions as to the propriety of removing solid or cystic tumors by laparotomy, when such removal involved the necessity of ablation of the uterus, that this clinical condition was made.

The paper embodied the results of seven cases, in one of which the whole fundus, in another the whole body, and in five of which the entire uterus was removed. Four of the tumors demanding the operation were large solid fibroids with no cystic elements. One was a fibro-cyst, partly solid and partly fluid, and one a peculiar ovarian tumor which, developing between the layers of the broad ligaments, lifted the

uterus entirely out of the pelvis, and made it a mere addendum to their walls.

Out of the seven cases four recovered and three died. The three fatal cases were all operated on for large solid tumors. Of the four successful ones, one was a case of solid uterine fibroid, one a case of large fibro-cyst, and two cases of ovarian cysts with large amounts of solid material in their walls. On recognizing this fact it was to be borne in mind that a tumor susceptible of diminution of size by tapping was not so dangerous for laparotomy as one which, being entirely solid, involved the necessity for a long abdominal incision.

As far as Dr. Thomas knew, no one in this country had had so large an experience, and, he was glad to add, so gratifying a success in this formidable operation as their distinguished fellow, Dr. Gilman Kimball, of Massachusetts. He removed the uterus thirteen times (nine times for solid and four times for fibro-cystic tumors), with the excellent result of eight recoveries and five deaths. In some of his cases the whole, in others a part only, of the uterus was removed.

During this session the following committee in regard to papers presented was appointed: Dr. Bartlett, of Wisconsin; Dr. Marcy, of Massachusetts, and Dr. Morris, of Maryland.

SECTION ON DISEASES OF CHILDREN.

Dr. S. C. Busey, of Washington, D. C., Chairman.
Dr. Frank Woodbury, of Philadelphia, Secretary.

The new temporary Section on Diseases of Children was organized with an attendance of about forty members. On motion of Dr. A. Jacobi, of New York, Dr. S. C. Busey, of Washington, was elected Chairman; and Dr. Frank Woodbury, of Philadelphia, was elected Secretary of the meeting.

The Chairman said that this new Section owed its existence to the Committee of Arrangements, and to the need that has been felt for such an opportunity for special studies of diseases of children.

THE CLAIMS OF PEDIATRIC MEDICINE.

An address, by Dr A. Jacobi, of a very appropriate and interesting character, reviewed the claims of pediatric medicine. In commencing the address, he very pointedly referred to the difference between special practice and special study. His statements of the gradual encroachments of the various specialties upon the domain of the general practitioner created some amusement. In replying to the question: "What is left for the general practitioner?" he said, "The general practitioner will in future obtain, as the legitimate province of his practice, the male half of mankind, and very old women, and very young children, provided he will keep his hands off their eyes, ears, nervous system, lungs, and heart, urinary organs, venereal diseases, nose, pharynx, larynx, skin, hair, and corns." He pointed out the fact that the multiplication of specialists is due, first, to the immense progress of the science; and, secondly, to the attainment of special skill and dexterity by certain individuals, that leading them to select certain branches as their favorite practice.

The pathology and therapeutics of childhood do not mean the same as in adults; the difference is not merely a matter of dose, as is frequently supposed. The light that has been recently thrown upon infantile disorders, due to malformation, defective evolution, or to abnormal development, has led to great improvement in the methods of treatment. The peculiar characters of infantile bowel diseases, pulmonary affections, and zymotic diseases, require special study of children's diseases for intelligent practice. Functional disturbance also acquires more prominence in disorders of children than in adults. Since twenty per cent. of children do not survive the first year, and a very large proportion of these unfortunate cases of premature death are due to defective feeding, it was pointedly inquired whether special study is not required for the practice in this field of medicine, whose importance it is difficult to overestimate. A special section on the pathology of children would include the consideration of questions of hygiene, such as feeding, nursing, clothing, and baths. He concluded by declaring that the establishment of this section was required by practice even more than by theory, as the majority of the general practitioner's patients are infants and children with a symptomatology of their own, diseases of their own, and therapeutics adapted to their special requirements.

Dr. Jacobi moved that this meeting recommend the American Medical Association to adopt such an amendment to the Constitution as would create a Section on Diseases of Children.

Dr Busey, of Washington, and Dr. E. W. Schauffler, of Missouri, spoke in favor of the resolution, which was unanimously carried.

BRIGHT'S DISEASE IN CHILDREN.

Dr. S. C. Busey, by invitation, read a paper entitled "Bright's Disease in Children Caused by Malaria," in which he gave the clinical reports of three cases of children suffering from malarial cachexia, who subsequently presented all the appearances of marked renal disease. In these cases life is usually terminated by uræmia, pulmonary œdema, or cardiac insufficiency. Nutritious and easily digested food, and chalybeates constitute an essential part of the treatment; the citrate of iron and quinia is generally preferred in these cases. Digitalis (the tincture, or in the form of digitalin), cathartics such as elaterium and compound jalap powder, are especially indicated. In dropsy, Eberle's formula (without the tartar emetic) he had found very valuable. Diuretics are indispensable in proper cases, but unreliable in many.

Diaphoresis by the hot-air bath, or by pilocarpine is a useful adjunct to the treatment; and multiple puncture for the relief of œdema, was much lauded as a means of relief.

Dr. Schauffler, of St. Louis, did not see the direct connection between malaria and Bright's disease, and thought that the proposition was not proven.

Dr. Busey disavowed supporting the view that there was any direct relationship between renal disease and malaria; but if the latter be neglected it may lead to organic changes in the tissues, of which nephritis is a sequel.

Dr. Jacobi suggested that in such cases the renal disorder might be caused in two ways: first, lowering of circulation leading to albuminuria; though this is not inflammation; a spontaneous thrombosis may, however, occur from debility of the circulation under such circumstances, which might be the centre for such inflammation; malaria leads to extensive destruction of red-blood cells and the pigment circulating in the blood is known to lead to embolism

in other organs, and may give rise to nephritis, for there are some cases on record of Grainger and Rosenstein in which nephritis was due to malaria.

Dr. James L. Greene, of Elizabeth, N. J., reported a case of

CONGENITAL MULTIPLE LYMPHECTASIA,

in a male, born at eight months of utero gestation, who presented at birth a large cystic tumor upon the posterior portion of the pelvis. In the abdominal region in front, and at the right side, were two other cysts which had no connection with each other, or with the posterior tumor. Two days later the fluctuating tumor was aspirated and 120 grammes of fluid removed, which was clear, straw colored, specific gravity, 1007, slightly saline, and albuminous (about ½ on boiling); nothing but a few blood corpuscles were observed under the microscope. In ten days the sac refilled to its former size. Dr. A. Jacobi now saw the case and pronounced it one of lymph angiectasis, and recommended removal of a small portion of the fluid, and injection of a small amount of iodine. On two subsequent occasions this operation was repeated, very little disturbance being produced; the slight uneasiness of the child passed away in two hours. This tumor has considerably diminished in size, but the tumors in front, upon which no treatment was attempted, have increased, and a small one has been developed upon the left hip opposite the acetabulum.

Dr. Busey, being invited by Dr. Jacobi to discuss the paper, spoke at some length upon the pathology and treatment of lymph tumors, and said that a lymph tumor may be distinguished from varicose veins by the multiple character of the former, and by the isolation of the latter. If the vascular connection of the tumor can be reached, so that they may be obliterated, a good result may be hoped for. If treatment is neglected, the patient generally dies from phthisis after puberty.

Dr. Jacobi said that since the tumor is now smaller than at the beginning, the tincture of iodine injections should be continued, and more frequently repeated, being careful, however, not to excite too much febrile reaction in the child. He distinguished two forms, one in connection with lymph trunks, and the other isolated. In the former the injection of iodine is the best treatment; the latter kind may be extirpated, and he had twice dissected out such isolated tumors in adults.

A variety of methods of treatment by ablation and actual cautery, pressure, slow drainage, and other plans, were suggested.

Dr. Schauffler reported a successful case of excision of two such lymph-tumors, in the practice of Dr. Taylor, of Kansas City, since deceased. The child recovered from the operation, but subsequently a hard brawny growth appeared, like elephantiasis, which the same surgeon removed by dissection. The patient died on the second day without obvious cause, having completely rallied from the operation of the day before.

The Chairman of the Section, Dr. Busey, was authorized to present to the General Session, tomorrow, the resolution passed by this temporary Section, requesting the adoption of an amendment to the Constitution, creating a permanent Section on Diseases of Children.

The papers read were referred to the Committee on Publication.

SECTION ON MEDICAL JURISPRUDENCE, CHEMISTRY, PSYCHOLOGY, STATE MEDICINE, AND PUBLIC HYGIENE.

James P. Hubbard, M.D., Richmond, Ind., Chairman.

Thos. P. Wood, M.D., Wilmington, N. C., Secretary.

FIRST DAY, TUESDAY, JUNE 1st.

The Section was called to order by the Chairman at 2.15 P.M.

A paper by Dr. C. R. Drysdale, of London, Eng., on the

DEATH RATE OF THE RICH AND THE POOR,

was read by the Secretary in the absence of the author. He stated that the death-rate was higher among the poor, because of the low wages which they receive. Statistics were given to show that in countries where the people were prosperous, as in New Zealand and Australia, the mortality was not so great. Alcohol had been cited as one of the frequent causes of high death rates. This the author sought to disprove by means of various statistics. As to the mortality of trades, it was not the trade of itself that caused the increased number of deaths, but the small amount of wages that was given, insufficient for persons engaged in them to provide for the necessaries of life. In conclusion, the author said, if we wished to lower the death-rate, the birth-rate must also be lessened.

On motion, the paper was referred to the Association, with a request for its publication.

The next paper, on the

NATIONAL BOARD OF HEALTH,

was read by the author Dr. J. S. Billings, U.S.A., in which a summary of the formation of that Board was given, together with the work done by it, also its objects and purposes. In the course of the paper Dr. Billings recommended that the Chairman should appoint a Committee from the Section to report to the Association on several matters looking toward co-operation with the National Board.

On motion, the paper was referred to the Association, with a request that it be published. At a later stage of the proceedings, the chairman appointed Drs. A. N. Bell, of Garden City, N. Y., Thos. Antisell, of Washington, D. C., and E. M. Moore, of Rochester, N. Y., as a committee to carry out Dr. Billing's proposals.

The next paper, on

THE RELATIONS OF THE MEDICAL AND LEGAL PROFESSIONS TO CRIMINAL ABORTION,

was read by the author, Dr. E. H. Parker, of Poughkeepsie, N. Y. The article was based on three cases of criminal abortion, in two of which the parties implicated escaped punishment, in the third the physician who operated was convicted, but pardoned before completing one-half of the term for which he was sentenced. The main object of the paper was to rid the community of the prevalent idea that abortion was not a grave offence. He advocated that the full penalty of the law should be inflicted. In concluding, the following resolutions were offered:

"1. Abortion should never be brought on by the use of medicinal or instrumental means, unless necessary to the safety of the mother, in consequence of pathological complications.

"2. The destruction of the fœtus in utero for any

other reasons properly ranks with other forms of murder.

"3. Abortion produced artificially always places the mother's life in jeopardy, and thus becomes a double crime.

"4. The severe punishment of the operator, whenever possible, without any probability of executive clemency, is due in justice to the honorable members of the profession, and yet more to the community at large."

The discussion which followed was participated in by Drs. Antisell, of Washington, D. C.; Stevenson, of Poughkeepsie, N. Y.; and Edwards, of West Virginia, all of whom held that the law was already sufficiently explicit on the subject. On motion of Dr. J. M. Jones, of Washington, D. C., the resolutions were, on division, laid upon the table, and the paper was referred to the Association, with a request for its publication.

The next paper, on

UNSANITARY ENGINEERING AND ARCHITECTURE,

was read by the author, Dr. A. N. Bell, of Garden City, N. Y. Details were given of the defective sanitary arrangements of various public buildings and the means of remedying it. The paper was discussed by Drs. Antisell, of Washington, D. C.; Whitney, of New York State; Mead, of Philadelphia, and Moore, of Rochester, N. Y., without eliciting any new facts. The paper was referred to the Association, with a request for publication.

On motion, the Section adjourned at 4.50 P.M.

Second Day—Wednesday.

The Section was called to order by the Chairman at 2.20 P.M.

The proceedings were opened by the reading of some resolutions by Dr. A. Clendennin, of Fort Lee, N. J., which had been passed by the Association. They are as follows:

"Whereas there have been many complaints as to the centralized imperial character of the present National Board of Health; and, whereas, the bills which have been pending before Congress for the increase of the executive power of the present board have been withdrawn,

"Therefore, be it resolved that the proposed act, entitled an act to amend an act . . . to create a Board of Health for the United States be referred to the Section on State Medicine and Public Hygiene for its consideration and report."

The act was then read, the main provisions being that it abolishes the present Board of Health, and in its place substitutes a board composed as follows: One medical officer each from the Army, Navy, and Marine Hospital Service; the chief officer of the Weather Bureau; also one officer each from the Engineer Corps, and Department of Justice. These to be appointed by the President, with the advice and consent of the Senate. Each State or Territory to be represented by a member of its State Board of Health, when such exists, who shall be appointed by the Governor of the State or Territory; and also an additional member selected from the Board of Health of the most important seaport in such State. There shall be no more than two members from each State, each of whom shall receive ten dollars per diem when serving. Then follows details as to the duties and powers of the board.

Dr. Edwards, of West Virginia, offered resolutions to the effect, that the passage of the bill would be impracticable and unadvisable, and also, that the present National Board is satisfactory in its workings and organization.

Dr. Billings, U. S. A., said that the present organization was as good as could be obtained from Congress. He spoke of the cumbrous character of the proposed board, as well as the extra expense involved, the cost for each day's sitting being over eight hundred dollars, exclusive of travelling expenses.

Dr Clendennin said that the National Board had asked for additional powers which Congress had refused to grant, and that the bills had subsequently been withdrawn by the Board. He also stated that the proposed bill sought to remedy existing defects.

Dr. Billings made some further remarks, in which he showed that three bills had been introduced during the present session of Congress, one had been passed; another, which the Board did not approve, had been shelved, as well as the third one, which conferred slight additional powers.

Drs. A. N. Bell, of Garden City; E. M. Hunt, of Metuchen, N. J., and E. G. Janeway, of this city, participated in further discussion, after which Dr. Edwards' resolutions were passed.

In the absence of Dr. R. C. Redzie, of Lansing, Mich., a paper by him on the

TEMPERATURE OF LIVING ROOMS,

was read by the Secretary. There was no discussion.

Dr. A. L. Carroll, of New Brighton, N. Y., read a paper on

THE PERSONAL FACTOR IN THE ETIOLOGY OF PREVENTIBLE DISEASE.

The author spoke of there being two factors to be considered in all preventible diseases, viz.: the exciting causes or predisposing influences and the susceptibility of the patient. There was a marked proclivity of some persons to being affected with certain diseases, when others exposed to the contagion would remain free from the malady. Examples of such were given. A third factor often exists, formerly spoken of as the "epidemic constituent of the atmosphere," when there was was increased tendency to the reception of contagion. This is seen when persons escape from attacks of disease, at one time, and are attacked at another season, when the system is more susceptible to the effects of the person. There was no discussion.

Dr. E. C. Angell, of this city, then read a paper on

HOT-AIR BATHING AS A MEANS OF PROMOTING HEALTH AND PREVENTING DISEASE,

in which he gave an account of baths in different countries, and spoke of the lack of bathing accommodations for the poorer classes in this city. There was no discussion.

An abstract of a paper on

MICROSCOPICAL SECTIONS FROM CASES OF DISEASES OF THE BRAIN AND SPINAL CORDS,

was read by Drs. Chas. R. Mills and Carl Seiler, of Philadelphia. Numerous sections through the cerebro-spinal matter were shown, which had been taken from the following cases—one of posterior spinal sclerosis terminating in general paralysis of the insane; one of hydrocephalus; two of epilepsy, and one of hydrophobia.

On motion, the Section adjourned at 4.55 P.M.

SECTION OF OPHTHALMOLOGY, OTOLOGY, AND LARYNGOLOGY.

Dr. Lawrence Turnbull, of Philadelphia, Chairman.

Dr. Eugene Smith, of Detroit, Secretary.

The second session of this Section was called to order by the Chairman at half past two o'clock. A paper entitled

THE THERAPEUTIC VALUE OF THE GALVANO-CAUTERY IN DISEASES OF THE NASO PHARYNX,

was read by Dr. W. H. Daly, Pittsburg, Pa. The author proceeded to elucidate the application of the galvano-cautery in destruction of the turbinated bones, granulation tissue, and adenoid growths, alluding to its possible accidents, as erysipelas, destruction of the septum nasi, eschar of the mouth of the Eustachian tube, with consequent otitis media purulenta and perforation of the membrana tympani. Dr. D. has used the cautery extensively in these cavities with success. Subjective and objective symptoms following its use were detailed, as, for instance, pain in the eye of the same side when the cautery is applied to the anterior ends of the turbinated bones, pain in the opposite ear when the cautery is applied farther back, etc. It is found that the more posterior the application the more insensitive are the parts. Some patients exhibit symptoms of approaching chill and fever after the application of the galvano-cautery. Dr. D. doubts its general acceptance on account of its expense and capricious behavior; its application, however, is attended with less pain and more surety than the usual caustics, nitrate of silver, caustic potash, etc. No remarks followed the reading of this paper.

Dr. H. Knapp proceeded to a demonstration of models to illustrate

THE REFRACTION OF LIGHT BY ASYMMETRICAL SURFACES,

to be followed by remarks on the determination and correction of astigmatism.

The principles of astigmatism are well known. Refractions from asymmetrical surfaces, and Sturm's focal intervals were detailed on the blackboard. Intermediate surfaces between the principal meridians have no foci. Suppose these surfaces are applied to the cornea; as these surfaces are rotated around an antero-posterior diameter, a parabolic ellipsoid is formed, the normals of whose principal meridians (vertical and horizontal) form regular surfaces, and have constant foci; but the intermediate meridians furnish in rotation no regular planes; this irregularity of planes of the intermediate meridians makes the location of focal points impossible. An ellipsoidal spheroid was introduced with vertical, horizontal, and intermediate meridians represented by pins, by which it was easy to see that the last-named planes were irregular and "askew" (K.).

Sturm's model makes the demonstration of ametropia possible, but not that of astigmatism. The familiar model of Helmholtz renders the demonstration of astigmatism possible, as may be seen by the different adjustments of the safety pins upon the strings.

With this theoretical demonstration the statement was made that the determination of astigmatism was possible by the direct application of these principles. Dr. K. always uses Snellen's test-types, first applying spherical glasses and then correcting the refinements of refraction by the successive application of weak cylindrical glasses, as in the ordinary way.

Schweigger and Scholer, of Berlin, determine astigmatism with a Stokes' lens. Scholer uses also a double disked ophthalmoscope, one disk containing spherical, the other cylindrical lenses, which is not practical, nor is the Stokes lens. The latter, however, is used by Horner, of Zurich, one of the most practical European oculists. The old principle of endeavoring to see the smallest retinal vessels in the horizontal images is the most correct one to follow. K. introduces a model illustrating three points of retinal focalization at different positions on the same vertical meridian.

A vertical line, divided into three colored threads, gives dispersion lines, and final dispersion images in the same vertical direction, but these images are superposed over each other. Dr. K. deduces from this the use of simple spherical lenses in the ophthalmoscope disk, as the most feasible. A case was detailed of compound hyperopic astigmatism in the right eye, and of simple hyperopic astigmatism in the left eye of the same patient, which was diagnosed within $\frac{1}{24}$ Eng. or 0.5 dioptry. Dr. K. does not correct a power of astigmatism less than $\frac{1}{24}$, as the physiological astigmatism is from $\frac{1}{24}$ to $\frac{1}{12}$. The scope of this paper was happily attained in so far as it served to elucidate the interesting subject of relief for astigmatic patients. The physics of astigmatism as brought out years ago by Airy and Young, and studied latterly by Helmholtz and Knapp, have not changed; to correct spherical aberration in astigmatic eyes by a system of glasses, constructed after proper scientific and mechanical laws, is the aim of the oculist.

Dr. Smith, the Secretary, presented an enucleated eye, in which there was a bony degeneration of the lens, or an osseous proliferation proceeding from the choroid. The eye was shrunken from preservation in spirits.

Dr. S. S. Jones, of Chicago, volunteered a paper

ON THE INTRODUCTION OF LIQUIDS INTO EUSTACHIAN TUBES AND MIDDLE EAR.

The attempts of Sir Astley Cooper, in 1800, by puncturing the membrane, and pushing air through the external meatus and Eustachian tube; and, later, of Horner, of Philadelphia, of Hinton and Allen, of London, induced the author to resort to one or the other means of introduction of entrance into the tube—that is, by the nares or external ear. He has used liquids in this way for nine years, and is convinced of its advantage in dry, chronic, non-suppurative inflammation of the middle ear. Dr. J. reverses Horner's method of procedure, and introduces liquids through the Eustachian catheter into the tube. He claims that the tube is thus more easily dilated, and will finally better admit air. He has abandoned bougies as dilators. He argues from the benefit derived by proper applications to the post-nasal cavity and pharyngeal vault a similar benefit from the local contact of fluids of proper temperature to the Eustachian tube or cavity of the middle ear. He thinks, too, that the bad influence of sea-bathing upon the middle ear has been overestimated. In a service of two years as naval surgeon in the war of 1861-65, extending from Maine to Georgia, he noticed less acute inflammation of the middle ear when the temperature allowed sea-bathing on the part of the sailors, than when the thermometer was so low as to prevent it. Dr. J. advised slightly saline tubal injections on account of their better tolerance than pure water, or weak

solutions of borax, chlorate of potash, etc. Their temperature should be at blood-heat, no force should be used, and the quantity should be regulated by the amount of effect desired. The comfort of the patient, and the subsequent improvement in hearing operate in the author's hands as warrants for the continuance of the practice.

Dr. Ritchey, of Washington, D. C., finds great advantage in the use of warm injections into the tube. He first uses warm air, and later warm solutions. In a practice of five years he has not found a single acute inflammatory result. In the cases hitherto noted a chill has preceded the inflammatory symptoms, showing changes in the general circulation.

Dr. Knapp's experience is entirely opposite to that of Dr. Jones.

Dr. J. J. Chisholm, of Baltimore, agrees with the author, provided the injections are weak and warm, and uses muriate of ammonia, bicarbonate of soda, or any of the milder alkalies.

Dr. Noyes, of Detroit, corroborated the benefits of judicious tubal injections; he details a case in which a bulging membrani tympani is punctured, with an exit of pus; the Eustachian way is then washed out with warm water successfully. A later case was unsuccessful, and Dr. N. has since abandoned the use of intra-tubal injections.

Dr. Reynolds, of Louisville, Ky., would limit such local medication to cases of drum-membrane sloughing.

Dr. Pomeroy, of New York, is much opposed to the injection of all fluids on account of inflammatory results in the middle ear. In chronic cases of proliferating catarrh, he treats the tube alone and not the tympanic cavity. There is danger of making too strong applications to the ostium tubæ Eustachii; even these must be sparingly and moderately used. Retention of foreign fluids in the tympanic cavity is a danger always to be thought of—as well as the reaction upon the tubal walls themselves.

Dr. Chisholm, of Baltimore, in an experience of over 1,000 injections into the tube, has not found more than five or six cases of resulting inflammation. He injects the post-nares in the ordinary way, and drives the residual fluid into the tube by air-inflation.

Dr. Ritchey thinks that Dr. Jones's method of injecting through the catheter is preferable, because it is more under control, and the quantity of entering fluid can be accurately estimated. He has never seen any bad results, having confined his medication to mild alkaline solutions.

Dr. Holcombe, of New York, has long since abandoned such injections. The use, as of old, of injections of nitrate of silver, and the salts of iron, should be abandoned. Dr. H. still uses iodized vapors, with impunity. In 1852, he first saw Triquet inject air into the Eustachian tube.

In recapitulating the points adduced, Dr. Jones, the author, thinks it not only possible to enter the middle ear by the tubal way, but also practicable. He would not use such strong agents as solutions of the metallic astringents. Here enters the question of possible advantage of an induced attack of non-suppurative catarrh. While it is not a risk to be taken *ad voluntatem*, it has, nevertheless, certain advantages.

Dr. E. Gruening, of New York, volunteered a paper on Wickersheimer's preservative fluid for animal substances.

The Prussian Government, a few months ago, bought and published the following formula: To 3,000 parts of boiling water put 100 parts of alum, 25 parts of common salt, 12 parts of saltpetre, 60 parts of carb. of potash, 10 parts of arsenious acid. Cool and filter, and add to ten parts of this solution, 4 parts of glycerine, and 1 part of methylic alcohol.

In the *Centralblatt f. die med. Wissenschaften* for January, 1880, Dr. Boersicke states that the formula published by the Prussian Government contains two errors. B. obtained a different formula directly from Wickersheimer, in which, instead of 10 parts of arsenious acid and 1 part of methylic alcohol, there should be 20 parts of the acid and 4 parts of methylic alcohol. Dr. G. presented specimens of both mixtures as prepared by different chemists. The government formula is slightly opalescent, while that of Boersicke is perfectly clear. The first preserves the refractive media of the eye, while the second does not.

A small, soft eye, which had lain three months in the Government fluid, shows the same depth of anterior chamber, a clear cornea, and an unchanged blue iris. The glioma retinæ, for which the eye was removed, can still be diagnosed by the naked eye. An albinotic rabbit's eye having lain in the same formula the same length of time, shows the media clear, and gives the pink reflex. With the Boersicke mixture, preservation is less perfect; the lens becomes opaque in a few hours, and the cornea dim after a few days, as if it had been placed in absolute alcohol.

On motion of Dr. Burnett, of Washington, an unanimous vote of thanks was tendered Dr. Gruening for this valuable acquisition.

At 4.30 P.M. the Section adjourned to meet on Thursday at 2 o'clock.

GENERAL SESSION.

Thursday, June 3—Third Day.

The Association was called to order at 10 A. M. by the President.

The first business in order was

THE REPORT OF THE COMMITTEE ON NOMINATIONS.

Dr. W. O. Baldwin, of Alabama, Chairman, read the following report:

For President—John T. Hodgen, M.D., of St. Louis, Mo.

For Vice-Presidents—1st, W. H. Anderson, M.D., of Mobile, Ala. 2d, Levi G. Hill, of New Hampshire. 3d, Henry T. Holton, of Vermont. 4th, H. Carpenter, of Oregon.

For Permanent Secretary—W. B. Atkinson, M.D., of Philadelphia, Pa.

For Treasurer—R. Dunglison, M.D., of Philadelphia, Pa.

For Librarian—William Lee, M.D., Washington, D. C.

For Chairman of the Section on Practice of Medicine, Materia Medica, and Physiology—Dr. Charles Denison, of Colorado.

For Secretary—Dr. T. A. Ashby, of Maryland.

For Chairman of the Section on Surgery and Anatomy—Dr. H. McGuire, of Richmond, Va.

For Secretary—Dr. D. A. Eve, of Tennessee.

For Chairman of the Section on Obstetrics and Diseases of Women—Dr. James R. Chadwick, of Boston, Mass.

For Secretary—Dr. J. Taber Johnson, of Washington, D. C.

For Chairman of the Section on Medical Jurisprudence and State Medicine—Dr J. T. Reeve, of Wisconsin.

For Secretary—Dr R. O. Young, of Arkansas.

For Chairman of the Section on Ophthalmology, Otology, and Laryngology—Dr D. S. Reynolds, of Ky.

For Secretary—Dr. S. M. Burnett, of Washington, D. C.

For Members of the Judicial Council, to fill vacancies—Drs. J. K. Bartlett, of Wisconsin; F. Staples, of Minnesota; D. R. Wallace, of Texas; J. S. Billings, of U. S. Army; J. H. Warren, of Massachusetts, and A. F. Woodward, of Vermont.

The Committee recommended that the next meeting of the Association be held in the City of Richmond, Va., on the *first Tuesday* in May, 1881.

As Chairman of Committee of Arrangements—Dr F. D. Cunningham, of Richmond, Va.

The Committee further recommended that the Committee on Necrology and the membership of the Section on Medical Jurisprudence, State Medicine, and Public Hygiene remain as now constituted. The report was adopted unanimously.

Dr. Denison offered his resignation, which was accepted, and referred to the Committee on Nominations.

Dr. Bigelow, of Massachusetts, offered the following preamble and resolution, which was adopted:

Whereas, The published proceedings of various sections of the Association does not receive the practical expression desired, and does not represent the labors of its members; and whereas, the members of the Association have long felt that the present mode of introducing the Transactions to the profession has been unsatisfactory to all concerned in the advancement of medical science; therefore

Be it Resolved, That a committee of five be appointed by the chair to report at the next session regarding the practicability of formulating all the proceedings in journalistic form, as recommended by the President in his Annual Address. Carried.

MEMBERS BY INVITATION.

The following were elected as members by invitation: Dr. D. H. Shields, of Hannibal, Mo., endorsed by Drs. C. H. Hughes, John T. Hodgen, A. J. Steel, P. G. Robinson, T. E. Holland, Geo. Homan, B. W. Hughes; Dr. W. J. Lumsden, Elizabeth City, N. C.; Dr. W. B. Chase, of Brooklyn, N. Y.; Dr. Wm. Stevens, of Cairo, N. Y., and Dr. A. Nellis, Jr., Montgomery Co., N. Y.

The Report on Sanitaria, presented by Dr. H. I. Bowditch, of Massachusetts, was read by title, and referred to the Section on Public Hygiene.

The members of the Association were invited by Dr. J. Jeffries, of Boston, to test their eyes for color blindness.

Dr. J. S. Billings, of Washington, D. C., reported on

THE CATALOGUE OF THE NATIONAL LIBRARY,

that Congress had made provisions for the publication of the volumes, of which the first would probably be published in July, 1880, and the second in July, 1881.

The following amendments to the Constitution, proposed by Dr. John H. Rauch, were adopted:

Article II., second paragraph, after "Army and Navy," insert "and the Marine Hospital Service of the United States."

Article II., fourth paragraph, at the end insert "the Marine Hospital Service of the United States shall be entitled to one delegate."

SECTION ON DISEASES OF CHILDREN.

Dr. S. C. Busey, of Washington, offered an amendment to the By-Laws, making provision for a new Section to be designated as Section VI., Diseases of Children. Adopted, and referred to the Committee on Nominations.

The consideration of the report of the

METRIC EXECUTIVE COMMITTEE

being next in order, it was read by Dr Atkinson, who moved its adoption. Discussion followed which was participated in by Drs. Brodie and Fairbanks, of Michigan, and Bronson, of Massachusetts, who opposed it, and Cole of California, Hunt of New Jersey, Antisell, of D. C., and Lyons, of Connecticut, in favor of the report, which was adopted by the Association.

The following were the propositions recommended by the Committee, and adopted by the Association:

First. That it recommends the teaching and practice of the metric system in medical colleges, clinics, dispensaries, etc.

Second. That it charges its Executive Metric Committee with the duty to report annually on the above institutions which teach, and those which do not teach the metric system.

Third. That it authorizes said committee to enter into communication with the Metric Committee of the British Medical Association, in order to concert such plans as may render the use of the metric system simultaneous and uniform in both countries.

Dr. Theophilus Parvin, Chairman; Dr. Edouard Seguin, Secretary; Drs. Edward Wigglesworth, and F. R. Weist, Executive Metric Committee.

RESOLUTIONS.

Dr. Reynolds, of Louisville, offered a resolution requesting Congress to remove every obstacle to the full execution of the plans of John Gamgee, for the building of a refrigerating ship, etc., which on motion by Dr. Hunt, of New Jersey, was laid upon the table.

Dr. W. M. Beach, of Ohio, offered a resolution making provisions for the appointment, by the President, of a committee of *five*, whose duty it should be to endeavor to secure for the medical staff of the army and navy a social position co-equal with that for like grades in any department of the service. Adopted.

REPORT FROM THE JUDICIAL COUNCIL.

Whereas, A protest without signature, against the registration of the delegates from the Medical Staff of the U. S. Navy, and unaccompanied by charges, had been placed in the hands of the Judicial Council, therefore,

Be it *Resolved*, That the protest against the registration of delegates from the Medical Department of the U. S. Navy is not sustained, and therefore there was no cause for action thereon. Adopted.

Resolved, That the Hannibal Medical Society of Missouri is not entitled to representation in the American Medical Association, because it is not in affiliation with its own State Medical Society. The protest therefore was sustained.

Dr. James F. Hibberd, of Richmond, Ind., Chairman of the

SECTION ON MEDICAL JURISPRUDENCE, STATE MEDICINE, AND PUBLIC HYGIENE,

then delivered an address, of which the following is an abstract. After some general remarks, in the course of which the interesting fact was brought for-

ward that *in all previous time*, with reference to public hygiene, there had been published 459 documents of all kinds as against 1,525 published during the last year, Dr. Hibbard passed to the consideration of certain questions under the head of *medical jurisprudence*. Passing the literature of the subject, which was meagre, the Chairman spoke of the request made by Congress of the Academy of Sciences to report upon some better way of legally taking human life than by hanging. It seemed unaccountable, while life was destroyed so easily, so surely, and so promptly by the taking of prussic acid or by the aid of a powerful current of electricity, that the process of hanging should have continued so long without effective remonstrance. In connection with this topic, allusion was made to the step of progress made recently by Judge Heller, of Indianapolis, in fixing *Wednesday* instead of Friday as the day upon which the law should be executed by hanging, and thereby breaking into the almost universal custom that had sustained and nourished prejudice and superstition which had been specially unhealthy in its influence upon all classes of people.

The second part of the address was devoted to certain questions connected with *psychology*, which in its general sense had had a very active state imposed upon it by recent investigations concerning the functions of the brain. Of psychologists there were two classes; first, theological, and second, scientific. The former were earnest, active, positive, and the latter, to which physicians mostly belonged, had become thoroughly aroused to the necessity of investigations to determine whether certain parts of the brain give rise to certain attributes of mind, or whether the brain as a whole is the organ of the mind as a whole.

There was no broad dividing line between the theological and the scientific investigator, yet their courses were entirely distinct from each other. There was not necessarily, however, any conflict between them. For a long time the brain had been recognized as the organ of the mind; but to the investigations of Hitzig and Fritsch was the new impulse due which had led many observers subsequently to pursue study in the same direction.

In connection with this topic, reference was made to the increase in the number of the insane, and that led to the consideration of the questions, How far should the State assume the guardianship and maintenance of the insane? and What was the best method of proceeding?

These questions were fully discussed, with an expression of opinion that special training was not necessary to the proper treatment of the insane, any more than for the application of therapeutics in the treatment of any other brain disease or morbid condition of the system generally.

The speaker then directed attention to a social aspect of psychology, and spoke of it from the point of view of hereditary transmission of disease, and, as belonging thereto, the transmission of the tendency to intemperance and the commisson of certain crimes. Would it not be discovered presently that all such irregularities—crimes if you choose—are due to imperfect nervous systems, and may not the tendency to such be transmitted? If due to a disordered brain, may not that react and lead to degeneration and disease of other organs? Under the head of *State Medicine*, Dr. Hibbard referred to the lack of uniform and well-considered plans with municipal and local boards of health for operation, and then entered somewhat into detail with reference to the working of the National Board of Health and its ability to meet the demands of the hour without in any way interfering with local or State organizations. Some of the criticisms upon the work performed by the National Board were then considered, and special reference made to the fact that sanitary science was yet in its infancy; that it was only a few decades since offerings had been made to Hygeia. Its influence was felt not only in this country, but had already become international.

Dr. Gama Labo, of Brazil, was introduced to the Association.

COMMITTEES.

The President announced the following committees: To carry out Dr. Bronson's resolution offered in the early part of the session: Drs. W. W. Dawson, Ohio; J. R. Bronson, Mass.; W. H. Pancoast, Pa.; N. C. Husted, N. Y.; J. S. Green, N. J. On the President's Address, Drs. Chaillé, La.; S. D. Gross, Pa.; J. S. Weatherley, Ala.; J. R. Bronson, Mass., and W. R. Gillette, N. Y. To report in 1881.

Dr. J. M. Toner, of Washington, D. C., then read

THE REPORT OF THE COMMITTEE ON NECROLOGY,

which was referred to the Committee on Publication.

DELEGATES TO THE CANADA MEDICAL ASSOCIATION.

Drs. C. N. Brush, Buffalo, N. Y.; James R. Leaming, New York, N. Y.; D. H. Goodwillie, New York, N. Y.; Wm. Brodie, Detroit, Mich.; W. B. Ulrich, Pittsburg, Pa.

DELEGATES TO EUROPEAN MEDICAL SOCIETIES.

Drs. R. Beverly Cole, Cal.; Benj. Lee, Pa.; M. A. Pallen, N. Y., and L. D. Bulkley, N. Y.

LIBRARIAN'S REPORT.

The Secretary then read the report of the Librarian, in which it was stated that the library contained 1,302 distinct titles, constituting 3,258 volumes. The Librarian asked for $200 with which to carry on the work of the library.

The report was accepted, ordered entered upon the minutes, and an appropriation for the amount of money named granted.

The Association then adjourned to meet at 10 A.M. June 4th.

SECTION OF PRACTICE OF MEDICINE, MATERIA MEDICA, AND PHYSIOLOGY.

J. S. Lynch, M.D., of Baltimore, Chairman.
W. C. Glasgow, M.D., of St. Louis, Secretary.

The first paper was by Dr. A. D. Rockwell, of New York, on

ELECTRICAL TREATMENT OF EXOPHTHALMIC GOITRE.

In regard to the current to be used in exophthalmic goitre, every physiological consideration and all experience points to galvanism as prominently indicated, and yet he would bear testimony to the fact that the faradic current is not altogether useless. The applications, however, must not be local, but *general*, after the method of general faradization; and in a certain proportion of cases, where there is anæmia, with marked nervous irritability, benefit will certainly follow. In the use of the galvanic current upon which we are mainly to rely, Dr. R. had obtained good results by placing the cathode over the cilio-spinal centre, and the anode in the auriculo-

maxillary fossa, gradually drawing the anode after a few moments of stable treatment along the inner border of the sterno-cleido muscle to the lower extremity. The second step in this process consists in removing the anode to the position occupied by the cathode, not leaving for a minute or no longer a greatly increased strength of current. In one case, failing after considerable effort to accomplish more than a very moderate degree of amelioration, the speaker made use of currents that were rapidly increased and diminished every few seconds by means of a rheostat, and with very great benefit. Subsequently to this, he came across a case published originally by Dr. Ancona in the Giornale Veneto di Scienze Mediche, where an obstinate and severe example of Graves's disease had been cured by distinct interruptions of the current, the electrodes being placed on either side, just below the angle of the lower jaw. The cure was accomplished only after the administration of 100 applications. In addition to the four cases that he had previously published, Dr Rockwell gave in detail the history of five additional cases. Of a total of nine cases, four completely recovered, one approximately recovered, two were much benefited, while in two cases no form of treatment proved of essential service.

In another case the pulse only was improved. In a fifth case there was an intermittency in the pulse, which ceased on the application of the galvanic current. The paper being open for discussion.

Dr. Chas. K. Mills, of Philadelphia, spoke of the importance of knowing definitely how much galvanic applications really affected the sympathetic system. He believed that they were of benefit in certain cases, but he did not see how any electrical applications could be said directly to affect the sympathetic. He thought it probable that the sympathetic was affected reflexly, if at all. Dr. Rockwell spoke of applying the current to the solar plexus. He (Dr. Mills) hardly thought it possible to do this. Dr. Mills had used the galvanic current in exophthalmic goitre, and it had produced good results, but he thought these were probably caused by the general tonic effect of the electricity, and perhaps also by its reflex influence.

Dr. J. J. Caldwell, of Baltimore, said: We should be thankful to Dr. Rockwell for his clear ideas in the causes and treatment of exophthalmic goitre. We can truly say that he and Dr. Bartholow have now done much to clear up the mysteries in this rare occult neurosis. Dr. C. thinks this a disease of the vaso-motor centres, and gave an illustration to prove the same—especially through the demonstration of Kidder's faradic electrical apparatus, preferably, because of their full and reliable currents with steady tension.

Dr. Geo. M. Beard, of New York, said that it was known positively that we can affect the cervical sympathetic by the electrical current. But the effect is very small and it is a question how much the therapeutical results caused by electrical applications are due to this. Another point which he would refer to was that the results produced by electricity are not caused by electrolysis or by any chemical decomposition.

Dr. Mills said that it is very indefinite to speak of diseases or influences on the sympathetic system. It might possibly be just as well to place the electrodes in other parts of the body as on the neck, for the neck is a somewhat dangerous place to apply electricity.

Dr. Rockwell said, in reply to a question by Dr. Harrison, of Ontario, that he generally placed the anode in the fossa behind the ear and the cathode on the back of the neck. This position he at intervals reversed, putting the cathode where the anode was, and the anode on the opposite.

Dr. J. Solis Cohen then described a new method of treating chronic pulmonary complaints by

ARTIFICIAL INFLATION OF THE LUNGS.

He showed a small rubber instrument like the bulb of a Davidson syringe, with a short rubber tube attached. The end of the tube is placed in one nostril, and air is then forcibly injected. This enables the patient to get rid of accumulations of mucus and pus, relieves cough, and often secures sleep the same as an opiate.

A paper was read by Dr. L. Duncan Bulkley, of New York,

ON THE USE OF SULPHUR AND ITS COMPOUNDS IN DISEASES OF THE SKIN.

Dr Bulkley spoke of the great popularity which sulphur had had in the treatment of skin diseases, and of the indiscriminateness of its employment. His present aim was to show in exactly what diseases sulphur really relieved and how it should be administered. He proposed to discuss its effects when given internally and externally, and also the effects of its different compounds and of the mixtures containing it.

First, as to its internal use. Pure sulphur was seldom given alone for skin disease. In eczema about the anus and genitals, however, it is very useful, especially if there is any constipation or piles. It may be given with equal parts of cream of tartar, in teaspoonful doses. Sulphurous acid (SO_2) is rarely used internally.

Sulphide of calcium is very valuable in skin lesions attended with suppuration. In *acne* it is often useful, but chiefly in those cases which have a considerable pustular element. It is not of much use in acne rosacea. In *furunculosis*, relieving not only the symptoms, but preventing further crops of boils. Like testimony may be given regarding its effects in carbuncle and suppurating bubboes. True, non-parasitic *sycosis* is sometimes benefited by sulphide of calcium. The drug is liable to be poor, and should have its characteristic smell of sulphuretted hydrogen. Dr. Bulkley usually gave gr. $\frac{1}{4}$ q. i. d.

Sulphuret of potassa probably has the same effect as the sulphide of calcium.

It is undoubtedly the sulphur that does the good in these cases, for other combinations of sulphur, such as the hypophosphite and sulphuric acid, have been found similarly beneficial. A wonderfully valuable combination of sulphur is that known as "Startin's Mixture":

R. Magnes sulph.	ʒ i.
Ferri sulph.	ʒ i.
Acid sulphur. dil.	ʒ ij.
Tr. gentian	ʒ i.
Aquæ	ʒ iij.
M. Sig.—ʒ i. dose after meals	

This is very potent in reducing cutaneous congestion in such conditions as erythema multiforme, erythematous eczema, and urticaria.

In regard to the use of natural sulphur waters, some benefit is obtained from them, but it is impossible to speak definitely of them until more data are

collected. The speaker would be pleased to receive help from any in collecting such facts.

Externally, sulphur has gained its widest reputation in the treatment of scabies, for which it is almost a specific. It should be remembered that sulphur is an irritant to the skin.

Besides scabies, sulphur is beneficial in acne, either in the form of the pure sulphur or the hypochloride, the latter being used as an ointment, about ʒ i. to ℥ i. Sulphur will also destroy the parasite of favus, ringworm, and tinea versicolor, pure sulphurous acid being the best form for these.

Sulphur vapor baths are of value in very few diseases of the skin. They stimulate the skin and liver, and they destroy skin parasites. But not much more can be said for them.

The paper being open for discussion,

Dr. Chancellor, of Virginia, testified to the great efficacy of mineral spring waters in skin diseases. In strumous troubles, in syphilides and eczemas, he knew that the sulphur springs of Virginia and other States were very efficacious. In parasitic diseases they are also very valuable.

Dr. Ulrich, of Pennsylvania, commended Dr. Bulkley's paper because it defined the limits of the usefulness of sulphur.

Dr. Brodie, of Detroit, Mich., said that he had not seen the benefit from sulphur springs that many claimed. Even parasitic diseases could be cured more easily by simple local treatment. In lead-poisoning, however, he had seen very good results. He thought that, as a rule, cleanliness and local applications were just as good as sulphur baths.

Dr. J. V. Shoemaker, of Philadelphia, said that he differed from the speaker in regard to the little value of sulphurous acid internally and the great value of sulphide of calcium. He had used the acid very successfully in urticaria. The sulphide he had found to disagree with the digestion.

Dr. Turnbull, of Philadelphia, had found that the sulphide of calcium interfered with digestion so much that he often had to give it up. The bisulphite of soda, however, was an excellent substitute.

Dr. Chapman, of Brooklyn, spoke of the value of diet in skin diseases. In a case of eczema related he gave sulphurous acid and glycerine, 1 to 3, locally, and cured the case, diet alone having failed.

Dr. Stackpole, of New Hampshire, spoke highly of sulphurous acid in skin diseases, but commended diet as of the greatest importance.

Dr. Galligan, of Pennsylvania, spoke favorably of sulphide of calcium, and had not found it to interfere much with digestion. He thought that the sulphur springs were often of benefit in syphilides. In pruritus vulvæ, he had used the yolk of egg with benefit.

Dr. Bulkley said that he did not understand how the sulphide of calcium should interfere so with digestion. He had never seen this effect when the drug was given in ordinary doses. He thought that it helped acne in only about half the cases.

The Chairman, Dr. J. S. Lynch, did not think the sulphide of calcium often interfered with digestion.

The paper was referred as usual.

The next paper was by Dr. V. P. Gibney, of New York, on

THE STRONG GALVANIC CURRENT IN THE TREATMENT OF SCIATICA.

In thirty-two cases treated as above at the Hospital for the Ruptured and Crippled, twenty-four were entirely relieved, three moderately relieved, and five not relieved. The currents were given daily; sixteen of the cases had no relapses at date, several others had only slight relapses, and only four had a permanent return. Several cases were related. In one, twenty-seven cells were applied for ten minutes daily for several days, with rapid relief.

The duration of the disease in the cases reported varied from a few weeks to several months.

The current should be a stabile one; the labile current is not a constant one. The speaker described the best form of battery. The current should be just as strong as the patient can bear it. The application should be given for ten minutes, or even fifteen, if possible. It should be given twice a day at first, if possible, and kept up for fifteen or twenty days. If by that time no good results ensued, it had better be discontinued. Six to ten seances may secure success. The descending current is preferable.

The paper being open for discussion,

Dr. A. D. Rockwell, of New York, said that electricity in any form will not always cure sciatica. He cited cases cured by the faradic current.

Dr. L. D. Bulkley, of New York, referred to two cases relieved by the strong galvanic current.

Dr. Geo. M. Beard, of New York, spoke of the relative value of strong and weak currents; said that it is true that, in whatever way electricity may be given, it will sometimes cure neuralgia. Practically, Dr. B. did not find much difference in results whichever way he applied the current—although, on the whole, the positive pole is somewhat soothing, and the negative irritating. He thought that there was much value in the treatment suggested, but there was a caution needed, for he had seen cases injured by overdoses of electricity. He would never begin a treatment of sciatica with such powerful currents, but would use weaker ones at first.

Dr. Caldwell, of Baltimore, said: This paper is so well discussed that I will only consider some salient points unmastered. This is the largest nerve-trunk outside of the bony cavities; hence, many causes of neuralgia are due to mechanical interferences, enlargements, tumors, and other pressures. When no form of electricity will avail except to diagnose—and here the surgeon is the proper party to relieve this painful malady—it would be unscientific to continue electricity and palliatives indefinitely.

Dr. L. Turnbull, of Philadelphia, read a paper on

HYDROBROMIC ETHER.

The history of the discovery of the ether was given with great fulness. Two cases of its use in labor were related.

Dr. Turnbull's mode of using hydrobromic ether was to crowd it a little at first. This was quite necessary, and an omission to do it had sometimes caused failures to secure anæsthesia.

The method of manufacture of the ether was described, and the necessity of its being pure insisted on. The conclusions of Dr. Ott as to the effect of various anæsthetics on the circulation were given. [They have already appeared in the Record.]

Referring to Dr. Sims's case, where death followed the use of hydrobromic ether, he said that the operation itself was a very serious one, as serious as ovariotomy; further, that there was disease of the kidneys, and that the bowels were moved, after the operation, by ʒ iij. gr. xiv. of sal Rochelle. These and other things in the case led him to believe that

the hydrobromic ether was not the cause of the death.

Dr. Truscott believed that bromide of ethyl was a safe anæsthetic, specially adapted to operations not exceeding forty minutes.

He also stated that he had never claimed, even at the beginning, that it was a *substitute* for ether or chloroform, but that it was a most valuable supplement to those anæsthetics.

Another point made was that, the more powerful an anæsthetic, the more danger is to be attached to it. This may be laid down as a rule.

In the discussion Dr. Taylor, of Philadelphia, related a case in which the bromide of ethyl had acted remarkably well.

Dr. Denison, of Denver Col., introduced the following resolution:

Whereas, The maps were omitted from the last Transactions, giving in shades of color the absolute humidity of the air, in grains of vapor per cubic foot, for each season, for the whole United States, also one giving the preponderance of the sunshine similarly illustrated, which maps were voted by this Section to be obtained from the Signal Service Bureau at their actual cost value, to accompany Dr. Denison's report; therefore, be it

Resolved, That as these are now promised by the Signal Service Office, at the very reasonable cost of $6 per 1,000 for each bare map, and $5 per 1,000 for each additional color, making the cost $11 only for the maps completed, that the Secretary be instructed to obtain them for this year's Transactions.

A paper was read by Dr. J. J. Caldwell, of Baltimore, on

THE STUDY OF SPECIAL NERVE-CENTRES.

Referred to the Committee on Publication.

A paper was offered by Dr. E. Cutter, of Boston, on

THE SALISBURY METHOD OF TREATING CONSUMPTION,

and referred to the Committee on Publication. Dr. Cutter made a few remarks explanatory of the paper. Consumption was, he believed, a systemic disease due to a vegetation in the blood.

The Section then adjourned.

SECTION ON SURGERY AND ANATOMY.

W. T. Briggs, M.D., Nashville, Tenn., Chairman.
C. Powell Adams, M.D., Hastings, Minn., Secretary.

In the absence of Dr. Adams, of Minnesota, Dr. E. C. Wendt, of New York, acted as Secretary of the Section.

THE PATHOLOGY AND TREATMENT OF SYPHILIS.

Dr. F. N. Otis, of New York, read an exhaustive paper on syphilis, giving his views on the pathology of this disease, and extensively quoting the literature of the subject. Excessive local accumulation of leucocytes was said to account in a rational and satisfactory manner for all the various syphilitic manifestations of the second or active stage. Mechanical pressure of such cellular aggregations produced the great variety of symptoms observed in connection with syphilis.

The therapy must therefore have in view the elimination of such superfluous and deleterious cell-elements. Nature got rid of these products by tissue metamorphosis—a process known as fatty degeneration.

Small doses of mercury, long continued, materially assisted this process. Ricord's name was here cited in support of the writer's views. The value of iodide of potassium was also dwelt upon.

The virus of syphilis was said to be merely an influence, not a physical entity.

In closing this instructive paper, Dr. Otis expressed himself as in entire accord with the views of authorities such as Jonathan Hutchinson, H. Lee, and McLane, of London—practically supported by Lancereaux, Ricord, and Baumüller. He shared their opinions on the pathology and proper treatment of the disease. The late so-called tertiary and quaternary manifestations were considered simply as sequelæ, and not as necessary effects of syphilis. This view was in entire agreement with known pathological processes, and did away with the necessity of supposing a specific virus as the cause of the malady. In addition, he concluded, it was in the fullest harmony with recognized physiological and physical laws.

THE DEVELOPMENT OF THE OSSEOUS CALLUS.

Dr. H. C. Marcy, of Cambridge, Mass., read a paper on the development of the osseous callus in the different fractures of the bones of men and animals, which was illustrated by microphotographs. Various specimens were also demonstrated. The writer summed up the different factors which entered into the modes of repair in fractures, as follows:

The germinal matter which was effused in the vicinity of a fracture must be placed under certain definite conditions to secure therefrom an ossific development. In periosteal transplantation, Ollier had already shown that the periosteum must furnish an exudation *sui generis*, and that this occurred only under irritation. The process of consolidation was not uniform, but varied with various influencing factors. Strictly speaking, there was no primary union in bone, similar to that of other tissues; but, by careful and complete adaptation of fractured surfaces, we placed the various factors of repair in such a relation that they might most readily combine to aid in the repair and produce a more certain and satisfactory result.

Beautiful microphotographs were then shown and explained.

Dr. Nancrede, of Philadelphia, took exception to the term necrosis of the periosteum, as employed by Dr. Marcy, of Cambridge. He thought there was merely a return to the fœtal state of this membrane in cases of fracture. His own views on the pathological conditions involved in the production of callus, after fractures, were then explained.

Dr. Herrick, of Ohio, thought that softening of the fractured ends of the bone always occurred. This, in his opinion, would account for the shortening resulting after fracture, in spite of the employment of extension.

Dr. Marcy stated that he agreed with his predecessors, but that his paper had been so shortened from want of time that he had not been able to fully elucidate all the points bearing on this important topic.

Dr. Sayre rose to a question of privilege, stating that the patient he had operated on for hare-lip was four hours old, and not four days, as had been stated in the report of the daily edition of yesterday's Medical Record.

Dr. H. G. Piffard, of New York, then spoke on

LUPUS,

and illustrated his subject by excellent demonstrations with the magic lantern. After some remarks on the terminology of the disease, the writer stated his belief that the pathological significance of lupus was that of a scrofulous skin affection. Three varieties were given:

1. Superficial, non-ulcerative lupus, or erythematous lupus; 2. Ulcerative lupus with superficial ulcerations, never penetrating beneath the skin; 3. Lupus with deep ulcerations invading deeper tissues.

The histological changes characteristic of these three forms were then given.

The first variety showed small cellular infiltration, the second giant cells, the third also cellular accumulation.

The usual course taken by the malady was next set forth, and its ordinary termination described. The simultaneous occurrence of cancer and lupus was mentioned. After giving the diagnosis and prognosis of the disease, the writer went on to state his views on the therapy of lupus.

Thorough local treatment was emphasized. His method consisted of complete removal by the scoop, with subsequent application of the actual cautery. Excision might also be followed by the application of chloride of zinc. Still, relapses were apt to occur.

DR. HUTCHISON, of Brooklyn, then read a paper on

THE TREATMENT OF SYPHILIS AT THE COMMENCEMENT AND END OF THE NINETEENTH CENTURY, BY DR. CHAS. R. DRYSDALE, OF LONDON, ENG.

After a short historical résumé, the author explained his usual method of treating syphilitic patients. These had usually been young women under the age of twenty-five, the occupants of the Rescue Society's Hospital, at London. He had used no form of mercury with the girls but the green iodide. At first he had given one-third of a grain twice daily; but his experience soon showed him that even these small doses not unfrequently caused salivation in the course of a month or so of daily treatment. For this reason he had latterly given only one-sixth of a grain of that salt, in combination with two grains of extract of henbane, in a pill twice daily.

This dose seemed to be well tolerated and did not produce salivation, even when continued for months. Under this treatment the disease went on in a favorable manner. For the most part the secondary eruptions were benignant, accompanied occasionally by slight alopecia and mucous tubercles, which latter symptoms were amenable to local treatment by means of chlorine lotions and isolation.

The occasional occurrence of iritis, rupia, sore throat, and apparent rectal syphilis, were noted, and the paper closed with the following conclusions:

1. The initial lesion requires no mercury.

2. Syphilis, when iodine is used without mercury, is usually mild.

3. Syphilis, when treated with very small doses of iodide of mercury, is usually mild.

4. Iritis may supervene while patients are taking courses of mercury; but it is usually amenable to treatment by blisters and atropine.

5. Tertiary syphilis is rare after iodide of potassium and iodide of mercury,

6. It is best treated by large doses of iodide of potassium, adding mercury when that remedy fails.

7. Cerebro-spinal syphilis supervenes in some cases early in the disease, and we may then give both specifics, or iodide of potassium alone. The same holds good in syphilis of the testis, liver, or lung.

8. Mercury and iodine probably act by their power of destroying low vegetable organisms in the tissues —the yeast of syphilis (Hutchinson).

9. The dose of mercury ought to be very small.

THE ELASTIC BANDAGE.

DR. MARTIN, of Boston, was then invited to speak on the subject of his elastic bandage. He said that he had not intended to bring this matter up before the Section; but since it was the wish of the delegates, he would read that portion of his somewhat exhaustive paper concerning the application of the elastic bandage, which related to the treatment of articular affections. He first said that the bandage should be applied with intermissions, otherwise vesication would supervene. Several cases illustrating the utility of the bandage were next described. The different sizes of the writer's bandages were then mentioned and their particular uses fully explained.

It was also stated that pain rarely attended the application of the rubber bandage, and Dr. Martin added that even a raw surface should not deter the surgeon from re-employing it, as this and similar conditions, however angry in appearance, were not essentially dangerous.

Some drawbacks, incidental to this method were then adduced. These were chafing, profuse sweating, and occasional extreme pruritus. The intervention of cotton or lint reduced such annoyances to a minimum. Washing with tar soap was useful in eczema; vaseline might also be employed. But all these disturbances disappeared before the great benefits connected with and following application of his rubber bandages.

DR. BYRD, of Quincy, cited an illustrative case.

DR. MARTIN, being questioned as to the method of application over inequalities, here came forward and illustrated on his own person the exact manner in which he commonly applied his bandage, by enveloping one of his knee-joints. In addition, he spoke of his successes in the treatment of non-ulcerative varicosities, and large ordinary ulcers. He also stated that he was now in the habit of employing much thinner bandages than formerly.

DR. NANCREDE, of Philadelphia, warmly advocated antiseptic surgery, taking exception to Dr. Martin's views concerning it. He said that the unanimous opinion of competent persons, in a certain Philadelphia hospital at least, was altogether in favor of Listerism.

ON THE RADICAL CURE OF INFLAMMATION BY LIGATION OF THE VESSELS OF SUPPLY.

DR. H. F. CAMPBELL, of Augusta, Ga., said he would not inflict the reading of his paper on the Section, but would confine his remarks to a very brief statement of his ideas on the subject. He observed that increased vascularity was the essential factor of inflammation. Heat, redness, pain, and swelling were usually mentioned as such, but increased blood-supply was certainly the principal one of these. In this connection he also took occasion to endorse the views so ably expressed by Dr. Martin.

He then related his experience with cases involving inflammatory processes, which had been treated by ligation of the supplying vessels. Seven cases affecting the lower extremity, and eight involving the

area had been thus treated. The results had been invariably satisfactory, reactions even unusually and unexpectedly so. Occasionally, as in a few cases of ovariotomy, collateral circulation became so rapidly established that the obstruction would soon be removed.

Injection to prevent inflammation, however, was dangerous and reprehensible. He only recommended injection for already existing inflammatory processes, with a view to effectually stopping their progress.

The next paper on "A Method of Treating Spinal Disease," by Dr. E. H. Conver, of Harrisburg, Pa., was read by title only.

ON THE TREATMENT OF FRACTURES.

Dr. W. D. Hoover, of Liberty, Va., read a paper on fractures, which had previously appeared in the "Transactions of the Third Annual Session of the Medical Society of Virginia." He then exhibited his appliance for the treatment of fractures.

On motion of Dr. Adams, it was resolved to read the remaining papers by title only.

The following were thus disposed of:

"Treatment of Fractures of Long Bones Involving Joints," by James S. Green, of Elizabeth, N. J.; "On the Present Standing of the Doctrine of Inflammation," by Dr. C. Heitzmann, of New York.

The paper announced by Dr. Burt G. Wilder, of Ithaca, "On the Foramina of Monro in Man and the Domestic Cat," was withdrawn by the writer.

A committee on publication, consisting of Drs. J. H. Packard, of Philadelphia, J. C. Hutchison, of Brooklyn, and A. P. Langford, of St. Louis, was appointed.

The Section then adjourned *sine die*, at 6.30 P.M.

SECTION OF OBSTETRICS AND DISEASES OF WOMEN.

G. M. B. Marcus, M.D., St. Louis, Mo., Chairman.

Robert Battey, M.D., Rome, Ga., Secretary.

The first paper was by Dr. Addisell Hewson, of Philadelphia, on

THE TREATMENT OF FIBROIDS OF THE UTERUS BY DRY EARTH.

For more than twelve years, he said, he had been engaged in the investigation of the value of the use of earth in surgery, and notwithstanding the opposition and ridicule that he had met with, he was glad to announce that its claims were now established to such an extent that he felt amply rewarded for his efforts in this direction. After alluding to its application, and the method of the same, in general surgery, he proceeded to speak of the subject proper of the paper. The first case in which he had employed it was one of very large multilocular fibroid. A layer of paste made of clay a quarter of an inch in thickness was placed around the abdomen and back, covered with a thin sheet of cotton batting, and secured by a many-tailed bandage.

The earth was put on moist in order that the dressing might be more perfectly adjusted. The patient was immediately relieved of all pain, and a reduction in the size of the abdomen was noticeable from the first. At the end of no more than three weeks the abdomen was diminished one-half. Eventually a perfect cure was obtained. It was known that this was no phantom tumor, since at one time the abdomen had been opened (by another surgeon) under the impression that there was an ovarian cyst, when it was found that the tumor was attached to the uterus, and weighed thirty pounds. Fifty cases had been treated in the same way he has, and with almost equally satisfactory results, except in one instance where the patient died of an intercurrent affection. In measuring the size of the abdomen before and at intervals during the treatment, a strip of soft lead was employed. The writer then proceeded to detail several of his cases. However great the pain previous to the application of the earth, this was so completely relieved that anodynes were never necessary subsequently. The tenderness on pressure was also immediately relieved, and within twenty-four hours the reduction in size was often very remarkable.

In the case where the patient died an autopsy was secured, which was looked to with great interest, as no opportunity had yet been afforded for the examination of a tumor which had been under treatment. A large fibroma of the uterus undergoing cystic degeneration was found, the principal cyst, containing twenty pounds of fluid, and as the solid portion weighed twenty-seven pounds, the total weight of the tumor at the time of death must have been forty-seven pounds.

The effect of the earth Dr. Hewson considered to be a chemical one. In all cases where it was at all likely to be of service it was a curious fact that the relief of pain commenced before the first dressing was completed.

In conclusion, he exhibited the material he preferred to use, which was the fine yellow clay, such as is employed for making the best Philadelphia brick. Potter's clay did not seem to produce the same beneficial effects.

The next paper was by Dr. B. F. Dawson, of New York, and was entitled

CLINICAL REPORT ON A MODIFIED OPERATION FOR CYSTOCELE.

In aggravated cases of cystocele, the writer said, three things were necessary: (1) the restoration of the uterus to its normal position; (2) the restoration of the bladder; and (3) the repair of the perineum. Having spoken of the operations of others, he claimed for the one devised by himself the advantages of more certainty of cure and less liability to abscess. It was somewhat similar to the operation of Schroeder, but had been performed (1876) before the latter had been called to his attention.

The denudation was similar to that of Schroeder, but the procedure differed from his in the folding of the redundant anterior vaginal wall into the bladder. He described upon the blackboard his plan of operating, and then proceeded to give the history of five cases.

The first case was one of complete prolapsus (the uterus measuring, from the external os to the fundus, five and a half inches), with rupture of the perineum extending to the sphincter ani. The recto-vaginal and vesico-vaginal walls were completely invaginated, and a sound passed into the bladder showed that organ wholly involved in the prolapse, and occupying the anterior aspect of the tumor.

The first procedure undertaken was to diminish the calibre of the vagina by narrowing the anterior wall. The anterior vaginal wall was denuded of mucous membrane by means of Emmet's scissors to the extent of four inches in length by three inches in breadth, the denuded surface resembling an oval in outline.

Eight silver sutures were then passed successively, by means of a needle armed with silk, through the vesico-vaginal tissue immediately below the denuded surface, entering and emerging about one-quarter of an inch from the edges, and introduced first at the upper portion of the wound. After all the sutures were passed, with a stiff curved sound, the denuded surface was folded into the bladder, traction at the same time being firmly made upon all the silver wires by means of their ends held in the left hand. This procedure doubled and folded the sutures within the tissues in such a manner as to cause them to act as splints in retaining the resulting fold of the vagina in position, and the denuded surfaces in apposition, even when the sound was withdrawn and before the sutures were twisted. Each suture was then carefully twisted, and perfect apposition of the raw surfaces accomplished. The whole mass was then carefully returned into position. Nine days afterward the vaginal sutures were removed and complete union was found to have occurred. The perineum was then restored, and the case resulted in a perfect cure.

The other four cases were of similar character, and in all of them the same excellent results were obtained. In the last one mentioned, however, the operation for the restoration of the perineum was performed the same day as that for the cure of the procidentia and cystocele. The result was that a short time afterward the perineum gave way in consequence of violent exertion made by the patient, and the cystocele also returned to a slight extent. But subsequently both operations were repeated at an interval of nine days between the two, and the patient had no further trouble.

These five cases were selected as the worst of the eight upon which he had operated, and a sufficient time had now elapsed since they were all performed to demonstrate the efficiency of the method employed. The next paper was by Dr. Robert Battey, of Rome, Ga., on

STILLBIRTH—RESUSCITATION AFTER TWO HOURS AND FIVE MINUTES.

The case referred to occurred after a breech-presentation. The child when born was still, and deeply cyanosed, the cord pulseless, and the heart's action very feeble and irregular. Presently the heart seemed to cease to act altogether. Artificial respiration, in various forms, was attempted without any result, and the nurse was then ordered to keep the child wrapped in hot flannel, while he himself kept up inflation by the mouth.

It was more than an hour before the first respiration was made, and it was not until ten minutes afterward that the second breath was drawn. After that the respiration gradually became more and more frequent, and at the end of two hours and five minutes both the respiration and the circulation seemed nearly normal, while the infant was able to nurse heartily. The child did well for about ten hours, when it had a difficulty of breathing, with mucous râles, and died suddenly.

This case, Dr. Battey thought, taught a useful lesson of patience and perseverance in such cases of asphyxia of the new-born.

Some authors, indeed, advocated the continuous efforts which he had employed in this case; but most physicians, he believed, were inclined to give up too readily. At all events, he had never read of a case where the child remained asphyxiated for such a long period as in this instance. An infant, he claimed, should not be regarded as dead because its heart had apparently ceased to beat, although this was too often done. The writer concluded the paper by a reference to the views of many of the best known authorities on obstetrics and the diseases of children, and urged the desirability of reviving the child, even if it were but for a short time.

Dr. Pallen, of New York, on behalf of Dr. T. Gaillard Thomas, presented a very remarkable dermoid cyst of the ovary which he had removed the week before, and in which there was a large patch of very perfect skin and a considerable number of teeth implanted in a kind of superior maxilla.

On motion, a vote of thanks was tendered to Prof. Thomas for his kindness in presenting this fine specimen.

The next paper, entitled

REST AFTER DELIVERY—TREATMENT OF PERITONITIS,

was read by Dr. R. Tauszky, of New York. He deprecated the practice of Dr. Goodell and other authorities in allowing the puerperal woman to get out of bed within a very short time after parturition. In his public and private gynecological practice, he said, he had frequently seen the bad effects of too early rising after delivery in abnormal conditions of the uterus, vagina, and ovaries, and he dwelt for some time upon the evils thus liable to result, not the least of which was septicæmia.

He then related a case recently terminating fatally in the Mount Sinai Hospital.

At the autopsy the most marked evidences of pelvic cellulitis and peritonitis was found. The colon and rectum were immensely distended with fæcal matter, and the case showed the importance of attending to the bowels after delivery.

In the treatment of pelvic or general peritonitis, he advised the methods practised in Vienna at the present time.

In the first place, the cause, if known, should be removed. Warm fomentations should then be employed, but if there was very high fever, cold applications should be used instead.

If the bowels did not move naturally, no interference should be made so long as there was no tympanitis.

When this occurred, however, warm enemata and oil were to be used. If there was very active inflammation, the local abstraction of blood by means of leeches should be resorted to, and he sometimes placed a dozen leeches on the abdomen. Opium, of course, was to be freely used. In chronic cases fomentations and counter-irritation by tincture of iodine or by blisters were recommended. In some instances blue ointment suppositories were also of great service. In acute peritonitis, when the patient was strong, digitalis acted most happily, and it was very efficient in bringing down the pulse.

Dr. R. Beverly Cole, of San Francisco, then made some

REMARKS ON SPONGE-TENTS AND THEIR MODE OF PREPARATION.

In gynecological practice it was conceded by all that it was sometimes necessary to dilate the os and cervix uteri. The sponge-tent he considered better than all others used for this purpose, for the reason that none of the others could be made to remain *in situ*. As to the sponge-tent, its forms and mode of preparation were exceedingly various.

The objections to those commonly kept in the shops were: *First*, that they were not of the proper

size or shape, generally being altogether too large. Second, that these were apt to be made of a very coarse quality of sponge, and hence the dilatation could not be carried to the extent desired. Third, the sponge-tents, as usually prepared, gave a great deal of unnecessary pain on account of their coarseness and roughness.

Instead of employing these, therefore, he made his own tents out of fine cup sponge, such as surgeons use. The sponge was dipped in melted wax, and then subjected to very great pressure (which could best be secured by a letter press), which forced all the superfluous wax out of the sponge, and flattened it out to a thin cake. It was very necessary in selecting the sponge employed that it should be entirely free from all coral or other mineral impurities. After being pressed out in this way, the sponge could then be cut with the knife or scissors into any shape desired, care being taken to cut it in the direction of its long axis.

In many instances it was necessary to begin with a tent not larger than a knitting needle. Before using, it should be provided with a thread by which it could be removed.

Dr. Pallen thought that Dr. Cole's method of making sponge tents was most ingenious; but he could not permit this opportunity to pass without expressing his strong disapproval of the use of sponge-tents in general. He knew of nothing in all gynecological practice that had caused so much evil as the sponge-tent. He was opposed to its use on account of the great dangers attending it, and because there were so few cases (except for purposes of dilatation, when other agents might be employed) in which it was applicable.

Dr. Pallen spoke for some time with great force and eloquence in setting forth the very serious dangers which he believed to be inseparable from the use of sponge-tents even when every precaution was resorted to to render them innocuous.

Dr. Bayley then exhibited

A UNIVERSAL CATHETER,

which consisted of an ordinary soft-rubber catheter, to which was attached some rubber tubing sufficiently long to reach to the chamber-utensil on the floor, and made some remarks on its use.

The hour for adjournment now having arrived, the minutes of the proceedings were read and approved, and the Section adjourned.

SECTION ON DISEASES OF CHILDREN.

Dr. S. C. Busey, of Washington, D. C., Chairman.
Dr. Frank Woodbury, of Philadelphia, Secretary.

CONGENITAL ATROPHY OF LIVER.

Dr. A. Jacobi read the history of a case of Congenital Atrophy of the Liver. In this case the liver was reduced to one-tenth or one-twelfth of its normal size. The microscopic examination showed scarcely anything but interstitial tissue, and he believed it to have been a true case of interstitial hepatitis occurring in the infant. The capsule of Glisson was greatly thickened, giving the appearance of chronic peri-hepatitis. A history of the child did not give any positive evidence of syphilis, but the lecturer believed the case to have undoubtedly been one of this character. Peri-hepatitis had been regarded as an adult disease until recently, when several cases have been reported by the German pathologists as occurring in children. As a rule, syphilitic disease gives rise to enlargement of the liver, which, according to Marchinson, may be of two kinds: first, gummatous deposits; and, secondly, diffuse syphilitic cirrhotic degeneration, which leads generally to atrophy.

In speaking of the case, Dr Jacobi also reported a case of syphilitic liver which had recovered—the only infant that he had known to survive the disease. The child is now a year old, and appears to be healthy.

In the treatment, where the evidence of syphilis appears early a prompt mercurial impression is required, and he had followed Lewin's plan of giving the bichloride hypodermically, with excellent results. The salt was dissolved in water and filtered before using. In other cases, where such a rapid effect is not needed, he had followed the usual plan of mercurial inunction.

Dr. J. B. Bryson, of New York, by invitation of the Chairman, opened the discussion. He regarded the case as interesting, and, as presented by Dr. Jacobi, seemed to have no other explanation than had been given. In the specimen, however, he saw no evidence of syphilitic lesion. He had had no experience in the treatment by hypodermic injections, but preferred to medicate the child through the mother's milk. His hospital colleagues had tried the hypodermic injections but had failed; but by any method of treatment, except in those where the aid of maternal medication was invoked, no good results had been observed. In his experience, where syphilitic skin affections, such as furuncles, etc., are very early and very marked in their manifestations, he had learned to hope for but little in the way of treatment. When syphilis appeared from the fifth to eighth week, a fair chance of recovery was present, and he had regarded these subjects as presenting the most marked results from the medical care, and very satisfactory to treat. But in such cases he would always avail himself of the mother's milk as a method of administering the specific remedies wherever it was practicable.

Dr. H. A. Hoxsie, of New Jersey, said that he had not used mercury hypodermically, but had employed inunctions and nursing from a mother who was under antisyphilitic treatment. If the exfoliation of skin and nails occur before five days, the infants almost invariably die, but if after five days, good results might be hoped for.

Dr. E. A. Cuthy, of New Jersey, inquired if the hypodermic injections of mercury had caused anæmia in these cases? It was found to have this effect when he was at the Edinburgh school. He could see no other explanation of the case reported by Dr. Jacobi than the one given by the lecturer.

Dr. Jacobi, in answer to a question, said that he used a mild solution of the bichloride (two to four grains to the ounce) for injections. Where inunctions are resorted to, in cases where the emergency is not so pressing, the oleate may be used for this purpose, containing six per cent. of mercury, but the ordinary blue ointment is also very efficient.

Dr. Cuthy reported a case of a synovitis in a so-called scrofulous child, to which he gave twelve one-grain powders of gray powder—one to be taken each night. After taking these powders, the child had improved so much that the prescription was refilled without the authority of the physician.

He was called again at the end of the second series of powders, the child was anæmic, emaciated.

and cachectic, but afterwards improved, and the knee got entirely well.

Dr. Jacobi said that the effect of mercury on specific disorders was so great, that in such cases we are obliged to use it. In small doses, long continued, its action is plastic rather than antiplastic, as it is in larger doses. Dr. Keyes has pointed out that in syphilis, the small doses increase the globular richness of the blood. Mercury has formerly been given indiscriminately for almost every complaint, and doubtless did a great deal of harm; but, properly administered, is a very valuable agent in the treatment of just such cases as the one described in his paper.

Dr. Hopper said that the reason why a change had occurred in medical practice, was, that the advance in our knowledge of pathology and the effects of medicines, has led physicians at the present time to be sure that the indications for its use were present, before ordering it, just as Dr. Jacobi had pointed out.

Dr. Jacobi reported

A CASE OF SUPRAPUBIC LITHOTOMY

in a child, six years of age, which had suffered with the symptoms of stone in the bladder for a year.

The operation was performed without difficulty, under chloroform, and a medium-sized phosphatic stone removed. This was followed by persistent suppuration, which was more than would be expected simply from a mucous membrane. The case had not yet entirely recovered.

In discussing the case, Dr. Jacobi referred to recent observations upon sub-mucous gastric abscess, and inquired whether a similar condition could not exist in the bladder. These accidents of peritonitis and extensive suppuration, as a consequence of epicystotomy, may prove to be a serious bar to a method of operation for lithotomy that otherwise has much to commend it. It may be that the preliminary distention of the bladder required may have injurious results in a bladder which is contracted, and the subject of concentric hypertrophy and chronic irritation from the presence of the stone. If the bladder be much diseased, the forced injection may of itself produce serious consequences, In the case reported, no injury or irritation of the bladder was caused in operating, beyond the simple incision.

Dr. Jacobi also presented a specimen taken from a child, who was admitted into the hospital at the same time as the preceding case, and also exhibited the rational signs of stone in the bladder. In this case operation was delayed on account of some fever present in another case. This boy subsequently died of meningitis without any operation having been attempted. The bladder, very much contracted and hypertrophied and with its mucous membrane thickened, inflamed, and ulcerated, was found closely embracing a stone as large as a small pigeon's egg. This specimen of diseased bladder, taken in conjunction with the preceding case, was very interesting, and showed very clearly the risks of the operation. The kidneys were quite healthy. The urine was alkaline, phosphatic, and contained ropy mucus and pus.

In commenting upon the case operated upon, Dr. Jacobi referred to the large doses of opium which had been given during the attack of peritonitis, which, commencing with five drops of tincture of opium, had been gradually increased until twenty drops had been administered every hour, which would generally be considered a very large dose for a boy six years of age. It is astonishing how much of the opiate is required in cases of peritonitis, and, at the same time, how little effect it produces. He cited an instance in which a woman suffering from peritonitis, in the same hospital, had had administered to her fifteen hundred grains of morphine in the course of twenty-five days, or, on an average, a drachm a day. Upon one occasion it was found necessary, in order to relieve her pain, to give her ninety grains of the sulphate of morphia hypodermically inside of twenty-four hours. Strange to say, these cases rarely contract the opium-habit. This woman recovered.

In answer to a question from Dr. E. W. Schauffler, of St. Louis, as to whether he believed that the bladder presented could have been distended so as to rise above the pubes, as required in the operation of suprapubic lithotomy, Dr. Jacobi replied that he had no doubt that it could have been so distended as to permit the operation. In reply to a question from Dr. F. Woodbury, he said that the tincture of opium used was of proper strength, as it was what was commonly used in the hospital, and he knew that it affected other cases in the ordinary doses.

The Chairman, Dr. S. C. Busey announced that, in accordance with instructions, he had submitted to the General Session, this morning, the resolutions passed by the temporary Section at its meeting yesterday; and that the necessary by-law creating a permanent

SECTION ON DISEASES OF CHILDREN

of the American Medical Association had been adopted, and that, at the next meeting of the Association at Richmond, the Section will be duly provided with officers and papers.

Dr. Jacobi said that he had taken much interest in the formation of a section upon the special subject which he had presented in his opening address yesterday. He apologized for taking up so much of the time of the Section with his remarks, but he said that no papers had been referred by the Committee, and it had occurred to him that he had better present such papers as he could prepare in the short time, rather than to call them together to organize, with nothing to present for their consideration.

After a vote of thanks to Dr. Jacobi the section adjourned.

SECTION ON MEDICAL JURISPRUDENCE, CHEMISTRY, PSYCHOLOGY, STATE MEDICINE, AND PUBLIC HYGIENE.

James F. Hibberd, M.D., Richmond, Ind., Chairman.

Thos. F. Wood, M.D., Wilmington, N. C., Secretary.

The Section was called to order by the Chairman at 2.15 P.M.

Dr. Billings, U. S. A., moved that Dr. Wines, of the Census Bureau, be permitted to explain the blanks upon which the present census is being taken. Carried.

Dr. Wines then proceeded to describe the different forms of census blanks, after which

Dr. Billings offered the following resolutions, which were adopted:

Resolved, That this Association approves of the plans proposed by the Superintendent of the Tenth Census for the collection of data, with regard to the insane and idiots of the United States, and that it urges upon physicians that they should aid in this

work, so far as possible by correspondence, to the schedule of questions on this subject which will be sent them from the Census Office.

Dr. Chas. W. Page, of Hartford, Conn., then read a paper on the moral treatment of the insane.

He asked a share of the interests of having able and honest officials in charge of institutions for the insane as the first step in the right direction. He alluded to the advantages to be derived from having the insane sleep in dormitories which communicated with each other, as well as to the more frequent association with each other. Great stress was laid on the benefit to be derived from educating the patients, so that their minds might be diverted from their malady, and as a possible means of improving their condition. Manual labor and exercises of various kinds were mentioned as other ways of influencing the minds of the insane. The author said that the hopelessly insane should be separated from those who could possibly be cured. The experienced hands and those having charge of asylums should be physicians.

The next business coming before the Section was the report of the committee appointed at Buffalo, two years ago, to take into consideration the subject of "The Intervention of the Physician in Education." The report was read for Dr. R. J. O'Sullivan, of this city, by Dr. A. N. Bell, of Garden City, N. Y., was based on a similar one made some time ago by Dr. E. Seguin, of this city, and alluded to the necessity of better sanitary regulations in schools, such as ventilation, sewerage, etc.

Drs. Wm. F. Thoms, of this city, and J. P. Quimby, of Jersey City, in the discussion which followed, spoke of the necessity of impressing the laity with the fact that something should be done in reference to having better school accommodations.

The next report was read by Dr. A. N. Bell, in the absence of the Chairman, Dr. H. P. Bowditch, of Boston. It was on the subject of the "Establishment of Sanitaria, etc." The committee arrived at the conclusion that it was inexpedient to recommend any particular sanitarium.

Dr. Bell offered the following resolution, which was adopted:

Resolved, That a general sanitary organization is a necessity of every enlightened commercial nation, and the service of the National Board of Health of the United States, since its organization, has been such as to impress us that both in its personal and organization it is entitled to the confidence of the government and the people, and we join the American Public Health Association and the National Academy of Sciences in earnestly recommending to Congress that the suggestions and estimates of the Board receive their legal sanction, believing that the money asked for is necessary to the work of the Board, and will be a most judicious expenditure of money.

Dr. A. L. Carroll, of New Brighton, N. Y., offered the following resolution, which was carried:

Whereas, The value of vital statistics depends upon their scientific accuracy, as regards the etiology as well as the diagnosis of disease, this Section would urge upon the Association the importance of recommending that every medical school within its jurisdiction establish a Chair of Public or State Medicine as an essential part of its curriculum.

Dr. J. V. Quimby, of Jersey City, then read a paper on the

CRIMINAL USE OF CHLOROFORM.

The author gave the main points in the Smith murder case, he having been consulted as to the possibility of chloroforming a patient while asleep without awakening him. It was determined, by experiment in three cases, that a person could be chloroformed without disturbing him, and that he would sleep for some time after the administration.

Dr. W. H. Lamson, of Lewisbury, Mass., followed with a paper on

THE SOCIAL CONDITION OF THE INSANE,

in which a description of the author's idea of how to build asylums were given.

Dr. Antrim, of Washington, D. C., then read a paper on

HYPNOTISM OR MESMERISM,

in which he advocated the appointment of a medical analyst, to act in conjunction with the coroner. The precautions to be taken in cases of suspected poisoning were also mentioned.

Dr. W. F. Thoms, of the city, read the last paper, entitled

HUMANE SOCIETIES.

Dr. A. N. Bell then offered some resolutions, among which was a proposition to change the name of the Section to that of "State Medicine." All of which were carried.

On motion, the Section adjourned *sine die*, at 4.35 P.M.

SECTION OF OPHTHALMOLOGY, OTOLOGY, AND LARYNGOLOGY.

Dr. Swan M. Burnett, Washington, D. C., Chairman.

Dr. Eugene Smith, Detroit, Secretary.

The Section was called to order at 2 P.M., by Dr. S. W. Burnett, of Washington, D. C.

Dr. B. Joy Jeffries, of Boston, spoke on

COLOR-BLINDNESS,

alluding to the experiments of Holmgren, Purkinje, and others.

The methods of Dr. J. are used in the marine service of the U. S., and by certain railroad companies. In examinations of 13,000 persons, about 4 per cent of males and only 0.1 females have been found color-blind, in this number. A chart of worsted squares was introduced, which might be of practical service to a naval surgeon. The last edition of Stilling's atlas of colors and nuances was introduced. Donders' frame of wound threads (sent by D. to Dr. Jeffries) was further introduced. Pflüger's method consists of detecting the complementary colors through tissue-paper. The question is asked by railway officials, *how* color-blind is an employee? Donders has proposed a means by which at a distance of 3 metres a quantitative examination of color upon a black ground can be measured. Already Connecticut has a law demanding such examinations by railway officials. There is also, through Donders' influence, such a national law in Belgium. Dr. J. has already tested 185 members of the American Medical Association, and found 5 color-blind. He is unable to answer why so few females are color-blind.

Dr. David Hunt, of Boston, read a paper on

VARIABILITY OF THE HUMAN EYE,

in which he stated that myopia has caused most interest on the part of specialists, but hyperopia and astigmatism abound in countries where myopia

prevails. The eye of civilized man has a tendency to vary from a nearly normal standard, such as characterizes most savage people and the domesticated animals. Myopia has been generally considered as the direct result of near vision; in the same way hyperopia has been treated of as the direct product of a relatively greater exercise of the eye in distant vision, while the cause of astigmatism has received but partial explanation. In attempting to apply the hypotheses founded upon the above considerations, it will be seen that they fail; for instance, they do not explain in any manner the relation of astigmatism to the vast amount of myopia and hyperopia in the same nations, as among the Germans and Italians.

In studying the embryology of the eye, its formation from a simple bud of brain-tissue, as exhibited in the plates introduced, suggests the possibility that in the phenomena of the variability of the human eye we have an instance, not of *direct* variation, as has been hitherto supposed, but rather an illustration of correlated variation; that the eye varies not directly as its function varies, but that, as a bud of brain-tissue, it partakes of the inherited stimulus to increased and varied growth, which we know affects just that portion of the brain from which the primary eye vesicle is produced. We see the direct result of this stimulus to increased cerebral development in the greater frontal development which civilization has produced; and, just as the growth of brain-tissue has shaped the skull, so we believe the increased growth of retina, while it is yet a simple bud of brain-tissue, influences the shape of the sclerotic, which is to be formed from the connective tissue immediately surrounding the embryonic retina. Given this variability, then causes—which we can not believe produce the variations, since they do not do so in animals—may modify and increase the variations so caused.

One other point of interest in the study of the development of the eye was briefly alluded to. Staphyloma posticum has been a fruitful theme of discussions of phenomena hitherto unexplained by any hypothesis. The great trigeminus ganglion, the only mass of nerve-matter excepting the brain in the head of young embryos, may furnish a clue to this peculiar weakness of the temporal half of the posterior portion of the sclerotic. In the plates it will be seen that at an early stage of development the ganglion is situated a short distance behind and back of the temporal half of the globe. Now, any increase of the ganglion, such as most surely accompanies the increased growth of the brain in civilized man, will cause the ganglion to encroach upon the layer of connective tissue, from which the posterior portion of the temporal half of the sclerotic is to be formed; more than this, as the ganglion in its development breaks up into the separate ganglia, and as these in turn undergo the relative decrease in bulk which they pass through before they are enclosed in the cartilage which is to form the skull, it will be seen that the curve, which this portion of the sclerotic forms, must be directly proportioned to the primary increase of the ganglion; and that, other things being equal, the sclerotic will be thinner and looser in texture, as the connective tissue lying between the eye and the ganglion is encroached upon by their increased growth.

The trigeminus ganglion is situated at the base of the first branchial arch, and, as it influences the eye, so I believe its increase influences the development of the arch, and thus accounts for the decrease of prognathism characteristic of civilized nations; it is difficult for us in America to believe that the marked change which occurs in the maxillary protuberance of the descendants of our Celtic and other emigrants, is caused by changes in diet and thus of function of the jaws, as Darwin and Spencer have supposed. We should expect, if change of function had any result beyond changing the development of the muscles concerned in mastication and the bony ridges, which mark their insertion, that the prognathism would increase; since it is surely the case that many emigrants have a diet requiring less mastication, and in America begin upon diet consisting more of animal food and requiring more; that an increased strain upon the nervous system is made in changing from a peasant to a citizen, I think no one will deny.

No discussion followed this most interesting paper.

A paper entitled

THE PROBABLE CAUSE OF SOME FORMS OF GLOBUS HYSTERICUS

was read by Dr. Richard C. Brandeis, of New York. The author proceeded to enumerate the different symptoms noticed in the various forms of globus, and dwelt upon the fact that this affection was as frequent in females of the lower as in those of the higer classes The commonest form is attended by a sensation of a ball or lump in the throat. The larynx is most commonly the seat of the distressing sensation, but sometimes the pharynx and œsophagus are also affected; when this is the case, the patient may be unable to swallow food or drink. In the more marked cases every ingestion is followed by a regurgitation, and this is attended with a spasm of the glottis and dyspnœa, owing to the irritation of the peripheric sensitive nerve-fibres of the pharynx, which is reflected to the pneumogastric nerve at its origin, the floor of the fourth ventricle, and is then communicated to the gastric and recurrent laryngeal branches of this nerve. Uterine and spinal affections are also frequent causes of this chain of symptoms.

In some cases, however, no neural cause can be discovered, and every form of constitutional treatment will fail. Dr. B. has observed many cases in which all the symptoms of globus hystericus may be attributed to a local cause, and that is irritation of the epiglottis. This is generally due to an enlargement of the papillæ circumvallatæ, situated at the base of the tongue, which may assome such a size that the movements of the epiglottis are interfered with, owing to the fact that it is firmly held by the enlarged glands. If the epiglottis is extricated from its confinement, these symptoms will disappear, but may return if the enlarged papillæ are not destroyed. This may be done by means of caustic applications, the knife, or the galvnnocautery, care being taken that the delicate epiglottis itself is not interfered with. In no case in which the papillæ were removed was there a return of the symptoms.

Dr. E. Gruening, of New York, exhibited a

MAGNET FOR THE REMOVAL OF PARTICLES OF STEEL AND IRON FROM THE INTERIOR OF THE EYE.

Allusions were made to the hook, scoop, etc., and their occasional failures.

McCuen first published a notice of removal of metallic bodies in 1874, with a magnet, but Hirschberg first actually employed a magnet for such purposes. Hirschberg's apparatus was a cylinder, the ends of

which were drawn out and connected with wires that formed its positive and negative poles. The amount of magnetic polarity was, however insufficient, and a permanent apparatus was demanded in addition. Dr. Gruening was experimenting at the same time as Hughes, but in another direction. His idea was to have a permanent battery. His instrument consists of an armature of six parallel cylinders connected, the end of the bundle of cylinders being furnished with a tapering needle, about 22 mm. long. In his first experiments upon dogs' eyes, Dr. G. broke all the needles. Two monkeys, or "executives," were presented, the larger being less highly organized than the smaller one. The latter carries the weight of two steel key and ring, about 28 grammes. A dog's eye, in which a piece of metal had been inserted, was shown, and from which the soft iron was duly extracted. The better instrument was made by Reichers, of New York.

PERICHONDRITIS AURICULÆ

was the subject of remarks, with a case, by Dr. H. KNAPP. It is very rarely seen. Began in cartilaginous portion of meatus, whence it spread over the entire auricle, with the exception of the lobule. No pus was found at any time. The case was relieved in about three months, since which time there has been marked atrophy of the auricle.

Remarks being in order,

Dr. POOLEY said that he had also seen a case of perichondritis in which he had applied continuous pressure, and thus had checked the progress of the disease.

Dr. MCKAY, of Wilmington, Del., had also had a case in which a cure was effected by means of applications of nitric acid. Dr. SHAKESPEARE, of Philadelphia, was observing a case in which there was a marked formation of pus.

The next paper was by Dr. T. R. POOLEY, of New York,

ON THE DETECTION OF THE PRESENCE AND LOCATION OF PIECES OF STEEL AND IRON IN THE EYE, BY THE INDICATION OF A MAGNETIC NEEDLE.[1]

The meagre literature of this department of ocular surgery was commented on by the author. Smee, of London, in 1841, was the first to publish any authentic results of the detection of metallic substances in the human body by means of magnetism. In Gaillard's *Medical Journal*, April, 1880, Prof. J. H. Pooley, of Columbus, Ohio, instituted kindred experiments on the human body with undoubted success. This was the first suggestion to the author that the same means might be utilized in their detection in the eye. Ten experiments were instituted with pieces of watch-springs, iron and steel wire, and cast steel, of different weights and shapes. A table was incorporated, detailing also the distance at which a magnetic needle of 41 mm. in length was deflected toward the different substances, some of which were non-magnetized, others rendered magnetic by induction, while others had been in contact with a magnet. The substances weighed from .004 to .136 grammes, and while non-magnetic caused deflection at distances varying from 3 to 12 mm. The results depended on the size of the body, as well as on its position in the eye.

The first desideratum was to render the metallic body a magnet. With cast steel the deflection was the greatest. This detectibility of magnetized bodies having been proved, Dr. P. began experimenting with freshly enucleated eyes of pigs and sheep. He used highly magnetized watch-needles, and double pointed needles with a cork at the centre. Experiment No. 3 was that of a steel wire entered behind the sclero-corneal margin and passed deep into the vitreous. The needle was deflected by it in every instance. In experiment No. 4 a horse-shoe magnet was presented through a cork with the spot from which the enucleation had been withdrawn, and the needle was deflected as before. In experiment No. 9 a piece of watch-spring was introduced just behind the sclero-corneal margin of an eye lying upon the table, the cornea looking upward. The needle indicated its location 6 mm. below its point of entrance, where, by an incision it was not found. The eye was then turned over, when the needle was deflected toward a new point. Upon cutting down, the body was found in the vitreous, partly covering the papilla and partly lying on the retina.

In experiments Nos. 12, 13, and 14 a living rabbit's eye was used, and several hours after the introduction of a bit of steel wire the vitreous was turbid, the iris dull, conjunctiva chemotic, and purulent chorioiditis had set in. The needle deflected as before. The last three experiments were more germane to the subject, as they were made upon living rabbits' eyes. In all of them it was impossible to see the metallic body, on account of the turbidity of the vitreous, and in none was there a failure of the needle to be deflected toward its habitat. Pagenstecher, of Wiesbaden, first called attention to the rapid formation of a dense exudation about a foreign body. Pooley saw this occur in the three experiments on rabbits, and found the magnet almost powerless in the removal of the body.

The author's conclusions were as follows:

I. *That a metallic iron body in the eye may be detected by a suspended magnet when the body lies near its surface.* II. *The presence and position of such a foreign body may most surely be found by making it a magnet by induction, and then testing for it by a minute suspended magnet.* III. *The intensity of deflection of the needle is proportionate to the depth of the body.* IV. *Changes of deflection of the needle indicate changes of position in the foreign body.*

Discussion being in order,

Dr. GRUENING asked how the magnet was suspended, and Dr. P. answered that the suspension was by a thin fibre of silk. Another query was as to the manner of attaching the magnet. The answer was that in all the laboratory experiments the magnet was held at right angles over the upturned eye by a rectangular support attached to a table. Dr. G. has lately instituted experiments, in which his magnetic needle was suspended by cocoon silk, the needle pointing downward in mid-air within a glass box. Dr. G. was able to overcome the terrestrial polarity, so that the north pole became the south pole of his magnet, but was unable to satisfy his thesis as to the detection of a metallic body.

Dr. KNAPP had had two opportunities of removing foreign bodies from the eye by the magnet, in one of which he was successful, in the other not. In the second eye, which suffered from suppurative iridochoroiditis with hypopion to the height of 3 mm., three attempts being made with the magnet introduced between the internal and inferior recti, and directed in every direction across the globe, failed to "get the click" and deliver the foreign body; the latter, however, was found in the wound later, and extracted by forceps.

Dr. POOLEY emphasized the scientific necessity of

rendering the foreign body a magnet by induction, whereby Gruening's experiments had failed.

Dr. S. D. Risley, of Philadelphia, volunteered a paper noting various

EAR-TROUBLES,

one of which was a case of mastoid inflammation, with meningeal complications. Trephining of the mastoid and good hygiene saved the patient's life. Two cases of inspissated cerumen, giving in one symptoms of meningeal compression, in the other those of locomotor ataxy, were read. Other cases were detailed, all of them examples of reflex irritation.

Dr. Risley further showed a photograph of a characteristic dermoid tumor of the cornea.

Dr. Jones, of Chicago, emphasized the necessity of a more accurate use of the mirror in ear disease.

Dr. D. H. Goodwillie, of New York, volunteered a paper on

ERECTILE TUMORS OF THE TURBINATED BONES.

He first called attention to the surgical interference necessary in exostoses of the vomer and turbinated bones, adenoid growths of the vault of the pharynx, nasal polypi, etc. A large variety of wax casts of deficiencies of structure and neoplasms was introduced, together with the surgical engines, which have lately been published in detailed form, with woodcuts, in the Medical Record, insufflators and other nasal instruments used by Dr. Goodwillie.

By invitation, Dr. E. S. Peck, of New York, presented a case of

PRIMARY CONJUNCTIVAL LUPUS

which had been under observation fourteen months. The present ulcer was the fourth of a group of successive ulcers, all confined to the conjunctiva and integument in the immediate vicinity. The first ulcer was situated upon the outer portion of the conjunctiva of the upper lid; the second upon its middle portion; the third was a group of ulcers at the inner canthus, and had an anatomical division into three ulcers. The ulcerated surface had not, as yet, invaded the ocular conjunctiva, and vision was perfect. The treatment had been mainly nitric acid, as a caustic, and anti-scrofulous formulæ. The ulcer was purely lupoid and a scrofuloderma. Its exceeding rarity was shown by the fact that in a summary of 167,318 eye-diseases, tabulated within a few years in the New York eye hospitals, only seventeen cases of lupus of the lid had been recorded. The case is elaborated in Seguin's *Archives of Medicine*, Vol. III., No. 3, June, 1880.

Dr. W. F. Holcombe, of New York, presented three papers, which were read by title:

"Removal of Secretions from the Tympanic Cavity and Mastoid Cells."

"Causes and Relief of Tinnitus Aurium."

"A Treatment suggested for Subacute and Chronic Otitis Media."

Dr. Turnbull, of Philadelphia, was prevented from reading a paper on "Observations with Cases of Aural and Auditory Vertigo," on account of a similar duty in the Section on Practical Medicine.

A note of apology from Dr. C. S. Bull, of New York, was read by the Chairman, on account of failure to present his "Contributions to the Pathology and Treatment of Vascular Tumors of the Lids."

The Section then adjourned.

Receptions were held during the evening at the houses of Mayor Cooper, August Belmont, and at the Academy of Medicine. In the latter place the members were entertained by Fordyce Barker, M.D., LL.D., President, and Prof. T. Gaillard Thomas, M.D., Vice-President of the Academy.

GENERAL SESSION.

Friday, June 4—Fourth Day.

The Association was called to order at 10 A.M. by the President.

The following were appointed as Committee on Dr. Beach's resolution concerning the social position of the members of the medical staff of the U. S. Navy: Drs. Wm. M. Beach, London, Ohio; C. Goodbroke, Clinton, Ill.; H. McGuire, Richmond, Va.; Wm. S. Briggs, Nashville, Tenn.; D. W. Yandell, Louisville, Ky.

A communication from Dr. Charles W. Stillman, of Plainfield, N. J., concerning the "sector splint" and letters of patent thereon, was laid upon the table.

A communication from Dr. Frederick Horner, Jr., U. S. Navy, containing a resolution adopted by the State Medical Society of Virginia, instructing its delegates to the American Medical Association to ask that body to take the necessary steps for establishing a mutual medical aid association was received favorably, and referred.

A resolution offered by Dr. Octerlony, of Louisville, Ky., and expressing disapprobation of the practice indulged in by some of distributing gratuitously medical journals among the laity, was laid upon the table.

A communication from the Philadelphia County Medical Society, concerning the abuse of medical charities, was received and referred to a special committee appointed by the chair, consisting of Drs. B. Lee, H. G. Piffard, S. W. Gross, and J. W. Green.

A resolution was offered by Dr. A. L. Carroll, of the Richmond County Medical Society, N. Y., as follows, "Whereas, The County Medical Society of New York has admitted to membership graduates of schools not recognized by this Association, therefore be it resolved, that societies which admit irregular practitioners to membership be debarred from representation in the American Medical Association." Referred to the Judicial Council.

The Treasurer's Report was then read, and showed the receipt of $5,025, and a balance in the treasury of $579.59.

The report was received, and referred to the Committee on Publication.

The Committee on Publication presented their report, which was received and referred to the Committee on Publication.

Dr. Pratt, of Michigan, offered a resolution, instructing the Committee of Arrangements to publish one programme of the work to be done in general session at the next Annual Meeting during the whole four days, instead of a daily programme, which was adopted.

Dr. Pratt also offered the following resolution, which was adopted, That the Committee of Arrangements be instructed to so place the proposed amendment to the Code of Medical Ethics upon the programme that it shall be made the special order at 10.30 A.M. of the second day's general session, and that it shall remain as a special order until disposed of.

The Committee on Nominations completed its report by offering the following:

For Secretary of Section—Dr. J. G. Cabell, of Va.

For Chairman of Arrangements—Dr. Cunningham, McGuire, and Culley, of Richmond, Va., with power to select others to make it a Committee of [illegible].

For Chairman of Publication—The same as last year—Drs. W. B. Atkinson, T. M. Drysdale, William Lee, R. J. Dunglison, Albert Fricke, S. D. Gross, and Caspar Wistar, all of Philadelphia.

For Chairman of the Section on Practice of Medicine—Dr. Wm. Pepper, of Pa.

For Chairman of the Section on Diseases of Children—Dr. A. Jacobi, of New York.

For Secretary—Dr. W. H. Bradford, of Boston.

The Committee also recommended that the following resolutions, passed by the Association last year at Atlanta, be recognized as remaining in force until further orders by the Association:

"That the Committee of Publication be instructed to advertise for proposals to publish the Transactions of this Association in six of the largest cities of the Union, and that the contract be awarded to the lowest and best responsible bidder.

"That the Treasurer be instructed to deposit the funds of the American Medical Association, monthly, as Treasurer, in the name of the Association, in the Farmers' and Mechanics' Bank, of Philadelphia."

The Report as read was adopted.

Dr. H. G. Pitfard, of New York, offered the following resolution which was referred to the Judicial Council: That the Richmond County Medical Society, N. Y., which has members who have been irregular practitioners of medicine, be debarred from representation in the American Medical Association.

Dr. Keller, renewed his amendment, That in the election of Officers and in the appointment of Committees, the Association and its officers shall confine themselves to members and delegates who are present at the Annual meeting.

Laid over under the rule.

Dr. Pallen moved a reconsideration of the vote by which the resolution relating to the printing of the Transactions, reported by the Committee on Transactions was adopted. Carried.

Dr. Pallen then moved that the publication of the Transactions for this year be assigned to the Collins Printing-house, as last year, without advertising. Carried

The Minutes of the Sections were then called for, and responses were received from the Section on Practice of Medicine and the Section on Surgery and Anatomy. They were referred to the Committee on Publication.

The Secretary moved that the Secretaries of the other Sections have permission to send their minutes accompanied by the papers, to the permanent Secretary of the Association, and that they be referred to the Committee on Publication. Carried.

Dr. Brodie, of Detroit, offered a resolution tendering the thanks of the Association to Mayor Cooper and lady, to Mr. August Belmont and lady, and to Drs. Barker and Thomas, for their receptions, to Postmaster James, to the officers of the Western Union Telegraph Company, to the officers of the Young Men's Christian Association, to the Medical Profession of the city of New York, to those who gave the entertainment at Booth's Theatre, to Wm. Wood & Co., to Dr. George F. Shrady, editor, for the enterprise exhibited in publishing a daily Medical Record during the meeting of the Association, to the daily press, to the College of Physicians and Surgeons, and to all others who in any way have contributed to the comfort and entertainment of the members of the Association during their stay in the city. Unanimously adopted.

A [illegible] was offered and adopted tendering a vote of thanks to the Committee of Arrangements.

Responses were made by Drs. Thomas and Pallen.

On motion by Dr. Mann, of Massachusetts, an honorarium of $1,000 was granted the permanent Secretary.

Dr. Hurd, Chairman of the Section on Medical Jurisprudence and State Medicine, offered the following resolutions as set up from the Section.

First, Endorsing the National Board of Health.

Second, That the Association recommend medical schools to establish a Chair of State Medicine as part of the regular course.

Third, That the name of the Section hereafter shall be, "Section on State Medicine."

Fourth, That the Committee on Prize Essays shall be Drs. S. L. Charles, of La., J. L. Cabell, of Va., and A. N. Bell, of N. Y.

The resolutions were all adopted.

The delegates from Canada were invited to seats on the platform, and Dr. Howard responded, acknowledging the special compliments which the delegation had received from the Association.

Dr. Bigelow, of Massachusetts, reported progress from the Committee appointed to report upon the feasibility of publishing the proceedings of the Sections in journal-tic form.

The report was accepted, and the committee continued, to co-operate with the Committee on the President's Address appointed to report at the next annual meeting.

The President then introduced Dr. John T. Hodgen, of St. Louis, the President elect, who responded appropriately to the call of the Association.

On motion, a vote of thanks was tendered to Dr. Sayre for the ability and courtesy with which he had discharged the duties of President.

The motion was unanimously passed by a rising vote.

Dr. Sayre responded in words of feeling and thanks for the uniform kindness which had been extended to him, and especially for the manifestations of sympathy and support which he had received from members of the medical profession all over the world, in the hours of his great bereavement and prostration caused by the sudden death of his eldest son.

The Association was then declared adjourned to meet in the City of Richmond, Va., on the first Tuesday in May, 1881.

THE EXCURSION TO CONEY ISLAND.

The excursion given by Wm. Wood & Co., in honor of the American Medical Association, took place on Friday afternoon. The steamer Grand Republic started from the pier at the foot of West Twenty-fourth Street, at 1 P.M., having on board nearly one thousand delegates and their friends. The weather was cool and pleasant, and the trip was duly enjoyed by the guests. The steamer took a route up the river as far as Yonkers, and returning passed around the Battery, and Blackwell's Island, thence down to New York Bay to the Iron Pier at Coney Island, arriving at the latter place about 5 P.M. Gilmore's band was in attendance, and during the trip to and

from the island discoursed elegant music. On the arrival at the pier a sumptuous repast was furnished, and after an opportunity for promenading and enjoying a fine view of the Atlantic, the excursionists betook themselves to the boat.

During the homeward passage a meeting of the delegates was called to order in the main saloon by Dr. Wm. Brodie, of Michigan, when Dr. Toner, of Washington, was chosen Chairman, and Dr. Shrady, of New York, Secretary. Dr. Toner, in a few brief remarks, stated that the object of the meeting was to express the appreciation of the delegates present of the elegant entertainment which they were enjoying. Appropriate speeches were made by Drs. Beverly Cole, of California, Adams, of Minnesota, E. M. Moore, of Rochester, N. Y., A. C. Post, of New York City, E. M. Hunt, of New Jersey, and Wm. Brodie, of Michigan. On motion, Drs. W. O. Baldwin, of Alabama, and Wm. Brodie, of Michigan, were appointed to draft suitable resolutions, when the following was offered and unanimously adopted :

"*Whereas*, by the munificence of William Wood & Co., the members of the American Medical Association and their friends have, under very favorable auspices, obtained views of the Palisades on the Hudson, the cities of New York and Brooklyn, the Bay of New York and the Ocean, and have also been entertained with a lunch on Coney Island ; therefore,

"*Be it resolved*, That the delegates and members tender their sincere thanks to Wm. Wood & Co. for their kindness and liberality in giving the Association such a delightful entertainment.

"*Resolved*, That the preamble and resolution be sent to the MEDICAL RECORD, and to the different medical journals throughout the country, for publication in the same."

After repeated calls, Mr. Wm. H. S. Wood, the Senior of the firm of Wm. Wood & Co., spoke as follows :

Ladies and Gentlemen :—This courteous reception and the kind words you have spoken, so wholly unlooked for, almost takes from me the power of returning my thanks. Permit me to tell you again what I know you have been told before, with what pleasure we anticipated your coming ; to tell you also of the gratification it has given me to prepare for you this slight evidence of the welcome which in common with all our citizens I have felt toward you. But now, while we have welcomed your coming with all our heart, the sad time has arrived when we must speed the parting guest. In thanking you again for your kindness, permit me to wish you all a safe and prosperous return to your homes scattered over every section of this grand republic. God speed you.

The excursion was in every way a success, and the large number of guests returning to the city at 9 P.M. were exceedingly well pleased with their entertainment.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from May 22 to May 29, 1880.

HARVEY, P. F., Capt. and Asst. Surgeon. Granted leave of absence for four months. S. O. 113, A. G. O., May 21, 1880.

THE FRENCH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE has received a donation of $4,000 from M. B. Burnet for the advancement of scientific research.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending May 29, 1880.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.

May 29, 1880.	0	6	58	7	86	31	1	0

ANNUAL MEETING OF THE AMERICAN ASSOCIATION OF MEDICAL COLLEGES.—This Association held its annual meeting in this city, in the afternoon of May 31st. Its principal work was the unanimous passage of a resolution recommending the adoption of three full courses in separate years, as essential to obtaining a medical degree. It was also resolved that copies of the resolution be sent to the Association of Medical Editors, with a request for their co-operation in bringing about the three term course.

ENGLISH FEELING TOWARD FEMALE PHYSICIANS.—At a recent election of medical officers at the National Hospital for Paralysis and Epilepsy, in London, the trustees of the hospital, according to *The Medical Press and Circular*, subordinated the interests of the hospital to the gratification of an unreasoning prejudice. The way they did it was this : Dr. Allen Sturge had devoted himself for five years to the work of the hospital, and he was unanimously recommended by the medical staff to the position of senior assistant physician. The doctor, however, had married a lady of his own profession, and the trustees seemed to think that this act incapacitated him for a position on the hospital staff. He was, therefore, refused the position. Great indignation is expressed among his medical friends.

ASSOCIATION OF AMERICAN MEDICAL EDITORS.—The fifth Annual Meeting of this Association, was held in this city, May 31st, DR. FRANK WOODBURY, Vice-President, in the Chair, DR. DUDLEY REYNOLDS, Secretary.

An opening address was delivered by the Vice-President.

Dr. A. N. BELL read a very eloquent Annual Address, sent on by the President, DR. POWELL, that gentleman being unavoidably detained at home by sickness in his family.

A resolution of thanks for the address and of condolence for the illness which kept the President away, was unanimously adopted.

The question of adopting the metric system, after some debate, was laid on the table.

The Committee on Nominations then presented the names of the following gentlemen for officers for the ensuing year : for President, Dr. George F. Shrady, of the MEDICAL RECORD, N. Y. ; for Vice-President, Dr. R. S. Nelson, of the *St. Louis Courier of Medicine*, St. Louis ; for Secretary, Dr. Dudley Reynolds, of the *Medical Herald*, Louisville. Dr. Woodbury objected to the report, that it presented the names of gentlemen who were not members of

the association and were not present. He suggested that the report be returned to the committee. Upon being informed, however, that Dr. Shrady had been present, and was a member, he withdrew his suggestion, and the gentlemen named were unanimously elected.

The Association then adjourned to meet at the next place of meeting of the American Medical Association on the evening before the meeting of that body.

The Bill to Regulate the Practice of Medicine in New York State has become a law. We counsel all physicians therefore that it will be necessary for them to show their diplomas and register at the County Clerk's office before the first of October next. The fee for registration is twenty-five cents.

The Entertainment at Booth's Theatre to the American Medical Association.—On the evening of June 2, a complimentary entertainment was given to the Members of the Association, at Booth's Theatre, by Messrs. Reed and Carnick, Scott and Browne, and the New York Pharmacal Association. Shakespeare's Tragedy of Othello was presented, Mr. Edwin Booth taking the part of Iago, Mr. Robinson that of Othello, Miss Atkinson that of Desdemona, Miss Cummins appearing as Emilia. The orchestra was under the direction of Mr. Thomas H. Joyce.

Nothing was left undone by the hosts to make the entertainment in every way a success. There were no reserved seats and the house was crowded with delegates and their lady friends, so that there was scarcely standing room. The programmes were handsomely engraved and tastefully encased in beautifully colored ribbon and stamped in gilt with the head of Hippocrates and with the title of the Association.

The acting was superb, Mr. Booth being much better supported than usual. Altogether, the evening was one long to be remembered by each and every one of the large audience present.

Cure for the Tobacco Habit.—Dr. F. B. Millard, in the *Medical and Surgical Reporter*, revives the question of the value of "pine apple," as it is called, as a cure for the tobacco habit. This substance is a fungus that grows upon pine trees. Dr. M. says that he has used it himself, and has prescribed it often, and has never seen a case in which it did not eventually eradicate the craving for tobacco. The taste is not unpleasantly bitter, and it is to be used about as a moderate chewer uses tobacco.

Medical Night Service.—The bill of Dr. Henri Nachtel, for the creation of a medical night service, was passed by the New York Legislature, and is awaiting the signature of the Governor.

Trichinosis on a British School-Ship, Simulating Typhoid Fever.—Last fall a mysterious epidemic of what was thought to be typhoid fever broke out on the English training-ship "Cornwall." One of the boys died and a large number were ill, the symptoms resembling sometimes typhoid fever and sometimes simple continued fever. The remains of the boy who died were, after a period of fruitless investigation into the cause, exhumed, and abundance of trichinæ found in the muscles. This, with the fact that the boys had boiled American pork every week, settled the question of trichinosis. The closeness with which the disease simulated typhoid fever in some cases was remarkable.

Toxic Effects of Aconite in a Case of Acute Articular Rheumatism.—Dr. S. C. Dumm, of Canastota, Ont., reports a case of acute poisoning in a young lady who was suffering from rheumatic fever. Along with other remedies, including opium, three drops of tinct. aconite were ordered every three hours. By mistake ten drops were given every three hours. The next day when the doctor called the patient was almost collapsed, the skin cold and clammy, pulse hardly perceptible, heart's action irregular in rhythm and force, breathing labored, and an agonizing sense of oppression in the cardiac region. Brandy was administered, and in a few hours she felt as well as ever. Dr. Dumm is inclined to think that the opium she had previously been taking had some influence in preventing the worst effects of the aconite.

After recovery from the poisoning, nothing more was heard from the rheumatism: that disease was completely aborted.

Severe Gunshot Wound of the Shoulder; Amputation and Recovery.—Dr. David B. Capriles, of Caracas, sends us an interesting account of an operation performed by Prof. C. Avila and himself, assisted by Dr. W. Schoenbrunmark. A young man accidentally discharged his musket, loaded with shot, into his right arm and shoulder. An immense lacerated wound resulted, the deltoid and pectorales muscles being torn up from their insertions, and cavities formed large enough to pass in the whole hand.

There was great loss of blood, and almost fatal collapse; but the patient was rallied by stimulants. Next day the operation was performed, the humerus was dislocated, and an immense inferior flap formed, this being the only thing that the lacerated tissues allowed. The hemorrhage was controlled by pressure on the subclavian. While the anæsthetic was being given, the patient was attacked with epileptic convulsions, but these were finally subdued. The man made a rapid and complete recovery.

Further Reports Regarding Bromide of Ethyl.—*The St. Louis Medical and Surgical Journal* contains a report of two cases in which this new anæsthetic was given to a boy of four and a girl of fifteen. It nauseated the boy, and did not work very well with the girl.

The *Chicago Medical Gazette* reports a case in which the anæsthesia was satisfactory.

At the New York Marine Hospital, Dr. W. H. Heath has given bromide of ethyl in ten or more cases. There was considerable struggling, with spasmodic contractions, in two or three cases; nausea followed occasionally. On the whole, however, the results were very good.

A Corner in Opium is said to be already formed, and the price of the drug has risen from about $4.50 per pound to $6.50 or $7. There was a short crop last year owing to the heavy rains in Turkish Asia. The average crop is about 75,000 pounds, which supplies the demands of the world, with a little surplus; that of last year is estimated to have been one-half of the above amount. There are now 60,000 pounds of opium in the market; one-half of this has been bought up by a syndicate of New York and London men. It is considered probable that this syndicate will run the price up to $8 or $10 per pound, or more. Such a corner as this was made a number of years ago, and then opium was sold in job lots at $30 a pound. The present "corner" will not be able to create any such prices as this, however.

ETIOLOGY AND TREATMENT OF UTERINE DISPLACEMENTS.

By MONTROSE A. PALLEN, M.D., LL.D.,

PROFESSOR OF GYNÆCOLOGY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.

Part I.—Etiology.

Gentlemen:—The class of uterine cases to which I desire to call your attention to-day, will be that of which we see the greatest number in practice. I think about sixty per cent. of the cases which I have treated at this clinic have been versions and flexions, or upward and downward displacements. Now, there are so many theories, and such contradictory ones, it is but proper that we should have some correct idea of the conditions producing these various troubles. If we read "Hodge on Women," who, up to within ten or twelve years, was looked upon as the best authority in the United States, or such authorities in Great Britain as Ashwell, Bennett, Tilt, and many others, we get a confused idea that displacements of the uterus depend upon relaxation of the so-called ligaments. Now, I propose to show you that there never existed a case of uterine displacement dependent upon relaxation of the so-called ligaments of the uterus. First and foremost, there are no ligaments proper, the only approximation being what are known as the round ligaments; but even this is a misnomer, as the so-called round ligaments contain contractile tissue, analogous to the cremasters of the male. They pass out of the pelvic excavation through the abdominal rings and are inserted through the canal of Nuck into the labia and are expanded upon the dartoic sac, just as the cremasters of the male are expanded upon the testicles. Under certain physiological excitement, the round ligaments draw the uterus down, in the same manner that the cremasters in the male draw the testicles up, during certain physiological conditions, viz.: that of erection of the penis. If we examine the uterus we find it swung in the centre of the pelvic excavation, and in a line almost parallel with the axis of the inlet. If it were on a line drawn from the umbilicus to the coccyx it would be parallel with the axis of the pelvis, but its inclination is more forward, and the axis of the uterus corresponds with a line drawn from midway between the umbilicus and pubic bones to midway between the third and fourth bones of the sacrum. Now, what is it that holds the womb in that position? The old writers led us to believe that upon either side the entire support is received from the broad ligaments, and that anteriorly it is held by what is known as the round ligaments.

We are further led to believe that the uterus is prevented from tilting forward by some duplicatures of the peritoneum, through which run certain muscular striæ which are inserted just at the junction of the sacral with the lumbar ligaments. Therefore the uterus is suspended in the central portion of the excavation, and whenever it turns forward or backward it revolves upon its axis of suspension. It was a very plausible theory that this axis of suspension was controlled by the ligaments. The utero-sacro-lumbar ligaments, the posterior ones, are in reality the only ones that possess any sustaining power, as far as the position of the uterus is concerned; mark you, I say *position*. The reflections of the peritoneum are called ligaments. If they were ligaments in the proper sense of the word, they would probably be of a fixed and given size, and have a definite origin and insertion, as is the case with ligaments in other portions of the body. As it is, they are nothing more than a loose collection of fibres, slightly bound together by connective tissue. Now, is it probable that tissues of this kind could, without other assistance control the position of the uterus? I certainly think not. My opinion is that the uterus is held in position partly in consequence of these, but not entirely by them. If we prop up a weight, or column, for instance, and it rests upon a solid foundation, very slender cords upon either side will prevent it from swaying to and fro. We find that a flagstaff upon a house may be retained in position by very slight ropes or wires, and in the same way we find that these so-called ligaments hold the uterus in position. But the uterus is principally, if not altogether, retained in position by its attachment to other structures. First, let us examine its attachment to the bladder. There are what are called utero-vesical ligaments, bands of pelvic fascia and uterine muscular tissue passing between the bladder and the cervico-corporeal junction, to which points they are attached, and prevent the retreat of the cervix. We find that passing backward there is another reflection of the peritoneum, which is glued to the structure of the uterus by means of the sub-peritoneal tissue, and that it is again reflected upon the rectum. Thus we see we have an anterior and a posterior attachment. We have also a certain degree of fixation on either side, as a result of duplications of the peritoneum being glued to the uterine structures. These are nothing more than the ropes which hold the flagstaff in position, and the base upon which this flagstaff rests is the vagina, and it alone, practically gives support from below to the uterus above.

But the actual determining factor in the position of the uterus which is variable, is nothing more nor less than its vascular supply. The great mistake which has hitherto been made by all of the above named writers, is, that they either forgot, or did not know, that the pelvic contents are principally the generative organs, which consist of nothing more nor less than a series of erectile structures, and that these alone produce changes in consequence of changes in the vascular supply.

It is perfectly normal for a man's penis to become erected under certain conditions. So with the uterus; it is perfectly normal for the uterus to be in one position and subsequently in another, the position which it occupies depending upon the vascular supply.

If we examine the blood supply of the uterus, we find a very generous distribution of vessels, just as we find in the male organ. In the latter, if a single trabecula gets diseased, it interferes with the blood supply of that organ, and hence, during erection, we find greater or less deformity of the penis as a consequence. Where the meshes are broken there will be an irregular distribution of the blood, and the greater the injury the greater the distortion. There are cases upon record where the organ, when erect, was bent like a flexed uterus. Now mark you, I do not wish you to think that the penis is homologous with the uterus, but its vascular supply is analogous. An erection of the tissue depends upon an increased supply of blood, and so long as this condition obtains, so long does the organ remain erect. We find that in the female, the uterus becomes erect under

certain physiological conditions, and in many other conditions which are pathological, for instance, when the blood-vessels of the uterine and ovarian plexus and tissue around the clitoris maintain a retention of blood. Under these circumstances the uterus (in its normal, non-erected condition, lying suspended, flabby and flaccid) becomes engorged, increases in size, stands up in the pelvis, and after awhile becomes globular in form. If displaced posteriorly, retroverted, the convexity of the posterior segment will be increased. With the female, there is always a menstrual hypertrophy of the uterus which is purely physiological. After the subsidence of menstruation, after the rupture sanguinis has passed, the organ assumes its previous relative flabby and flaccid condition. The only analogue that I can give you is that of the erection of the male organ in consequence of the bladder being filled with water. So the uterus is filled with blood during menstruation. By evacuation of the male bladder, thus relieving the mechanical obstruction to the return of blood, the vessels empty themselves, the reflex erection subsides. So in the female organs of generation.

No man has ever seen in the dead subject a displacement caused by the stretching of the so-called ligaments of the uterus, except where this organ is dragged or pushed down by some abnormal growth. Whenever we find the uterus changed in position without any interference in the circulation we find some extraneous, some foreign cause. But where we find cases of retroversion or retroflexion, we frequently have none of these foreign, outside conditions, those which I now explain to you as extra-vascular.

We have now come to that point in the study of the etiology of our subject where we may say that displacements of the uterus are divided into two classes. First, the vascular, due to conditions which I have just tried to explain to you. Second, the extra-vascular, due to such causes as tumors and new growths of various sorts, or any cause which produces pressure from above, dragging from below, or giving way of inferior support. By change in the vascular condition, we mean those alterations which take place in the blood-vessels themselves. CONSEQUENT UPON THESE CHANGES, THERE IS A LOSS OF THE ERECTILE POITION OF THE UTERUS AT THAT POINT WHERE THE DISORDERED BLOOD-VESSELS ARE DISTRIBUTED. Let us now examine a class of cases, of which many have been presented to you. A patient presents herself who says that from the beginning of her menstrual life she has had pain, that it increased with each succeeding menstruation. She is single, has borne no children, is twenty-three or twenty-four years of age, and has always been the subject of dysmenorrhœa—dysmenorrhœa proper—for there is obstruction to the escape of the menses. We examine the patient and find an undue bending forward of the uterus, an anteflexion, or we may find retroversion or retroflexion, though not so commonly as anteflexion. In a great majority of cases, the uterus is bent forward, and why? Because, in the prepubertic girl the normal position of the uterus is with its axis tipped forward, and the cervix markedly developed. Such a woman's uterus is exposed to an excess of the normal position — to an anteflexion. It has reached this point before the patient has her first menstruation. What is her first menstruation? It is that disgorgement of blood from the uterus which the pelvis contains in consequence of the first development of the mature egg in the ovaries or the ovary, as the case may be, where there is ripened Graafian vesicle, and this, through cell action and reflex excitability, begets erection. If from developmental action, if from some superincumbent weight, a flexion exists, it will be exaggerated, as the veins become flattened upon themselves and the nutrient vessels, the arteries, become thin and stretched—a diminution in the supply of blood ensues, and the probabilities are that the pathological process undergone at that first time may be only the obliteration of one or two little capillaries. There is perhaps a thrombus formed. It is the first drop of water upon the stone.

At the next menstrual period the parts undergo a little change in consequence of this microscopic thrombus. These small blood vessels become larger and larger, and the uterine walls more bent, and in the cavity of the uterus there is retention of blood that excites an irritation or inflammation, as the case may be, of the lining membrane. This begets hyperæmia, and hypersecretion, and an excessive quantity of mucus is retained, acting as a continuous source of irritation, so that at the next menstruation we have the mucous membrane more tender than it was before, and the capillary blood-vessels are more dilated or obstructed, hence increased perivascular infarction, and a larger area of subsequent ischæmia. There is more space to which nutrition does not go, and the framework of the uterus is increased upon the opposite side, because, if there is a cutting off of the blood in certain portions of the organ, the other side increases in consequence of hypernutrition. Hence, in anteflexion, we may have thickening of the posterior wall, amounting to actual hypertrophy. We have primarily degeneration and atrophy in the anterior wall, and on the opposite side (on the non-contracted side of the uterus) there is an increase in tissue because of the tendency of all organs to compensatory vascularization. Now we have a distinct pathological process undergone, and that pathological process becomes one of atrophy, the tissues finally undergoing fatty degeneration. The order of things is not as described by Dr. Emmet in his late masterly work on the "Principles and Practice of Gynæcology," namely, that fatty degeneration occurs in consequence of the flexion. It is just the other way, flexion takes place in consequence of fatty degeneration. This is the etiology of flexions of the uterus. They depend primarily upon a passive ischæmia, a local anæmia. If I press upon my forehead and then remove my thumb, I find the surface pressed upon has become white; that is ischæmia; a diminished supply of blood in the capillaries, mechanical ischæmia, or localized anæmia. The pressure upon these blood-vessels, for the time being, paralyzed the vaso-motor nerves, and the passage of blood was interfered with until the vaso-motor nerves could regain their power. Here you see illustrated the first step in the degeneration of tissue. Paralysis of the vaso-motor nerves interferes with the circulation, and we have engorgement in consequence. Subsequently amœboid movement of the white blood corpuscles may be detected, and following this we have inflammation.

Now, the same thing takes place in the uterus, only to a greater degree, because it is composed largely of erectile tissue. The arteries supplying the organ are arranged somewhat in the form of a helix, and by reason of this our writers have conceived the idea that it was for the purpose of accommodation to a larger blood supply by expansion. The blood-vessels are arranged in this way so that a

greater quantity of blood can be rapidly poured out at the time the erections which I have been speaking of, take place. If œdema take place, the blood is not prompted to return, and what are the consequences? Just what I have shown you by pressure upon the forehead with my thumb. We have primarily ischæmia; secondarily, amœboid movements of the white blood corpuscles, and then inflammation. When this takes place in women who have never borne children, then we have most frequently anteflexion of the uterus; in women who have borne children, the womb is liable to posterior flexions, and these latter displacements are frequently produced by tight bandaging after labor.

What is the consequence of this tight bandaging? The abdominal fascia and the abdominal skin which has been stretched during several months is at this time very flaccid. As involution goes on the bandage is from day to day drawn tighter and tighter. Let there be a thrombosis (at the point of the bending of the uterus produced by the bandage) and frequently as a result, retroflexion. All flexions are nothing more nor less than a bending of the organ upon itself, primarily in consequence of and subsequently producing changes in the vascular distribution; all versions are nothing more nor less than a turning of the organ upon its axis, in consequence, not so much of the distribution of the blood-vessels in the uterus itself, as in the distribution of the peri-uterine blood-vessels. Suppose we have in the uterus, as we do most always, a swelling in consequence of a thrombosis or varicocele of these blood-vessels; suppose, as we frequently do have, an obstruction to the return of blood in the mesenteric and hemorrhoidal circulation, and the blood is retained there: what is the consequence? Wherever these capillary blood infarctions take place, we find œdema of the parts, and a slight inflammation ensues at one point or another in the œdematous spaces. The large majority of these versions ensue in consequence of trouble at the menstrual period, or abortion, or after labor. The normal menstrual hypertrophy makes the uterus about three times its natural size, and abortion increases its size according to the month at which it takes place, and labor at full term increases its dimensions according to the size of the child. In proportion to the growth in the length of the uterus so does it increase in thickness. If the normal size of the uterus be represented by the figure I, its size during menstruation by the figure 3, its size at the time of an abortion by 80, 90, or 100, then its size at full term would be represented by 200 or 300. So, if we have a thrombosis occurring at such times in the way above described, we may look for displacement of the uterus in consequence of gravitation. Where there are effusions, there are always tendencies to displacement. In all parts of the body wherever there is an increase in the quantity of blood, and it is retained, it matters not where it may be, it has a tendency to get outside of the blood-vessels, to be effused, no matter where such retention occurs, whether in the scrotum, eyelid, or elsewhere. Now, when we know that these facts exist; when we know that there are no such things as true ligaments which support the uterus, when we know that the organ is displaced backward, downward, and forward in consequence of vascular changes, we know that these displacements cannot depend upon stretching of the so-called ligaments. It strikes me that such a deduction is unanatomical, unscientific, and absurd. The treatment of this class of cases will be considered in the next lecture.

Original Communications.

ON CYSTOTOMY FOR CYSTITIS IN THE MALE.

By ROBERT F. WEIR, M.D.,

SURGEON TO THE ROOSEVELT AND NEW YORK HOSPITALS.

(Read before the American Medical Association, June 2, 1880.)

THE thorough drainage of the bladder for the treatment of a rebellious cystitis and the placing of its inflamed walls at rest by an opening into its neck, as in lateral lithotomy, is analogous to various operations resorted to elsewhere in the body. The urethra, for instance, is tapped posteriorly to allow a fistula in front to heal; tracheotomy is employed to rest and aid in curing a specifically ulcerated larynx, and the colon is similarly opened to secure cicatrization of an ulcer or rest to an irritable neoplasm in the rectum below. This procedure applied to the bladder has now been fairly before the profession for thirteen years, for in 1867 it was brought to the notice of surgeons in this country by a paper read before the New York State Medical Society, by the now venerable and venerated Dr. Willard Parker.

The article was entitled "Cystitis and Rupture of the Bladder Treated by Cystotomy." Some two years since, while engaged in preparing a lecture on this subject, I met with some important points of historical interest connected with this operation, which concerned the question of its priority, and it seemed as if the palm should be awarded to some one else than to the distinguished surgeon just named. My discoveries were as follows: in a paper entitled "Observations on Lithotomy" by E. Bickersteth, published also in 1867, in the *Liverpool Medical and Surgical Reports*, for October, I found an account of a case in which this surgeon, thinking "that the rest," to quote his own words, "afforded to the bladder by an incision through its neck, permitting the constant escape of the urine without any muscular contraction on its part, might act beneficially," performed this very operation with marked success.

My regret that America could not claim this mode of treatment, on reading this, was great, but it became the greater when I furthermore learned that a Mr. McCraith, a surgeon in Smyrna, had also, in June of the same year, 1867,* detailed an account of a median section of the perineum with a subsequent incision into the prostate for the satisfactory cure of an obstinate cystitis. Here were three independent experiences in this mode of treatment emanating in the same year. To whom should the credit be given? This was apparently easy to settle, for Dr. Parker's paper was read earliest in the year, viz., in February, but McCraith's† paper referred to a case of Sir Wm. Fergusson's that had been published in 1855, which was imperfect not only in its details, but in its designs. Fergusson resorted to an operation which he describes as "not like lithotomy but more in the manner of Symes, or Allerton's operation, in the median line of the perineum, with the intention" (he says further) "of cutting across the nervous plexuses and irritable parts at the neck of the bladder." His operation was likewise followed by a com-

* Med. Times and Gazette.

† McCraith also refers to Bouchardat as having done the operation in 1803. A diligent search has failed to verify this reference.

ble recovery. On referring once again to the records of Dr Parker and Mr Beckersmith to determine the actual priority of the performances, not the publication, of the operation, it was ascertained that the Liverpool surgeon had first employed cystotomy in 1857, and that the American surgeon had done it first in 1859, seven years earlier, but what placed everything beyond a cavil was that Dr Stephen Smith had already published Dr. Parker's case in the *New York Medical Journal* for 1857. Thus the priority not only of the performance of the operation, but of its publication, belongs properly to our octogenarian surgeon, Dr Parker.

The operation in the male was not repeated here or elsewhere until 1866, when Professor Eve cured a case of cystitis by bilateral cystotomy, though previous to this time cystotomy had, in 1861,* been resorted to by Dr Emmet for cystitis in the female. Since 1866 the progress of this mode of treatment has been more rapid. In 1868-69 Dr Powell, of Chicago, used it in several cases, but I have only been able to obtain access to two of these, and one, somewhat singularly enough, was for an extravasation of urine. It is not clear why cystotomy should have been done in this case.

In 1869, Dr. Battey, of Georgia, also had recourse to this operation, with a successful issue. Up to the present time it has been performed some forty-seven times, and by the following-named surgeons, in addition to those already mentioned: Drs. Van Buren and Keyes, Erskine Mason, Briddon, Little, Conley, Post, Howe, and L. A. Stimson, of New York; Hutchison, of Brooklyn; Jones, of Toledo; Owens, of Chicago; Cummings, of Virginia; and Barss, of Massachusetts. While in Europe the operators are Parona, Modoro, Dolbeau, Virmontier, Teevan, and Bryant. Several of the European cases were for spasm of the bladder, or that condition where painful and frequent micturition was not usually conjoined with an altered urine. Without asking your attention to these cases at length, I would now venture to bring to your notice certain deductions that can be made from an appreciation of such a total as this.

The first question that arises concerning any new method of treatment refers to the risk of the procedure.

While in cystotomy for cystitis in the male the mortality of thirteen cases out of forty-seven collected, is great, yet a closer scrutiny shows that of these ten were due to advanced kidney changes, and that most of these complications were present in men past the meridian of life; or, in other words, that in the young subject, or in those where the cystitis has not been of very long duration, the operation is less hazardous—a conclusion that should be expected. In only three cases was death the result directly of the operative interference: one case, Conley's, within twenty-four hours, from a fatty heart; in another, Hutchison's, death ensued within a week from the operation from exhaustion; and in the third, Mason's, death was due to secondary hemorrhage on the fourteenth day.

The difficulty of recognizing the existence of a renal inflammatory process coincident with a cystitis must always be admitted, and its possibility must always be kept in mind in all operations on the urinary organs. Yet, as Bryant has well said, a clean cut into the bladder of a man with sound kidneys is not a very dangerous proceeding, and Dr Parker, in a recent letter to me, has laid stress upon the same point.

Next in order to the safety of the operation is the consideration of the amount of benefit that has been derived from it. Here we have an agreeable surprise. From what I had witnessed in some of the cases of my colleagues, and from the expression of opinion that had emanated in a recent discussion on this subject before the New York Surgical Society, based, it is true, upon the recital of a comparatively few cases, the impression had been created that the operation was hardly a justifiable one, not only by reason of its risk, for a large proportion of all the deaths were then presented (Briddon's, Mason's, and Hutchison's) or noted (Bryant's), but also from the very moderate amount of benefit that was stated to have been derived in the cases that had recovered from the operation. Dr Keyes, who had had, with Dr. Van Buren, an experience of two cases, believed that only a certain amount of relief was to be obtained, and that but of a temporary character, and that, as a rational means of cure, there was no special reason why the operation should succeed unless aided by other measures.

On looking, however, at the figures that have been here obtained, it is found that in the thirty-four cases that recovered twenty-three were cured—that is to say, either were cured absolutely or so greatly relieved as to be enabled to attend to their vocations, retaining their urine from three to four hours, etc. Seven were relieved, that is, were decidedly benefited by the operation, and only four have been reported as failures, the return of the symptoms dating from the closure of the wound. One of these failures, however, felt that the operation had so much relieved him that he was anxious later that another trial should again be made.

From this recapitulation it is evident that much encouragement can be taken in the continuance of the operation as a legitimate mode of treatment, and that experience fully justifies the words of Dr. Parker, written to me within the past ten days, that he never had greater confidence in the philosophy of the operation and the success of it than he had to-day.

A very interesting circumstance occurred in one of Van Buren and Keyes's cases: this was the removal, at the time of the incision into the bladder, of the hypertrophied median lobe, in a bifid state, and also of a pedunculated tumor as large as a marble, which was attached to the trigone, just posterior to the prostate. This patient recovered without any untoward symptoms, the wound healing at the end of the fifth week.

The operation was of great service, but the benefit that was derived from it was considered to be due not so much to the cystotomy as to the removal of the prostatic outgrowths. These same surgeons, in the removal of a stone from the bladder, in 1874, accidentally caught and purposely twisted off the hypertrophied median portion of the prostate, with the effect, after the recovery of the patient, of his urination being accomplished without the aid of a catheter—a means that, prior to the operation, had always to be employed to accomplish the voidance of a single drop of urine. Also in one of Dr. Mason's cases of cystotomy, the third lobe was removed.

This feature in lithotomy or cystotomy is not a new one, but a sufficient number of cases have been accumulated for a moment's consideration of the subject. Sir Wm. Fergusson, in 1849, presented to the London Pathological Society two tumors, the size of a filbert and horse-bean respectively, that he

* Emmet's paper was published in the Transactions of the New York State Medical Society for 1872, but in the Giornale Veneto, April, 1862, Aran published a case of cystitis in the female successfully treated by cystotomy.

had removed with the forefinger from the middle of the prostate gland during an operation of lithotomy; the patient making a good recovery. In the *Lancet* for January 1, 1870, in a lecture on "Lithotomy, and on Certain Cases of Enlarged Prostate," he further stated, that he had since repeatedly followed this practice, and advised that it should be admitted as a recognized surgical procedure. A counter statement has, however, recently been made by no less an authority than Sir Henry Thompson,* that, inasmuch as the median portion of the prostate when enlarged, was large and shapeless and not pedunculated, it would be therefore impossible to remove it. He also said that he had seen only one case wherein this procedure had been attended with benefit.

If the report of Thompson's remarks is correctly made, they are such as would be negatived by an examination of the specimens of enlarged prostate in any good-sized hospital museum. This enlargement of the prostate is not infrequently to be met with in such a condition as to be removable by an operation, and in a case of Dr. Markoe's, where lithotomy was performed, in 1860, for the extraction of twenty-six calculi, the median lobe was removed intact, having plainly quite a slender neck. To close this part of the subject, as well as to put in form all our knowledge of this procedure, your indulgence is asked to the following cases of Mr. Thomas Bryant, and to his conclusions deduced therefrom, which seem to me to be fully warranted. Nearly all the cases, however, are unfortunately defective in one important consideration, and that is: in none of them has the bladder been tested by the introduction of a catheter to determine the presence or absence of residual urine. Unless atony existed to a great degree, the removal of the obstruction would have probably overcome or lessened this symptom. Mr. Bryant's† first case occurred in 1865, in a man sixty-seven years of age, in whom, for stone in the bladder, the lateral section of the prostate was made by Aston Key's method. In extracting the calculus a portion of the prostate was caught in the forceps and removed by traction. It appeared to be the enlarged third lobe or median portion of the gland. The patient recovered, and reported, several years afterward, that he was still well in all respects and that he could hold his urine for hours and that he had no bladder trouble whatever.

The second case presented itself in a man seventy years of age, who underwent lateral lithotomy, in 1876, for stone, with Aston Key's staff. The perineum was so deep that the bladder could not be reached and a blunt gorget was employed. In removing the stone, which was a large one, some resistance was experienced, and on examination it was found that a portion of the prostate was caught. The forceps were rotated, the stone being still held, and the prostatic growth pressed back with the finger. Nevertheless, on traction being made, the stone and the portion of the prostate came away together. A depression could then be felt in the region of the third lobe. In six weeks the wound had healed, the patient then passing normal urine and being able to retain it during the day for three hours, and during the night for six. In fact, all his bladder symptoms had disappeared and he was in better health than he had been for many years. A microscopic examination proved the prostatic nature of the tumor, and no injurious action was exerted on the convalescence of the patient.

Bryant advises that surgeons in similar cases should adopt the same practice, and, indeed, he says, "I would advise, in all operations of lithotomy in the aged, that the condition of the prostate should be examined into with a view to the removal of such portions as may project into the bladder injuriously, and, though I am not prepared to recommend that the operation of cystotomy should be performed in all cases of chronic cystitis resulting from an enlarged third lobe of the prostate gland, I would venture to suggest the expediency of its applicability to exceptional cases, believing that a clean cut into the bladder of a man with sound kidneys is not a very dangerous proceeding and that the removal of a prostatic tumor projecting into the bladder, by some crushing forceps or scissors, would not greatly add to the danger."

Therefore, it is a fair conclusion, from the consideration of these remarks of Fergusson and Bryant, and from the facts so far presented, that not only is cystotomy of decided service in the treatment of cystitis, but that it is advantageous to join with it, when possible, the removal of the enlarged median portion of the prostate, or such tumors of the gland as are readily enucleable.

But the inquiry into the merits of cystotomy should not stop here. Not all the cases were treated by the lateral section of the prostate; in only 32 cases was this method of opening the bladder resorted to, in 5 cases the bilateral incision was made, and in 10 the median. Here a serious question may arise, for in the 32 lateral cystotomes there were 11 deaths, in the 4 bilateral sections 1 death, but in the median operations, 10 in number, only one death occurred. While it may be conceded that median lithotomy has a somewhat lower death-rate than lateral lithotomy, yet here the difference in mortality is more reasonably to be assigned to the coexistence of the lesions of the kidney already alluded to.

A priori, it would be said that the median section, as usually performed for the removal of a stone from the bladder, was not applicable to the relief of an obstinate cystitis, for by this operation no drainage, and therefore no rest of the bladder, can be obtained. Indeed, the advocates of median lithotomy claim as one of its advantages that the retentive power of the bladder is not interfered with by the operation, and hence the patient is saved the constant soakage of a continually wetted sheet, etc. In examining carefully these cases of cystitis treated by the median cut, it is however found that 6 out of the 10 were cured completely, consequently that the bladders were put at rest; also that in the 10 cases, 3 were supplemented by sections of the prostate gland to a moderate depth (varying from two to four lines), and in 5 others, by dilatation by a finger (once) or by a bivalved speculum (four times), to the extent of stretching the prostate to the diameter of an inch, or by the simultaneous forcing of two fingers into the bladder (once). In two cases the mode of procedure is not given in full.

Now, the researches of Dolbeau and Teevan have heretofore shown us that the prostatic urethra will dilate without rupture only up to a diameter that ranges from $\frac{1}{2}$* to $\frac{12}{12}$† of an inch; most forefingers at the second knuckle equal or exceed this greatest diameter. Therefore it is most probable that in the cases where the usual median incision into the membranous urethra was resorted to with the simple introduction of the finger into the bladder, and drain-

* Med. Times and Gaz., vol. i., p. 710, 1879.
† Trans. Path. Soc., London, vol. xxix., p. 164.

* Teevan. † Dolbeau.

age was thus effected, the prostate sustained a certain amount of rupture—which idea is borne out by the fact that a permanent fistula (not always, however, acting as a drain) was more frequently met with after the median operation.

In concluding these somewhat fatiguing statistical remarks, attention is called to a point alluded to by Dr Battey, that it was difficult to keep the wound open long enough to give ample rest to the bladder. This is, to a considerable degree, true. Excepting two cases, the time of the closure of the wound in the successful cases varied from two to twenty weeks; the average was nearly five weeks. In the two excepted cases, Battey's and Harris's, the wound was kept open for eighteen months; in the latter case a tube was worn all this time. By judicious management the wound can be kept open from five to eight weeks, and sometimes longer. This is best accomplished by inserting within the first ten days, preferably the finger, or a large, soft tube, from the perineum into the bladder every second or third day. After this period has elapsed, a flexible rubber catheter, just entering, but not projecting much into the bladder, will often be well retained, certainly better than if used from the beginning.

By the median section there were 10 cases, of which 6 were cured, 3 relieved, and 1 died.
" lateral section " " 32 " " 13 " 4 " 4 failed, and 11 died.
" bilateral section " " 5 " " 4 " and 1 died.

* In 6 cases, with 3 recoveries and 3 deaths, the mode of operation is not stated, but from Mr. Bryant's remarks elsewhere it is inferred that the lateral section was employed.

ON THE USE OF CERIUM OXALATE FOR THE RELIEF OF COUGH.

By HOBART CHEESMAN, M.D.,

NEW YORK.

(Read before a Stated Meeting of the Medical Society of the County of New York, April 26, 1880.)

MR. PRESIDENT AND GENTLEMEN:—By the request of the President of this Society I have the honor to read before you the following paper:

My notes on the use of cerium oxalate for the relief of cough were taken last autumn, and they, together with a statement of my conclusions and some other portions of this paper, were placed last January at the disposal of Dr. Andrew H. Smith, at his request, to form the basis of a more extended investigation, the results to be reported to the Therapeutical Society of this city. The conclusions reached by this investigation, and adopted by the Committee of that Society, and read at a recent meeting, were favorable, and corroborated the statement of my own, accompanying the notes which I furnished the committee, without any important modification.

The weight of authority thus given the subject increases my confidence in now presenting it.

The importance of allevinating cough in phthisis and in other diseases is recognized. Watson says: "Cough is usually present, more or less, during all the stages of phthisis, and it is often that symptom which most distresses and harasses both the patient and his family," and, it might well be added, the physician. Hühle, in "Ziemssen," remarks that in many cases "it is the chief cause of annoyance throughout the disease. The violent efforts exhaust the invalid, induce perspiration, disturb sleep, and excite vomiting; they also inflict direct injury, and unless moderated by treatment, they may hasten the course of the disease." The constant unrest caused by frequent and violent paroxysms of coughing, the exhausting efforts attending them, and the direct injury caused to the delicate diseased organs, present formidable obstacles not only to a possible cure, but are potent, active factors in hastening the fatal issue.

The demand is for a medicine which can be relied upon with reasonable certainty to relieve cough, which will not destroy appetite, derange digestion, impair nutrition, and produce nervous prostration, but which will allay gastric disturbances and aid digestion; one which will not clog the lungs nor lose its virtues by prolonged use. This is the ideal cough medicine, and its discovery is likely to afford employ-

ment to the enterprising therapeutist of the future.

Sir James Y. Simpson introduced the use of oxalate of cerium in the vomiting of pregnancy in 1859. Dr. J. S. Ramskill, Clinical Lecturer on Nervous Diseases in the London Hospital, in the *Medical Times and Gazette*, of January 4, 1862, speaks favorably of its use in cases of epilepsy, having as an aura some gastric commotion, and states his opinion that "it acts as a sedative and conserver of nervous force; the sedative action being exerted upon the periphery of the pneumogastric, conveys the influence to the grand centre of excito-motor action, the medulla, and thus not only prevents an impending attack, but diminishes the chances of future fits by lessening the morbid excito-motor sensibility."

A case of vomiting in laryngeal phthisis is reported as successfully treated in the next number of the same journal.

In the *American Journal of Medical Sciences*, of October, 1868, its use was first noticed in the vomiting of phthisis, hysteria, and in various dyspeptic conditions.

Nothing conclusive appears to have been published concerning its physiological action. Some, on account of its difficult solubility, suppose it to act mechanically only on the alimentary mucous tract.

Dr. Charles K. Mills, of Philadelphia, in the *Philadelphia Medical Times*, of December 25, 1875, and of January 8, 1876, gives a description of the drug and analyses of various of its preparations. The commercial preparations were found to contain a little more than one part of oxalates of lanthanum and didymium to two of oxalate of cerium. But from therapeutical tests made with them in comparison with others made with chemically pure cerium oxalate, the mixed salts seemed, if anything, more efficient than the simple cerium. The lanthanum and didymium salts are more soluble than the cerium, and, therefore, it has been suggested that the therapeutical virtues of the commercial drug are due to these substances. There were preparations which seemed to have no therapeutical value, and it was thought that this might be due to the presence of irritating foreign matter, such as silica, which was found in some of the preparations examined. The chemically pure cerium oxalate, when precipitated from a neutral solution, is an impalpable powder, but when precipitated from an acid solution and the commercial preparations, are coarser; they are gritty and granular. The color may be nearly white or faint lavender or salmon.

In the *Practitioner* of April, 1878, Thomas Clark, L.B.C.P., etc., in a short article first recommended cerium oxalate in cases of chronic cough and shortness of breathing, and reported two or three cases of phthisis in which it was used with marked success. Mr. Clark stated as his opinion, that the medical properties of the drug are only sedative. The only symptom which he observed from its use was a slight dryness of the mouth. His rule was to give five grains in the morning, half an hour before rising, and he claimed that its effects lasted twenty-four hours after each dose.

In the MEDICAL RECORD of May 25, 1878, Dr. James G. La Roe gave his evidence in support of Mr. Clark, but thought the dose too large, and cited the case of a lady to whom he had given five grains in the morning, with the effect of producing a condition of stupor lasting all day.

Dr. Frank Alport, of Ill., in the MEDICAL RECORD of Jan. 18, 1879, reported its successful use in chronic lung and laryngeal cough. Dr. Alport had noticed no ill effects from five-grain doses, except when given to small children. One lady to whom he gave seven grains was moderately affected with symptoms of a kind similar to those noticed by Dr. La Roe.

Dr. Benjamin Morjé, of New York, in the MEDICAL RECORD of July 14, 1879, reports having employed it in nine cases of pertussis with marked relief to the cough.

With the approval of the attending physicians of St. Luke's Hospital, I employed it in the cough of phthisis, and in various other coughs during the greater part of my term as resident physician, from July 1st to November 1, 1879. Three preparations were, at different periods, used. That of Charles Pfiser, of New York, for about two months; another American preparation for two or three weeks; and during the remaining two or three weeks E. Merck's, of Darmstadt. The first gave satisfactory results, the second did not, the third did, but was not used for a sufficient time to test it thoroughly. It may be important to know that the second wholesales at a little more than half the price of either of the others, and, therefore, is more apt to be sold by druggists. The most expensive wholesales for less than four dollars per pound.

In the course of the observations the oxalate was often intermitted for a time, to observe the effect of its withdrawal, and for other reasons, and then resumed. Thus it happened that sixty-nine distinct trials of it were made, although the number of patients was only twenty-eight. No trial unless of more than a week's duration is counted; the majority of the trials lasted two or three weeks. The reports of patients were not relied upon unless supported by the testimony of nurses, or by my own observations, and the results were noted at the time.

During the latter part of July the drug was employed in a few bad cases with such marked success that in the early part of August the use of all other sedatives, opiates included, and cough medicines was abandoned, and from that time until November 1st, with rare exceptions, the oxalate of cerium alone was used as a cough medicine among a daily average of about twenty-five phthisis patients, representing all phases and stages of the disease. There were stubborn cases in which other remedies were at times substituted, but in most of them the oxalate was finally adhered to as the most satisfactory. The general treatment was kept up as usual in all cases. The oxalate was generally given in dry powder simple upon the tongue, and was most successful when so administered. It was preferred to give it on an empty stomach, and from one to three large doses daily rather than an equal quantity in small and frequent doses. The initial dose was usually five grains at bed-time, or in the morning on waking, or both; the doses being increased from this, unless relief was obtained, to ten grains or more, three times a day. Occasionally large doses allayed cough at once when smaller ones had produced no effect. Sometimes the cough, after being for a time relieved by small doses, returned, and was again relieved by increasing the doses. The drug lost its effects altogether, after a time, in a few cases; in many its effects did not wear out, at least during the time it was found necessary to employ it. Its benefits were prolonged by reducing or stopping the doses as soon as relief came, and increasing or resuming them on return of the cough. In several cases, after one or more failures, a subsequent trial with the same patient was successful.

The wards were evidently quieter while those requiring cough mixt. were taking the oxalate than at other times. The remedy was on several occasions entirely interrupted in the wards for a few days, and then resumed as each case came to require it. In about twenty-four or forty-eight hours after stopping it, the noise and complaining would increase.

The best effects were noticed in the early stages of phthisis, or in chronic bronchitis; but a harassing cough, with profuse expectoration in the third stage, was in several cases relieved, the cavities being then emptied without violent coughing or great effort.

The drug was not thoroughly tested in acute cough, but my impression is that it is less efficient in acute than in chronic cough, whether pulmonary or laryngeal. Nausea and vomiting became rare among the phthisis patients during the time it was used. It never disturbed the stomach, but, on the contrary, appetite and digestion often were speedily improved.

In dyspnœa having an asthmatic element, it doubtless affords more or less relief. In dyspnœa due to loss of normal lung substance, it can give the relief only which is procured by checking the coughing; during coughing the legitimate functions of the still healthy portions of the lungs are more or less arrested.

Frequently sleep was restored, and occasionally considerable drowsiness attended its use for a time, but these effects were not attributed to any narcotic property of the drug, but to the relief of the cough, which allowed the patient to make up for previous loss of sleep.

The patients taking the oxalate were weighed weekly, and several very soon showed marked gain.

No dangerous symptoms were ever observed attributable to the drug. The largest dose given was twenty grains. This dose was never repeated the same day, but was given, in a few instances, to patients taking ten grains twice at other periods of the day. No complaint was ever voluntarily made of its causing dryness of the mouth, but several of the patients questioned on this point admitted that it produced this symptom at first, but declared that after taking it a few days they ceased to notice it. There were now and then complaints of its producing a sensation of tightness in the chest, and of its drying up the expectoration, but complaining of these symptoms was common when the oxalate was not being used.

The majority of the trials were upon males. Of the sixty-nine made, thirty-nine were markedly successful, nineteen more or less so, and eleven failures. Of the failures the majority were in the third stage of the disease, and eight of them were trials in which the Philadelphia oxalate was used.

Time and patience do not warrant reading all the cases; therefore a few have been selected, after condensing them, to show the method employed in the tests and how the notes are composed, and to illustrate the different degrees of success and of failure, and the various conclusions, so far as possible, with a few cases. Details of previous history, of physical examination, and other particulars, are fully recorded in every case, but for brevity will be omitted, as there is small probability of any important errors of diagnosis in hospital phthisis patients.

Case I.—American, æt. 27, carpenter; admitted July 14, 1879. Has coughed and failed in health for six months. *Diagnosis:* consolidation at the right apex, and thickened and adherent pleuræ at the right base. The usual phthisis treatment ordered.

July 26th. Patient has a severe, hoarse, hollow-sounding cough, with scanty expectoration. The cough has been troublesome for six months. Since admission different cough remedies have been tried, with only temporary relief. Other cough medicines now stopped. To have five grains of cerium oxalate on waking every morning and at bed-time every night, in dry powder on the tongue. August 1st. Patient reports the cough greatly relieved since taking the powders. 4th. Coughs very little; oxalate stopped. 15th. Complains of dry, teasing cough; oxalate resumed. 18th. Oxalate stopped by mistake; resumed again on August 20th. 22d. Has not complained of cough for two days. 25th. On questioning the patient reports the cough less frequent and severe, but tighter. 26th. Reports no coughing of consequence last night, and says that this is a great improvement on a few nights ago. 27th. Complains of coughing more yesterday and last night; oxalate increased to ten grains night and morning. 31st. No more complaint of coughing; patient is making rapid general improvement. Sept. 2d. Same report; oxalate reduced to one dose nightly. 8th. No more coughing; gained three and a half pounds in the past week. 12th. Coughs no more; complains of sore throat; laryngoscope shows tubercular laryngitis. 16th. Complains of coughing for the first time in two or three weeks, coughs during the day-time; to have ten grains of oxalate every morning. 18th. No coughing; stop oxalate. 25th. Discharged. This is a fair sample of a successful case.

Case II.—German, æt. 34, wheelwright; admitted July 29, 1879. Cough almost constantly troublesome for four years; feet and legs are now swollen, dyspnœa severe, face and extremities constantly blue, and the veins of the whole surface of the body are swollen. Examination reveals fibrous phthisis in the third stage.

Patient has a hard and harassing cough, with not very profuse muco-purulent expectoration. Tonics and a cough medicine of morphine, hydrocyanic acid, and camphor-water ordered. This cough medicine was stopped August 1st, and five grains of cerium oxalate ordered night and morning. Aug. 6th. Cough better. 18th. Patient has not complained of coughing since the last date. 24th. No coughing, but very distressing dyspnœa; gradually dying from suffocation. 25th. The night nurse reports no coughing all night. 26th. Same report. 28th. Died.

Case III.—German, æt. 38, housewife; admitted July 26, 1879. Coughed since last autumn and failed in general health. Examination of the chest reveals general bronchitis and phthisis in the first stage at the right apex.

Aug. 23d. Complains a great deal of coughing at night on going to bed, and says that she coughs at frequent intervals during the day, and complains that she also has vomiting in the morning. To have five grains of oxalate on waking every morning (first dose Aug. 24th). 25th. No coughing nor nausea this morning; coughed last night as usual on going to bed. 26th. Coughs much less. 28th, P.M. Coughs more than usual to-day. To have ten grains of oxalate at night in addition to the morning dose. 29th. Coughed less last night. 30th. Some coughing still. Morning dose of oxalate increased to ten grains. September 1st. No coughing. 2d. Same. Stop morning dose of oxalate. 8th. No more nausea nor cough; marked general improvement. Discharged.

Case IV.—Irish, æt. 28, single, domestic, admitted June 5, 1879. Patient has had several attacks of hæmoptysis, and now has considerable muco-purulent expectoration and night-sweats; family phthisical. *Diagnosis:* Second stage of phthisis.

August 23d. For about three weeks has complained daily of nausea or vomiting in the morning, also of coughing at this and other periods of the twenty-four hours. To have five grains of oxalate of cerium every night at bedtime. (First dose, August 23d.) 24th, A.M. No nausea this morning. 25th. No retching this morning. By mistake has had a small dose of Magendie on awaking for two mornings, which is now to be omitted. Patient still coughs some. 27th. No nausea, but the cough is not much better. Oxalate increased to ten grains every night before supper, in addition to the morning dose. 29th. Coughing and vomiting this morning. 31st. No coughing nor retching. September 1st. Complains again of coughing. Oxalate stopped. Magendie resumed. 14th. Failing; vomiting and coughing continue. Stop Magendie; give ten grains of oxalate night and morning. 15th. Less coughing; looks better this morning. 20th. No more nausea nor coughing. 21st. Discharged. This case illustrates a failure, for the second trial, although favorable, was too brief to be valuable.

Case V.—Colored, æt. 23, sexton, admitted August 20, 1879. Family phthisical, has coughed for six months and failed in general health. *Diagnosis:* Second stage of phthisis at both apices. August 22d. Has been kept awake at night since admission by almost incessant coughing. Patient states that before admission for several weeks his sleep had been badly broken. To have five grains of oxalate every night at bedtime and every morning early. 25th. Night-nurse reports that the patient coughed none last night. 26th. Patient reports that his cough is wonderfully relieved, and that he got seven hours of quiet sleep both last night and night before last. Laryngoscope reveals laryngeal phthisis. 27th. Not disturbed last night. 28th. No coughing. 29th. Coughed at one and at four o'clock last night. 31st. No more coughing of consequence; marked general improvement; sleeps well; stomach and bowels in better order. September 2d. Same. 10th. Caught a severe cold last night and is coughing some. 12th. Cough not troublesome. 18th. Same; stop oxalate. 25th. The cough has returned; oxalate resumed.

To omit further particulars, the oxalate was thoroughly tested several times during the next five weeks, but failed every time to give much, if any relief. At this period the expectoration became more abundant, although it was never free. This is the most marked case showing unlike results at different trials.

Case VI.—American, æt. 22, housewife, admitted May 10, 1879. Has coughed and failed in health since last autumn; family phthisical. May 15th. Ordered seven minims of Magendie's solution every night. July 9th. Ordered fifteen drops of tincture of opium every four hours for cough. In addition to this, patient required extra dosing nightly. August 12th. To have five grains of cerium oxalate night and morning. 25th. Less complaint of cough lately. 26th. Opium to be entirely omitted, night dose of oxalate to be increased to ten grains, and to be given before supper. Cough is worse to-day. 27th. Badly disturbed last night by coughing. 28th. Complains, but it is suspected to be due to stopping the opium. 29th. Slept well and did not cough much last night. 31st. Coughed none at all last night. September 1st. Same report. 2d. Same report. 8th. Complained for two days of coughing at night; to have a dose of oxalate before dinner. The expectoration is profuse. 12th. Slept well, and has not been disturbed for two nights by cough. 13th. No coughing. 18th. No coughing for a number of days; stop oxalate. 20th. Complains of coughing. 21st, A.M. Same complaint; does not sleep well. Ordered ten grains of oxalate night and morning. The cough is hoarse and loud. 22d. Reports that her cough was much softer and less troublesome last night; expectoration abundant. 26th. Cough troublesome in the afternoon only; to have a dose of oxalate every day before dinner. 29th. No more coughing; stop oxalate. October 2d, A.M. Complains of coughing; coughed badly for past two nights. 3d. Still complaining; rested badly last night; to have five grains of oxalate night and morning. 4th. Rested better and coughed less last night. 26th. No cough of consequence. 30th. Same report. This case illustrates the intermission of the oxalate to observe the effect of its withdrawal.

Case VII.—American, æt. 30, broker, admitted August 28, 1879. Lungs have given trouble for two or three years, more during the past year, and his health has failed much. For several weeks prior to admission had suffered greatly from cough and sleeplessness, and failed to get relief from large and increasing doses of opiates. Patient looks haggard and exhausted. *Diagnosis:* Third stage of fibrous phthisis; no opiates given after admission.

August 29th. A great deal of coughing at night, and considerable during the day. September 8th. Severe and frequent paroxysms of coughing. 9th. Complains of constant tickling in the throat and disturbance at night from coughing; to have ten grains of oxalate every night at bedtime. (Various anodynes and sedatives have been given, but are now to be omitted.) 11th. Some coughing to-day; give a dose of oxalate on awaking every morning. 12th. Has slept well for two nights; has no tickling in the throat nor troublesome cough. 13th. Cough not troublesome. 22d. Same report; stop oxalate. 23d, P.M. Coughed hard last night; to-day was observed sitting on the edge of the bed and coughing violently; cough loud and hollow; ten grains of oxalate to be given three times a day. 24th. Rested better last night. 25th. Slept well last night; cough relieved. 26th. Same report. 29th. Same; reduce oxalate to five grains twice a day. Oct. 3d. Coughed for two days some. 8th. Rests first-rate. 12th. Coughing all night; oxalate increased to ten grains. (The Philadelphia oxalate is being used.) 13th. Vomiting, but less coughing; Merck's oxalate substituted for the Philadelphia. 18th. No more coughing nor nausea.

Patient declares that the powders are not unpleasant to take. For the first few days they caused dryness of the mouth, but this soon ceased to be noticed.

30th. Very little coughing; no more nausea.

This case illustrates the experience of several cases with the Philadelphia oxalate, although not so decided as some of the others.

Case VIII.—American, æt. 26, meat carver, admitted September 29, 1879. Patient has coughed a year, has moderately profuse muco-purulent expectoration, and some dyspnœa; looks haggard.

October 3d. Has had a very harassing cough for a long time, worse than usual during the past two nights; ordered five grains of oxalate every night at bedtime. 5th. No better; increase oxalate to ten grains. 6th. Rested better last night. 7th. No better. 8th. No better. 10th. Same report; is taking the Philadelphia oxalate; Merck's to be substituted. 11th. No better; to have a morning dose of oxalate. 12th. Not much better. 14th. Same; oxalate stopped; Dover's powder ordered. 15th. Rested better. Even-

ing. Vomiting, Dover's powders stopped; ordered two grains of Merck's oxalate twice a day. 16th. Rested badly last night; oxalate increased to ten grains at night and five morning and noon. 17th. Coughed hard after midnight, morning dose of oxalate increased to ten grains. 19th. No more complaint of coughing, volunteers the statement that he was not disturbed all last night. 20th. Relief from cough has been marked since the oxalate was last increased.

In conclusion, I will quote a synopsis of the cases, in addition to my own, presented to the Therapeutical Society, and the conclusion adopted by the committee:

Of phthisis.—Five cases from Dr. Andrew H. Smith's private practice; one permanently relieved, three for a time, and one not at all. Fourteen from the records of St. Luke's Hospital, with various degrees of benefit in twelve, and failure in two. Dr. Smith authorizes the statement that in his experience he has found the oxalate of cerium beneficial in most cases of cough; a failure in a few.

Dr. C. E. Billington reported nine cases, with benefit in seven, permanent in only two of them. Five-grain doses only were given twice a day.

Dr. F. A. Castle, two cases, both favorable. One of them was relieved while taking one preparation of the drug, but the cough returned on changing to another preparation, and was again relieved when the former was resumed.

Dr. George Bayles, seven cases. He remarks: "Positive relief occurred in four of these, and in three the remedy failed every time it was tried." The maximum dose given was ten grains.

Dr. J. R. Leaming, five cases; four successful, one failure. Dr. Leaming states that other cases impress him that this remedy is, perhaps, the most valuable that he has used, inasmuch as no unpleasant consequences follow. Indeed, he says, the digestion is generally improved notably; but it seems to have less effect on the cough when the expectoration is free and abundant.

Presbyterian Hospital, three cases. Temporary relief in two, none in the third.

The cases from the Presbyterian Hospital were reported by Dr. Little for Dr. A. Hadden. Dr. Hadden remarked before the Society, in regard to them, that he did not consider the first a fair test, as the patient was suffering from delirium and other serious symptoms, probably from having been suddenly deprived of large dosing with opium; that the second was a case of fibrous phthisis in which the relief from cough afforded by the use of the oxalate was marked. The third was not benefited, but the trials were not thoroughly carried out, as his term of service was about expiring.

Of chronic bronchitis.—Dr. Bayles reported three cases, all permanently relieved. Dr. Bayles declared that every case of cough in chronic bronchitis treated by him with the oxalate had been "markedly and permanently relieved."

Of acute bronchitis.—Dr. Bayles furnished two, relieved, and remarked that several in which the cough was treated with the oxalate were not relieved.

Dr. A. E. M. Purdy, two cases of acute bronchitis, to one of whom four-grain doses of the oxalate were at first prescribed every four hours, "with little, if any benefit, but afterward ten-grain doses twice a day, no other medicine being given, were followed by immediate improvement, the cough ceasing almost at once." The relief was permanent. The other case was treated with equal success with ten-grain doses. Dr. Purdy had used the remedy in several other cases of which he had taken no notes, in most of them with favorable results.

Dr. Bayles reported one case of chronic laryngeal cough, of a croupy quality, "entirely and permanently relieved," three cases of cough in dyspepsia permanently relieved, one of cough in empyæma, very distressing. The cough "immediately subsided under the use of the oxalate," after which the pus, which was being discharged through the lungs, was expectorated with less effort.

A case of cough with asthmatic paroxysms, by Dr. Billington, with favorable result.

Two cases of spasmodic asthma and one of senile asthma, by Dr. Bayles, relieved; also three cases of pertussis relieved. He stated that several other cases of pertussis treated with oxalate were not benefited. Two cases of bad cough in rubeola relieved; one of chronic cough from gastric irritation, with the result of "putting a period to the cough."

Dr. D. M. Cammon reported a case of a lady with a cough without any determinable lesion and no expectoration, relieved on the second day. The use of the drug was continued five days and then stopped, after which the cough gradually returned.

The following are the conclusions adopted by the committee in their report.

"1. Cerium oxalate may be given safely in doses of ten grains or more three times a day, for many days in succession."

"2. The only symptom noted from such doses is a slight dryness of the mouth for the first few days.

"3. It is probably more efficient when taken dry upon the tongue."

"4. Its effects are not fully apparent until it has been taken two or three days and continued about the same length of time after its use is suspended."

"5. For chronic cough it is best taken on an empty stomach early in the morning and at bedtime, with other doses during the day, if required; the initial dose for an adult being five grains."

"6. It is in the majority of cases an efficient cough medicine, at least for a considerable time, and it is very valuable as an alternate with other drugs used for that purpose."

"7. It does not disturb the stomach as do opiates and most other cough remedies; but on the contrary it tends to relieve nausea and to improve digestion."

"8. The different preparations on the market are not of equal value, and when success is not obtained with one, another should be substituted."

THE MEDICAL CHARITIES of Manchester, England, have received a bequest of $200,000 from the late Mr. Thomas Wrigley.

THE CELEBRATED CASE OF BAGOT VS. BAGOT, which hinges upon the question of whether a man with advanced locomotor ataxia could procreate, has been decided by a compromise. Most of the medical evidence was to the effect that procreation was very unlikely or impossible after the disease was well developed.

A NEW METHOD OF DIAGNOSING RENAL CALCULUS with pelvic abscess is suggested and has been tried by Mr. Arthur E. Barker. It consists in passing a fine aspirator-needle into the side, half way between the crest of the ilium and the lower rib, directing the point toward the abdominal aspect of the spinal column and a little upward.

Progress of Medical Science.

Trichinosis on Board the "Cornwall."—On September 23, 1879, seven of the boys on board the British reform school-ship "Cornwall" were reported sick, all the ship's crew having previously enjoyed good health. Additional cases occurred until October 23d, when there were forty-three on the sick list. The symptoms were those of a continued fever, viz., disturbance of digestion, marked diarrhœa, hemorrhages from the bowels, and petechial spots of a rose color on the abdomen. Of the forty-three affected with the disease, one died on the eighteenth day after being attacked, seventeen were seriously ill, and twenty-five only moderately so. An investigation of the causes of the outbreak by Mr. Power, local government inspector, failed to show that it was one of continued or enteric fever. On examining into the character and quality of the food furnished to the boys, it was ascertained that it was different and cooked separately from that of the officers, and also that the latter did not suffer from the disease. On further inquiry, it was found that salt pork was given to the boys usually on Mondays, and it was thought that this might accounnt for the occurrence of fresh cases on particular Tuesdays, but further investigation in this direction only met with negative results. A post-mortem examination of the patient who died, and who presented all the symptoms of continued fever, was then made. The microscope failed to show any of the lesions seen in enteric fever, but, on the contrary, on examining the abdominal muscles, trichinas could be seen rather abundant in number. The discovery of the parasite finally settled the point as to diagnosis, both in this and the remaining cases, as all were similarly affected. As points of interest in the epidemic were the corroboration of views that are pretty generally held, viz., the close resemblance to one of enteric fever, and the difficulty of arriving at a precise diagnosis, even when the cause was suspected. It is to be hoped that the subject of trichinosis, which is even yet quite imperfectly understood, and the question of a careful inspection of American pork, will receive renewed attention.—*British Med. Jour.*, April 3, 1880.

The Hysterical Element in Orthopœdic Surgery.—Dr. Shaffer's article on the above subject is a valuable contribution to a subject about which the general practitioner is very slightly conversant. The first case reported is that of a girl, aged fourteen, who had always enjoyed good health. About five years previous to her visit to Dr. Shaffer she fell from a wagon, the lower part of her spine being hurt by the fall, a black and blue spot developing near the last lumbar vertebra; in a few days she recovered. When about twelve years of age she commenced exercising on horseback, and after a time complained of pain in the back, but soon recovered under treatment. About three months later she was thrown over her horse's head, when the spine was again injured. This time she became very nervous and irritable, complained of a tired feeling in the back on the least exertion, and also of tenderness over the spine. As a distant relative had had Pott's disease, the mother associated this disease with the affection existing in her daughter. The diagnosis of caries of the last lumbar vertebra was made by her physician, and she was treated accordingly, with an increase in the symptoms. Shaffer, on examination, found that there were several tender spots in the vicinity of the twelfth dorsal and first lumbar vertebra, but that there was more pain produced by slight irritation of the clothes than when deep pressure was made. There was some deformity, which disappeared when the patient was lying down; the spine was normally flexible, and the psoas and iliac muscles offered no resistance when put on the stretch, with pelvis firmly held, and the patient in a recumbent attitude. The diagnosis arrived at was neuromimesis, chiefly because of the superficial character of the pain, and the normal movements of the spine. In another patient there had been concussion of the spine, but previous to this she had complained of pains in the back. The spine presented an apparent curvature, both laterally and antero-posteriorly. On examination it was found that the deformity disappeared when in a recumbent position. Several points of tenderness existed over the spinous process; the psoas muscles were not contracted, and there was no muscular rigidity. In this the diagnosis had been Pott's disease, but Shaffer believes it also to have been neuromimesis for the following reasons: absence of rigidity of the muscles; also of the characteristic attitude and gait seen in Pott's disease, and nocturnal cry, both of which were wanting in this case; also in the true form of the disease the pain would be referred to the region where the spinal nerves from the diseased part runs. Other instances of these affections are recorded, and the following conclusions are arrived at by the writer, and given here in a condensed form: There is atrophy due to the lesion in chronic ostoitis, and muscular spasm, which disappears when the patient is under the influence of an anæsthetic, but which is not affected by the administration of opium or chloral. There is also reduction of the faradic contractility. In emotional contractions, the muscular rigidity, which is variable, disappears under the influences of anæsthetics, and when asleep, and there is normal reaction to the faradic current. The atrophy is only functional.—*Archives of Medicine*, April, 1880.

Estimation of Uric Acid by its Reducing Action upon the Ammoniated Cupric Test.—The accurate estimation of the amount of uric acid in the urine is often necessary in order to intelligently treat diseases complicated with a uric acid diathesis. Of the various methods hitherto employed, all either lack in precision, or cannot be used with facility. Dr. Pavy's mode of procedure, which is a simple one, depends upon the reducing action of uric acid in the ammoniated cupric acid, as used in the quantitative determination of sugar, and which was reported in the "Proceedings of the Royal Society," vol. xxviii., p. 260, and vol. xxix., p. 272. To determine the amount of uric acid in a given specimen of urine, its reducing power on the ammoniated copper is first ascertained, as a small quantity of sugar is always present in healthy urine. After this the uric acid is thrown down by means of acetate of lead, and the reducing power of the sugar on the test is then determined. The difference between the two results will give the amount of uric acid present, as it has been found by careful experiments that one atom of uric acid reduces three of oxide of copper.—*Lancet*, April 3, 1880.

The Oleomargarine Bill, requiring tubs of oleomargarine to be labelled in large, plain letters, has passed the Assembly and Senate.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, June 12, 1880.

THE WORK OF THE SECTIONS OF THE AMERICAN MEDICAL ASSOCIATION.

Those who take an interest in the American Medical Association, and who were present at the recent meeting in New York, must have been struck with the necessity for some changes in the methods of its management. Not that its organization does not in the main fulfil all requirements, but that its rules and regulations are either not sufficiently understood, or purposely ignored. Perhaps these shortcomings are in part due to the fact that, with the exception of the permanent secretary and the members of the judicial council, no sets of officers hold their position from one year to the other. The responsibility of office extends over one session only, allowing neither time nor opportunity for the incumbents to become acquainted with the details of their duties. This state of affairs is more particularly noticeable in connection with the usual management of the different sections. In these organizations a chairman and secretary are appointed the year previous to the time when they are to serve; generally they are from different parts of the country, and meet for the first time when the first session of the section is called to order. Their only guide is the programme of the Committee of Arrangements, and the consequence is that no selection as to the character of the paper or the time for reading it can be made by them. It seems sufficient that a member shall merely offer a paper, when it must be presented as a matter of course, and whether good or bad it must be referred for publication in the Transactions. We submit that this is all wrong, and until it is made right by some better regulation the scientific value of the proceedings of the Association will always be below par.

Some measures should be taken to select the proper papers before their authors are allowed to read them at the meetings of the different sections. There should be a committee of selection for each section whose duty it should be not only to examine all papers or abstracts sent to them before the meeting, but to do the same to all such communications which are delayed to the actual time of meeting. By such means, and with comparatively little trouble, it could be ascertained not only whether any paper was worthy of being presented to the section, but whether it had ever been read or published before. This plan of selection is very satisfactorily carried out by the business committees of the different State societies, who do their work in the intervals of the meetings. Another good reason for these preliminary examinations of papers is the prevention of the ultimate appearance in the volume of Transactions of everything presented, whether read or not before the sections. It has become the custom, in the crowd of business, to read many papers by title only and then refer them to the Committee of Publication. The Committee of Publication, not caring, as a rule, even if it had the power to do so, to ignore the tacit recommendations of the section, gives all such papers the benefit of a doubt as to fitness for publication, and they appear in due form in the yearly volume.

When we stop to reflect how such privileges of publication, under the circumstances mentioned, may be abused, we should be ready to listen to any argument in favor of a preliminary examination, by a suitable committee, from each section of every paper offered. A neglect of such precautions was strikingly manifest during the recent meeting. Not only was second-rate papers allowed to be read in extenso, in many instances occupying nearly an hour at a time, but others which were not as good have a chance of appearing in the Transactions merely because they were offered, and no time left to read them, while still others which were accepted were really second-hand, having been read before other societies. There is a rule of the Association which forbids the reception of second-hand material, but it was not enforced in any of the sections.

Bearing upon the general question of increasing the efficiency of the sections, one or two additional points offer themselves for consideration. In the first place, in order to insure the presentation of valuable material and abundance of it at the different meetings, it is quite necessary that authors shall not be restricted, in the publication of their papers, to the volume of Transactions. If it were otherwise, first-class writers all over the country would gladly come forward and contribute. As it is, however, they object to having their works buried in the yearly volume. In the second place, there should be full and accurate reports of the discussions before the different sections. Not only would this tend to preserve a great deal of valuable material which would otherwise be utterly lost, but it would encourage the members in presenting their views. During the last meeting no provisions whatever were made by the

Association for such reports, and the accounts of the discussions would have gone by default, except for their publication, independently, by the MEDICAL RECORD. There is no reason why the Association should not do as much in its own interests, and thus afford the right sort of encouragement to those of its members who are ready to work for the increase of its usefulness, and for the extension of its scientific influence.

In conclusion, it appears proper to suggest that some alterations of the by-laws should be made, to render it possible for each section to have a permanent secretary, who shall be under a sufficient salary to pay his travelling expenses, who shall be present at every meeting, and who shall be expected to understand such details of the machinery of said section as shall insure a full compliance on the part of every member with its rules of government.

THE ILLINOIS STATE SOCIETY.

THE Illinois State Medical Society has held a three days' session, as shown by our full report elsewhere. The meeting was a fairly profitable one scientifically, a goodly number of papers being read, some of them embodying, in certain directions, original investigation. The Society amended its by-laws so as to allow of the publication of papers in medical journals, as well as in the Transactions. This is a step in the right direction, and ought to be the action of all the State societies.

THE WORK OF THE RECENT STATE LEGISLATURE.

THE recent session of the State Legislature was an unusually long one, and, as regards its work in general legislation, was somewhat unsatisfactory. It undertook much and accomplished very little. As far as the medical part of its labors is concerned, however, we have no reason to complain. About sixteen bills, bearing more or less upon things of interest to the profession, were introduced, and the most important of these were either passed or disposed of satisfactorily.

One of the very last measures of the Legislature was the passage of the bill regulating the licensing of physicians and surgeons. This bill has been published in full and commented on in these columns. It is not a very radical piece of legislation, for it fixes no standard of qualifications, except a diploma, and creates no examining body, but leaves the matter of licensing as before, with the medical colleges. This is not all that could be desired; for there is a wide distrust of many of these institutions, and a feeling that the licensing of medical men ought not to be in the hands of those who educate them. There is no doubt, however, that if we could limit the practitioners of medicine in this State to those who have diplomas from legitimate medical colleges, as the new law provides, a horde of charlatans would be driven from the State, to the benefit of the community and the credit of the profession. We must hope, therefore, that there is enough of soundness and vitality in the law to permit of its being carried out. There is provision for this, but still it will depend largely upon the activity and alertness of regular medical organizations, a fact which we beg the profession to remember. We have an opportunity now to cleanse our State of some of its meanest elements. It will benefit all, if the opportunity is improved.

The State has shown more wisdom than its sisters in enacting the present law. During the past winter attempts to pass similar bills regulating the practice of medicine have failed in Massachusetts, Maryland, Wisconsin, and Iowa. Indeed, New York is the only State where such a bill was successful. This is partly due to the fact that our law is less radical than that proposed in other States. And it is also due to the good sense of our legislators, and the consideration in which our medical organizations and medical men are held.

The establishment of a State Board of Health furnishes also a matter of congratulation. The gentlemen who have been appointed upon it are men of ability and experience. There is, in addition, a majority on the Board of medical men, which is a preponderance that should always exist.

The bill to establish a Lunacy Commission failed by a few votes. This is much to be regretted, and we cannot draw any great consolation from the fact that a commission of three Senators has been appointed to investigate the Insane Asylums and report to the next Legislature. It is not the special defects of the various asylums that need reforming, so much as a change in the whole system. It can hardly be expected that three politicians, of however much ability and honesty, can appreciate the defects which have caused psychiatry to be an unknown science in this country. We shall, however, hope for the best.

The defeat of the anti-vivisection bill was a creditable measure, and deserves notice. The defeat was a decisive one, and although not accomplished without some hard work, it showed that the scientific spirit in this State is not to be smothered by a false philanthropy, as it to some extent has been in England.

The bill to regulate the practice of veterinary medicine failed to pass. This could hardly be expected otherwise, as it was a somewhat premature measure. It is well to encourage all proper measures for elevating the standard of veterinary medicine, but the practitioners of this art are not yet, as a rule, sufficiently advanced in education or scientific attainments to need the protection of regulation.

The appropriation of $35,000 to be expended in the prevention of pleuro-pneumonia, and the bill to compel oleomargarine manufacturers to stamp the

firkins containing their goods, are the only remaining measure of importance having any especial relation to medical men.

It will be seen that the Legislature has dealt very fairly with the medical and scientific interests of the State. We may feel encouraged to believe that a juster value is being placed upon those interests and upon medical opinion than has been the case heretofore.

Reviews and Notices of Books.

THE MEDICAL REGISTER of NEW YORK, NEW JERSEY, and CONNECTICUT, for the year commencing June 1, 1880. Published under the supervision of the New York Medico-Historical Society. WILLIAM T. WHITE, M.D., editor. Vol. XVIII. New York: G. P. Putnam's Sons. 1880.

THE first fact to notice concerning the Medical Register for this year is that it was published promptly on June 1. This is earlier in the year than any of its predecessors, and reflects great credit upon the enterprise of the editor and his associates of the Medico-Historical Society. The present volume in point of accuracy, in variety of information, and in general convenient arrangement of the different subjects, is fully equal to any of the other editions. There are 5,375 registered names of physicians. Of this number 2,491 belong to New York State, 635 to New Jersey, 412 to Connecticut, 1,409 to New York City, and 418 to Brooklyn. Of the 1,409 registered in this city 102 are serving in hospitals. As far as we have examined these lists they are found to be accurate, as is also the case with the accounts of the hospitals and medical societies. In this volume the complete code of ethics is published, as also an accurate statistical account of the mortuary returns of New York and Brooklyn, contributed respectively by Drs. Nagle and Wyckoff; also an exhaustive chronological record of the past year, by Dr. L. S. Horton, and an interesting contribution to the medical history of the City of New York, by Dr. John Shrady, of Harlem, N. Y. The volume is compact, is well printed, and is published in the usual uniform style with previous editions.

A NEW YORK AGENCY FOR TRAINED NURSES has been established by Miss A. S. Mabie at No. 30 East 14th Street. An agency of this kind is a very desirable thing, and has proved useful, we believe, in Boston. The present undertaking is very well endorsed.

THE QUARTERLY EPITOME OF PRACTICAL MEDICINE AND SURGERY is a new publication published by W. A. Townsend, and intended as an American supplement to *Braithwaite's Retrospect*. It appears to be a very good compilation, but covers the same ground as *Walsh's Retrospect*, to which it is not superior.

THE STAMP-TAX ON PATENT MEDICINES.—The druggists are making great efforts to secure the repeal of the stamp-tax on proprietary medicines, cosmetics, perfumes, etc. This, it is claimed, is unjust and burdensome. The income from it amounts annually to only $4,000,000. This represents a valuation of $50,000,000. Patent medicines make up a large part of this sum.

Reports of Societies.

THIRTIETH ANNUAL MEETING OF THE ILLINOIS STATE MEDICAL SOCIETY.

Held at Belvidere, Ill., May 18, 19, and 20, 1880.

FIRST DAY.—MAY 18TH.

(Special Report for THE MEDICAL RECORD.)

DR. E. INGALS, OF CHICAGO, PRESIDENT, IN THE CHAIR.

DR. N. S. DAVIS, for many years permanent secretary, sent his resignation, owing to ill-health.

DR. S. J. JONES, of Chicago, was elected his successor.

THE PRESIDENT'S ADDRESS

dealt with questions of hygiene chiefly. He referred to the questions of water, air, and sewage—their relations in large cities in particular.

The metropolis of the State, Chicago, was a problem to the whole State. The city had an endless supply of good water near at hand that could be had for the trifling cost of pumping, but the supply should be kept pure and uncontaminated by sewage. This would make it necessary for the city to empty its sewage through a canal, large enough for ships, to the Mississippi River, instead of into the lake. Sewage sufficiently diluted was made harmless by oxidation. Make the canal large and deep enough for an abundant supply, and no one could be offended by anything cast into it. The cost of such an enterprise was large, but that the people of the State would make it, there was no question.

So great was his faith in good drinking-water, and so thoroughly was he impressed with the value and purity of that of the great lakes that he saw in his fancy, in the future, great conduits reaching from the lakes to the tributaries of the Father of Waters, carrying a never-failing supply of pure lake water from which the cities and villages along their lines might draw for their domestic uses. He took the ground that the government should protect the people against contamination of air and water against infectious diseases, when possible. To this end physicians should be ready to aid the State in gathering vital statistics, and in all other ways that might tend to the accomplishment of this end. To ask for fees for doing this was to refuse to reciprocate for the various favors and prerogatives conferred upon the profession—exemption from jury duty and the like.

DR. CHUMBER, of Warren, made the major report on practical medicine, in which he gave details of several epidemics of

DIPHTHERIA.

He had watched three epidemics recently, and all the facts pointed to the great contagiousness of this disease. In the three epidemics there were 30 per cent. of deaths. In one school district, with fifty-nine pupils, an epidemic was started (no cases having previously existed) by two boys who visited a neighboring community where there were cases of the disease. In a few days both boys had symptoms of cold, received some domestic treatment for their little fever and sore throat, and soon returned to school, where other pupils complained of the offensive odor of their breath. Soon other cases appeared, and the number of persons attacked was 58, with 17 deaths.

Seventeen of his cases had nasal diphtheria, of which two only recovered. Cases with pharyngeal

inflammation only were the mildest. In the nasal cases he advised injections of 3 or 4 per cent. solutions of carbolic acid or salicylate of sodium.

He advised solutions of tannic acid to the throat, and bromine in watery solution of bromide of potassium, as advised by Dr. W. H. Thompson, of New York.

There had been quite an epidemic of

PNEUMONIA

in Northern Illinois during the past winter. The mortality was low, as the result of wide correspondence with physicians showed. Physicians, he found, differed very widely as to the value of blisters, but there was more unanimity in favor of the free use of stimulants in the bad cases, especially of double pneumonia.

In the discussion of this report, Dr. Bird lauded the Billington treatment of diphtheria.

Dr. Hollister advocated the early application of liquid subsulphate of iron to the throat in diphtheria.

Dr. F. H. Davis thought diphtheria, scarlet fever, and erysipelas, were much alike in nature and effect upon the system, and in the influences capable of inducing them.

Dr. C. T. Parkes thought the constitutional and local treatment were to be used together. He was partial to a mixture of equal parts of glycerine and liquor ferri subsulphatis for a local application to the throat, and a solution of boracic acid for injection into the nose in the cases where the nasal cavity was involved.

Dr. J. S. Jewell impressed the necessity in diphtheria of getting at both local and constitutional treatment early. The first few hours were all important.

Dr. B. F. Haller, of Vandalia, read a brief report of an epidemic of

MUMPS,

which had occurred in his section during the past winter and spring. Whole families, even whole communities were attacked at the same time, the cases occurring in rapid succession. Three schools were broken up for the time. Several hundred cases must have occurred in a few months. Men and women, and children of both sexes were attacked. Metastatic inflammation of the testicles was very common among the men and boys. The left testicle was oftenest affected. Metastasis to the mammæ occurred in a few women, but not in any girls so far as he had observed. In a few cases metastatic inflammation of the cerebral meninges occurred and was attended by severe and violent symptoms, a severe chill, pain in the head, limbs, and back, temperature rising to 105° F. often, the tongue becoming coated and dry, and sordes forming in the teeth. The cases lasted about two weeks. Delirium was present in some cases.

The metastasis occurred in the worst cases; in the mild cases it was rare. After the inflammation occurred in the testicles, it never attacked the meninges.

Where metastasis to the testicle occurred, the inflammation in this organ and that in the parotid gland terminated simultaneously. It did not disappear from the parotid on its appearance in the testicle.

There were no fatal cases, and so far, in his observation, no damage to the testicles had resulted; no atrophy had taken place.

The treatment consisted of hot applications to the inflamed points, mild anodynes, and otherwise the expectant treatment.

Dr. Hill, of Bloomington, read a report on surgery, in which he discussed the antiseptic surgery and advocated it, claiming that thymol was as good for the spray as carbolic acid.

He quoted from recent reports of extirpation of floating kidney, of removal of epithelioma of the rectum. One operation of extirpation of cancer of the rectum he had witnessed in Cook County Hospital, Chicago, by Dr. Isham. [This case died in thirty-six hours.]

He next referred to

RODENT ULCER AND EPITHELIOMA.

He advocated the scraping-out process for the rodent ulcers, and related some cases—his own practice.

Case I.—Case of rodent ulcer of lower lip, covering most of the lip. Glands at angle of jaw and cervical region enlarged. The ulcer was thoroughly scraped out with the handle of a scalpel till healthy tissue was reached at every point. Then the surface was scarified thoroughly to favor normal granulation. In four weeks the wound was healed, and there had been no return.

Case II.—A man of fifty years consulted him in July, 1879, for a rodent ulcer of the upper lip of twelve years' standing. Here the scraping treatment was resorted to. Recovery took place in less than a month, and there had been no sign of any return.

Case III.—A man of middle-age, with epithelial cancer of the lip. A V-shaped incision was made, and the mass removed. In two weeks healing was complete. Before many months the disease, or something akin to it, had returned. This was thoroughly scraped. Healing followed, and there was no return.

He next gave a synopsis of late literature on the subjects of genu valgum and fractures of the patella. He also spoke of the treatment of strangulated hernia by stretching upward with the thumb the ring at the point of obstruction and enlarging it—the thumb carrying before it, of course, the integument and subcutaneous tissue. He was himself the author of this treatment, and had used it in over a hundred cases successfully, and no need had been found for the cutting operation. He thought operations on strangulated hernia need rarely or never be made.

Dr. J. G. Harvey read a brief paper, in which was detailed a case of extirpation of the parotid gland.

The operation was done without particular difficulty, and no bad result followed, save a partial paralysis of the same side of the face, which made it impossible for the man to hold a cigar.

He also related a case of operation for femoral hernia in an old woman, in which the obstruction had existed for a number of weeks, and the hernial protrusion had been reduced; but obstruction of the bowels evidently remaining, he operated and found a band of fibrous tissue constricting the gut from above, and entirely within the femoral canal.

Dr. C. T. Parkes insisted that in cases of hernia where there was any evidence of obstruction remaining after a supposed reduction, or where reduction could not be effected, operation should be made. If anything was proved by modern surgery, it was that under antiseptic precautions the abdomen could be opened with impunity. He referred to the records

of such ovariotomists as Keith and Wells to show this.

The result was not as good as carbolic acid for the antiseptic spray. It had been thoroughly tried in Cook County Hospital, and was found in every way inferior to the carbolic acid. He referred to Callender's method of dressing, and thought it nearly or quite as successful in Callender's hands as was the Lister dressing in the hands of its author.

Rectotomy should never be made except where the diseased part was very small. If the whole circumference of the bowel was involved, to the extent of an inch or two in the length of the gut, it should be left alone. The statistics were all against it under these circumstances. He had witnessed five operations of this kind, and four deaths had resulted. In three cases the peritoneal cavity had been opened during the operation. This accident was mainly due to the fact that the operator always *will* pull down the cancerous mass to enable him to cut it loose from its surroundings, and this pulling down just allows the knife to cut through the septum between the bladder and rectum into the peritoneal cavity. No drawing down should be practiced. He thought electro-cautery better than the knife, and no sutures should be used to stitch the border of the cut bowel to anything. They were worse than useless, as had been shown by the experience of the past.

Dr. Bland had operated with the electro-cautery, and had succeeded in saving the sphincter ani muscle by stretching it widely open and cutting above it.

Second Day—May 19th.

Dr. G. W. Nesbitt read the report on Obstetrics. His paper was a plea for practical instruction in midwifery for students in medical colleges. He regarded the lack of such instruction as the greatest want of the undergraduate of to-day, and that if young doctors could go out to practice with practical and experimental knowledge on this subject, more would be done for humankind and for the usefulness of the profession than by any other one step.

He advocated the establishment of lying-in hospitals by medical colleges and dispensary out-services for this purpose.

Dr. W. T. Montgomery, of Chicago, then read the report on ophthalmology and otology.

It was devoted mainly to a discussion of acute and chronic suppurative inflammation of the middle ear. Although nothing new on the subject was offered, the paper embodied an abstract of the best views of the nature, cause, and treatment of this affection. He also reported a case of

Double Optic Neuritis

from a violent fit of anger, with recovery. The patient was a man of an insane diathesis who was exposed to extreme irritation of mind and temper for a week, when he received an unusual shock of aggravation, and had a violent fit of anger.

The next day failure of vision and other symptoms of this affection drove him to seek advice, when, by the ophthalmoscope, the papillæ were seen to be engorged to an extreme degree.

The treatment was free local blood-letting and large doses of chloral and bromide of potassium.

In three weeks from the beginning of the attack the neuritis was gone entirely.

When first examined vision was as follows: right eye, fingers at ten feet; left eye, [illegible]. In the recovery, sight was entirely restored, and has so remained.

Dr. S. J. Jones, of Chicago, emphasized the importance of middle ear troubles. They were greatly neglected by the average practitioner, were a constant annoyance to the patient and his friends, and occasionally led to death.

Dr. F. H. Davis read a volunteer paper on the subject of

Inhalations in Pulmonary Complaints,

more particularly those of the deeper pulmonary tissues. The claim that inhalations of benzoate of sodium would cut short tubercular consumption had been made. The claim was groundless. Inhalations were good for local disorders of the respiratory passages only, and only for a local effect. They were valuable for this purpose.

The vapor he thought the best form to take inhalations. Inferior to this were the gaseous form and that of the spray. He referred to his simple apparatus for the vaporization of medicaments in hot water [already published in the Record], and called attention to what he denominated the dry method. This consisted of a tin funnel, in which a sponge was placed, and on which was sprinkled the medicine, concentrated, only a few drops at a time being used. The patient inhaled from the tube of the funnel, elongated or not by a rubber tube and mouthpiece.

In the catarrhal form of bronchitis the method with water was best. In the purulent form, whether in phthisis or not, he preferred the dry method, using the ethereal oil of eucalyptus or pure carbolic acid.

In incipient phthisis, tuberculous, with dry cough and irritation of the bronchial mucous membrane, steam inhalations of one or two drachms of camphorated tincture of opium to the pint of very hot water, with a few drops of Scotch pine oil, was the best inhalant.

In the breaking-down process in phthisis, with much suppuration, the moist process with carbolic acid or oil of eucalyptus was the best.

He believed, in all such cases, it was important to save the stomach for the digestion of food by giving all medicines possible by inhalation.

Mrs. L. H. Cobb, M.D., of Carlinville, read a paper, very scholarly and logical, on

The Relative Value of Symptoms of Neurasthenia as such, and the Remote Symptoms of Uterine Disease.

All the symptoms of neurasthenia, so-called, although capable of being induced otherwise, were often, in women, the remote symptoms of uterine disease. In women with neurasthenia the cause was generally in disturbances of the generative organs.

In neurasthenia in women with uterine disease, the latter antedated the former in most cases, and must be regarded as causative to some degree. It was, perhaps, possible for neurasthenia to occur to woman from causes not peculiar to her sex, and for this to favor the development of uterine disease; but the remote symptoms of uterine disease were neurasthenia.

Among the profession there were two opposite modes of treatment resorted to for neurasthenia in women. One was rest, travel abroad, hygiene, and perhaps some general tonic treatment. Some improvement often followed this treatment, and of-

ten the patient thought herself well till her return home and resumption of her usual duties, when she usually discovered her old symptoms returning.

The other treatment was that of the gynecologist, and consisted in the treatment of the uterine condition alone. Of the two treatments this was the better, and produced the best results; and if either of these one-sided courses was to be pursued alone and exclusively, this was the one to adopt. The best results, however, would come, and did, to a treatment that combined both methods.

Dr. J. H. Rauch, Secretary of the State Board of Health, then made some statements regarding the work of the board. He gave a statistical account of the doings of the board, by which it appeared that the State had been freed from many irregular practitioners by the rigid examinations and dealings with the profession of the board. Twenty-four certificates to practice had been revoked (since 1877) mostly of itinerant quacks. These doctors had been practically driven from the State.

There were 900 less practitioners in Illinois, in proportion to the population, than in 1877.

Dr. J. J. R. Patrick, of Belleville, read a paper on

MEDICAL SPECIALTIES,

more especially the specialty of "Dental Surgery," in its intimate relations to the general practice of medicine. He took the ground that specialties were necessary to human progress, owing to the wide domain of medical science; that a strict line of demarcation between the different specialties and the general practice of medicine was impossible. He characterized as an abuse the constant habit of so-called dentists of using anæsthetics "as an auxiliary in the extraction of teeth, in order to replace them with others less expensive." He thought the intelligent dentist, as he was constantly observing the various diseases of the mouth, was the most proper person to treat many such affections, and the mouth, the vestibule of the alimentary canal, should receive more attention on the part of the general medical practitioner.

Dr. H. Z. Gill, of Jerseyville, read a paper on

CROUP AND DIPHTHERIA.

He reviewed at length the literature of the subject as to the identity or non-identity of these two diseases, as shown by the false membrane. His conclusions were, that there was no microscopic characteristic that was at all constant by which the two diseases could be distinguished from each other, or by which the cause of either could be determined. On chemical ground it was impossible to draw a line of distinction between the two affections. The nature of the cause, so far as acknowledged proof showed, was of a zymotic character.

His paper included a discussion of the treatment of these affections, particularly the operation of tracheotomy. He had gathered further reports of the operation, in addition to a table he had prepared a year ago, from which it appeared that of all the operations so far reported in Illinois—one hundred and thirty cases—the per cent. of recoveries was twenty-seven and a half. A year ago the per cent. of recoveries was twenty-six and a half per cent.

Dr. E. L. Harriott read a paper on

ANÆSTHETICS IN LABOR.

He advocated them strongly. There were no deaths on record from their use. He had corresponded with many physicians throughout the State on the subject. None had reported any bad effects from anæsthetics in labor; most had used them and all who had were delighted with them.

He took the unusual ground that anæsthetics were as useful in the first stage of labor as in the second. He was sure he had frequently hastened the first stage, the dilatation of the os, by putting the patient under complete surgical anæsthesia, certainly complete unconsciousness, and keeping her in that condition for an hour or more; then allowing her to return to partial consciousness. He invariably kept her in that condition most of the time till complete delivery. He had never seen any uterine inertia or unusual hemorrhage in cases where the anæsthetics were used.

He preferred chloroform as the anæsthetic agent. Of his correspondents who had used anæsthetics in labor, only one or two had used ether, all the rest used chloroform and had no desire to change.

Considerable discussion of this subject followed. From many members came the suggestion of the use of bromide of ethyl, instead of chloroform. No one, however, had used it in obstetrical cases.

Dr. E. W. Lee read a paper on

TRACHEOTOMY,

in which he made a strong plea for the more frequent resort to this operation. He also made several suggestions of improved steps in the operation. The operation itself was one of slight danger, usually. The after-treatment was most important. His cases were all treated after the operation with the constant spray thrown from a large spray producer. Formerly he had used a solution of chlorate of potassium with carbolic acid. Now he had entirely discarded the chlorate and used instead lime water, with an admixture of one per cent. of carbolic acid, and four per cent. of glycerine. This mixture was most beneficial in its solvent effect upon the false membrane. He thought chlorate of potassium should not be used. It was important in making the cut into the trachea, that the latter be held by a pair of tenacula between which the cut should be made. By this means the trachea could be held firmly upward and the edges of the cut held asunder for the more easy introduction of the tube. This latter could be introduced with much more facility, if its extremity was made oval, by being filled by the rounded end of a soft catheter, introduced so as to project slightly, the catheter being of a size to completely fill the cavity of the tube. The tube was, by its presence in the trachea, a constant menace, and should be removed at the earliest practicable moment. He usually removed it for an hour and then returned it, as early as the fourth day after the operation. Generally it could be kept out longer each successive day, until in two or three days it could be dispensed with entirely. He thought the plan of Martin, of operating without the tube, would and ought to become popular. One danger in the removal of the tube, and which always necessitated the presence of the surgeon, was the possibility of fits of dyspnœa which sometimes amounted to strangulation. When this occurred, of course the tube was to be at once reinserted. He believed, with others, this dyspnœa to be due to the projection forward, from the posterior wall of the trachea, of a large fold of the swollen mucous membrane, this bulging forward being possible by the absence of the rings in the posterior third and by the lateral displacement of the anterior cut ends of the rings included in the incision.

When asked the result of his own tracheotomies he stated the number was seventeen, with six recoveries—or something over thirty-five and a quarter per cent.

Dr. Bliss, of Quincy, advocated the operation without tubes at all. He had operated in this way. The sutures introduced into the borders of the incision in the trachea, for holding it open, usually cut out on the fourth day, but by that time the wound would remain open without their aid.

Dr. Cole would not make tracheotomy without having a physician in constant attendance on the case for at least thirty-six hours after the operation. The success of the operation always depended very largely on the minutiæ of the operation being thoroughly carried out.

Dr. Porter, of St. Louis, advocated as long a cut in the trachea as possible. A long incision facilitated the cleansing of the wound and the changing of the tube, while final healing was not delayed by it.

Before adjournment the Society amended its by-laws so as to allow members to publish their papers in medical journals, as well as in the Transactions.

Third Day—May 20th.

Drs. E. W. Lee and Ch. Fenger read a paper on

tuberculosis of joints,

with three cases of excision—all successful. The first was a case of excision of the knee, operated upon by Dr. F.

The patient was a boy of 15 years. He was free from any family history of tuberculosis, and he had previously been healthy.

Two years before he had been kicked in the knee by a playfellow. A little pain followed and it was soon forgotten. In three or four months, swelling appeared and pain. Exacerbations of pain and swelling occurred from time to time, each one successively being worse, till his admission to the Cook County Hospital. In the meantime small abscesses had formed on each side of the joint, superficial of course. They had closed, and again opened and closed.

On admission, his limb was flexed to about 110 degrees, and motion was only possible to 70 degrees, and there was positive genu valgum from weakening or partial destruction of the internal lateral ligaments.

There was no fluctuation, but pain and tenderness in the joint. The joint was painful on pressure at the sides.

Extension by weight and pulleys and fomentations did nothing toward correcting the deformity or improving the joint.

Excision was made under the spray by the aid of Esmarch's bandage.

A semilunar anterior incision was made. There was no fluid in the joint. The capsule of the joint was found whitish, and three to five millimetres thick, and thickest at the sides. The whitish tissue contained irregular sinuous cavities full of thick yellow caseous material. The cartilaginous surfaces of the joint were destroyed superficially, there being "irregular nodular surfaces in which islands of denuded carious bone were surrounded by fibrous adhesions" between the joint surfaces. The adhesions were broken up, the joint brought open and a disk, two millimetres thick, was sawn from the condyles of the femur, leaving healthy structure. A disk, one and a half millimetres, was cut from the tibia.

The patella was found fixed to the condyles of the femur, and was removed subperiosteally. The whitish firm tissue of the capsule was dissected and extirpated. Holes were drilled in the bones laterally and silver wires inserted for bringing the parts firmly together.

Two drainage tubes were inserted laterally, one anterior and the other posterior, and the parts brought together and fixed in a splint and dressed antiseptically.

The thickened capsule was shown, by examination with the microscope, to be studded with miliary tubercles. The after treatment was disturbed by a slight cystitis during the first week, which lasted two or three days and caused a little fever. Later, two or three small acute abscesses formed, which produced fever for a day or two, but rapidly healed.

Osseous union was complete in twenty-four days—as early as takes place in many simple fractures. The patient was out of bed on the thirty-eighth day.

The primary incision healed by first intention and did not reopen, but about the scar little entirely superficial abscesses of the size of a small marble formed. They contained shiny, clear fluid and shiny viscid blood, and were due to "excessive formations of miliary tubercles in oedematous adenoid tissue, then breaking down in fatty degeneration and making small tuberculous vomicæ, and leaving tuberculous ulcers with little or no tendency to heal." Such abscesses resist all local treatment. The only thing to do for them was to extirpate them with all their lining membrane—the latter being thoroughly scraped out. This was done in this case and the little wound of the operation healed rapidly and fully.

He thought the cause of these secondary local eruptions was to be found in the fact that at the primary operations some particles of the fibrous capsule, with its miliary tubercles, had been left, and these formed foci for other tuberculous developments. Such a tendency of tubercle to develop and grow in a scar should be a warning to us to remove every portion of a tuberculous lining membrane of a diseased joint cavity. (The patient was exhibited to the Society.)

The next case was one of

tuberculosis of the elbow joint,

operated upon by Dr. Lee. It was a case of primary osteo-tuberculosis of the head of the radius, with secondary tuberculous fungous arthritis tending to anchylosis.

The patient was a girl of 8 years. Her family history was free from any tuberculous tendency, and except the disease of the elbow she was healthy. When a year old she fell down-stairs. Three months afterward she was noticed to carry the arm flexed to an angle of 45 degrees. It was somewhat stiff, but without swelling, and remained in this condition six years. At seven years, Dr. Lee first saw the case and found the joint quite stiff, and the muscles wasted from disease. He etherized her and made free passive motions. This was attempted to be carried out afterward, and was, for a while, successfully. Finally, swelling and soreness came on, and soon the joint was as bad as at first. All subsequent attempts, of which there were several, were followed by similar swellings and pain.

Subperiosteal excision was made January 27, 1880, with the Lister precautions. A longitudinal incision was made posteriorly dividing the tendon of the triceps longitudinally. The periosteum was carefully removed from all the bony surfaces and parts making up the joint, and was left in connection with its mus-

cular attachments everywhere. The olecranon and head of radius were removed entire, and a cut of two centimetres in length was made from the end of the humerus. Drainage tubes were used, and the wound closed and fixed to an angular splint. In the cavity of the joint were a few drops of slimy grayish pus.

The cartilage of the radial head was gone, and there were found several small cavities or excavations two or three millimetres deep and the same in diameter.

The walls of these cavities were of white, smooth, and hard bone tissue. These cavities appeared to have been the seat of tuberculous development in the bone, which reaching the surface had infected the joint and caused the fungous tuberculous arthritis.

The articulating epiphysis of the humerus showed a different stage of development of the tuberculous process. Here was secondary, superficial, diffuse, osteo-tuberculosis or tuberculous caries, destroying the bone from the surface. The cartilages were all gone, the end of the bone changed in shape and reduced in size.

In places roughened surfaces of bone were exposed, and between them irregular layers of reddish gray fungus granulations; these latter were very friable and easily removed. Microscopically they were shown to be "adenoid tissue with spiculæ of bone undergoing absorption, and miliary tubercle." The articulating surfaces of the olecranon resembled very closely that of the humerus. The incision healed by first intention; tubes were removed in two weeks; in three weeks the wound was entirely healed. After four days passive motion was begun; in four weeks the splint was dispensed with. The well arm was strapped to the side inside the clothing, and the child rapidly gained in the use of the other.

Now she has a useful elbow and arm in every way. Flexion and extension was 90 degrees; pronation and supination about half the normal limit. The limb was short three centimetres, two of the arm and one of the forearm. There was an entire reproduction of bone; all the anatomical points being distinctly made out.

Dr. Lee would not promise that the range of motion would continue as great, but hoped it would. (The patient was exhibited.)

The third case was one of

TUBERCULOUS HIP-JOINT

in the practice of Dr. Lee. The synopsis of the case was as follows:

"Tuberculous fungous arthritis, caries, morbus coxarius of right hip-joint of three years' standing. Large anterior abscess. Excision subperiosteal by external longitudinal incision; the abscess emptied and scraped out from this incision. Drainage through two openings. Three months later the unclosed abscess again laid open by a large incision, and its entire wall of tuberculous tissue scraped out, the abscess closing entirely in eight days thereafter. The leg dressed in Sawyers' (*sic*) modification of Hodgen's splint. The dressings reapplied as often as required, by means of Lee's frame for dressing exsections of the hip-joint."

The patient was nine and a half years old. No tuberculous history. The hip disease was induced by a fall down three or four steps, but lameness and pain did not begin till six months thereafter. Early in the course of the case she had been treated in St. Luke's Hospital for two months with extension by weight and pulling. She was discharged much improved—nearly well. Afterward she had a fall from a chair, upon her back. Soon the hip disease reappeared, and later she was obliged to use crutches. In December, 1879, the abscess appeared anterior to the joint.

The operation was made December 24th, with Lister's method. At this time the limb was shortened an inch and a half, adducted and flexed.

The head of the femur was atrophied from superficial caries, and had a tuberculous cavity.

The bone was sawed off just below the lesser trochanter. The acetabulum contained several roughened surfaces of tuberculous matter, which were scraped off.

The splint referred to (that of Sawyers) is a modification of Hodgen's. It consists of an iron framework that passes along both sides of the crippled limb, extends up nearly to the axillæ and reaches across the body diagonally at the groins so as to encase the trunk on both sides. It is a Hodgen's splint applied to the trunk of the body and extended downward to only one of the lower extremities. The sides are fastened together by bones of iron thrown across and from which suspension pulleys are attached. The body and injured limb are suspended by bands of cloth passed across from side to side exactly as in H.'s splint.

In dressing the wound the patient drew herself up a foot from the bed, by means of the pulleys and the aid of an assistant. Then the Lee's frame was passed under her and she was lowered upon it. The frame was then drawn up by another system of pulleys to a convenient height, the bed was removed and the Lister apparatus applied at leisure and with the patient perfectly at ease.

The frame is made of wood six feet long and two and a half feet wide and has straps of canvas running across it four inches wide and four inches apart. After the patient was fully suspended the straps of the frame as well as those of the splint which came immediately beneath the dressing were loosened and removed. This gave free opportunity to cleanse the wound from below, and to reach it from below with the spray. The dressings were reapplied by laying the several layers in their proper position on the bed, a many toiled bandage being under all, the bed brought into position and the patient being let down upon them, when by bringing around her body the many toiled bandage, the dressing was secured.

The advantage claimed for this mode of redressing was the perfect comfort it gave the patient, even little children would talk and laugh while the dressings were being made.

The operation for the unhealed abscess was made March 30th. The lining of the abscess was found on microscopic examination to be studded with miliary tubercles.

The child had made a good recovery.

This closed the scientific business of the session.

A resolution was adopted declaring it to be the sense of the society that the advertising of quack medicines by newspapers was an imposition upon the people, to their pecuniary loss, and often to their physical discomfort and injury, and was unbecoming a publication making pretensions to teaching morality and religion.

The officers elected for the next year were, Dr. G. W. Jones, of Danville, for President; Dr. Hill, of Bloomington, 1st Vice-President; Dr. G. W. Nesbitt, of Sycamore, 2d Vice-President; Dr. J. H. Hollister, Treasurer.

The next meeting will take place at Chicago.

Correspondence.

NEFTEL'S ALLEGED CURES OF CATARACT BY ELECTRICITY.

To the Editor of The Medical Record.

SIR:—All we ask to say a few words on the reply with which Dr. Neftel favored my note concerning a cataract patient of mine whom he had treated, but whose cataracts I found, on a recent examination, more pronounced than before. I stated that the patient had posterior polar cataract and had grown nearsighted during its progress, which is not uncommon. Her visual acuteness was, and is still tolerably good, though the focus has changed. Dr. Neftel has no word to say about the persistence of the cataract. The result of the objective examination shows, beyond controversy, that the cataract was neither cured nor improved.

As to her alleged improvement of sight, Dr. Neftel writes that "the result of the galvanic treatment has been remarkable, since the patient, at the time she came to him, was unable to distinguish any features, or even to see only her own fingers. In the course of a few weeks, under the galvanic treatment she became able to read small print and see objects quite distinctly." To this my reply is as follows: The patient was able to read fine print at the time she came to Dr. Neftel, because she did it at my office, and would have done it at Dr. Neftel's office also had he taken the precaution to shade her eyes, or darken the room so that her pupils could sufficiently dilate. Patients with central opacities of the cornea or lens see almost nothing when turned toward the light, and see quite well when turned away from it. The lady was and still is in this condition, as I convinced myself the other day. This and the nearsightedness explain the apparent improvement of sight. In confirmation of this, I quote from a letter she wrote me March 31, 1880, when I asked her about her sight, the following passage: "I do not wish to give you the impression, nor have I to any one who has referred to me, that my vision is restored to the strength and clearness of younger years; for while my sight is so much improved in looking at things near at hand, objects at a distance and in the glare of outdoor light are still obscure." Thus, Mr. Editor, not only the objective examination, but also the subjective, and the statements of the patient furnish positive and sufficient proof that the electric treatment has not cured Mrs. W.'s cataracts, nor can even the slightest evidence be brought forward to show that it had any effect on the eye at all.

H. KNAPP, M.D.

NEW YORK, May 31, 1880.

ON THE RELATIONS OF NERVE AND MUSCLE.

To the Editor of The Medical Record.

DEAR SIR:—Though not pretending to any physiological lore, being as yet simply a student of medicine, I was struck by some, to me, seeming errors in conclusion in the first article published by you on this subject. The author of the article mentions seventeen facts which he claims cannot be accounted for by the theory of the day, but, as we are given to understand, are by his.

In regard to the first, I would like to ask him why, at the moment of death or cessation of the nervous functions, there is not an immediate muscular contraction; why is it that it is, as a rule, delayed till the animal heat is largely or entirely dissipated? Will he kindly explain why the muscles of a decapitated frog which, according to his theory, should be rigidly contracted, will still actively respond to the stimulus of electricity? Will he explain Robin's case of the executed criminal?

Under the third fact, will he tell what is the difference between dead men, whether they die of cholera or yellow fever, or something else, since he informs us that with the cessation of nerve-force the muscular fibres contract—why should the manner of death vary the degree of this passive action?

Under the fourth head, he evidently forgets the cardial ganglia. He forgets that the heart does not depend alone on the cerebro-spinal system. He forgets that the heart may be taken entirely out of the body, or more, be cut in pieces, and still evince muscular movement. Again, the uterus is not a voluntary muscle. The heart will continue to beat after its connection with the cerebro-spinal system has been severed; why impossible then, that the uterus should also for a time retain its activity after death. But I would ask Dr. Poole why this is not always the case in parturient women, why ever the necessity of Cæsarian section on the death of the mother?

From the sixth fact we might presume that the writer was a little inclined toward the "vital fluid" of Descartes. Does he consider nerve force, whatever it may be, a ponderable agent, that pressure on a nerve should prevent its passage? This is the weakest point in his whole argument, and is directly explained by the old theory. Irritation at any point in the continuity of a nerve fibre is only manifested in its terminal filament, consequently the pressure on the pelvic nerves cannot but manifest itself in the limbs of the woman, and hence, contrary to Dr. Poole, "is a potent argument" for this theory.

I cannot see how the eighth fact can be used as an argument in favor of the proposed theory; for in the set of cases cited we have no constant contraction, but a general muscular commotion. If we should decide in favor of Dr. Poole, certainly we should expect to see in every case of hanging every joint in the body flexed, since the movement of flexion is stronger than extension.

In reference to the ninth, I think no one will say that spasms and conditions are caused by nervous activity, but rather by irritation, direct or reflex, or by the emanations, which neither Dr. Poole nor any one else, I imagine, can satisfactorily explain. If he would have us claim that this is activity, we may surely claim that coma and syncope are states of nerve activity.

This brings us to the tenth, and here again there seems no breach in the old theory, for, in a depraved condition, what is more reasonable than to give stimulants? Even the argument Dr. Poole uses can be turned against him. Take, for instance, cholera. Admitting that relaxation is active and contraction passive, in this condition we have both, and if stimulants are inadmissible under one theory, they certainly are also under the other. Look at the prostration following a debauch, with the muscular reflexion and tremulousness. If this is a state of nerve activity, why does a stiff glass set him at rights again?

The eleventh fact may be reasonably explained by the old theory. Man only breathes as he feels the necessity. The more venous the blood the greater

the call for oxygen. Even if we cannot explain all the peculiarities of reflex nerve force, how much clearer does Dr. Poole make it?

In regard to the twelfth, we will only say that Ringer says that "aconite does not affect the vaso-motor centre or nerves, and therefore the lessened arterial pressure it induces is due to its action on the heart."

In consideration of the thirteenth, I would ask Dr. Poole if he would regard it too much of a stretch of his imagination to see how the pressure of the heart might influence the calibre of the arteries, and how the capillary attraction of the small vessels might affect their condition of emptiness.

Fourteenth.—The action of aconite, etc., on inflammation is very satisfactorily explained by its weakening the force of the heart, and thus retarding the blood-current and by promoting diaphoresis.

Under the fifteenth may not the same objection be argued against this theory, as he rises against Dr. Bastian. If the writer thinks it absurd that a twitching of muscles could occur in paralysis, under the theory of to-day, is it not equally absurd that a brain whose "functional manifestations have been stopped" should send sufficient nerve force to cause relaxation of the muscular fibres, which there must be if there be twitching?

The sixteenth says that the muscles of a frog are "seen to be more apt to enter into a state of contraction after the division of the principal motor nerve." How is this. An orthodox muscle would immediately contract forcibly, and remain so, and thus would have no lifting power at all, but sustaining power. We certainly should not be satisfied with "more apt;" it should be "infallibly." I do not attempt to say that Dr. Poole is wrong, and that the present theory is right, but I do confidently affirm that there is not one of the points which he raises which cannot be met, or is not equally disastrous to his theory. I doubt not but that he would be entertained by an illustration in Dalton's Physiology, showing the effects of division of the facial nerve. If relaxation is action, why is it that in paralysis of a group of muscles, their opponents are overcome and the limb is flexed or exteuded accordingly? Is tartar-emetic a nerve stimulant, are chloroform and ether? they produce muscular relaxation. Dr. Poole would certainly lead us so to think.

W. C. McGeffert, A.B.

Hudson, N. Y.

THE DETERMINATION OF SEX IN UTERO.

To the Editor of The Medical Record.

Sir:—In the Record of May 15, 1880, I observe an article on the above-named subject by Dr. Carlile, of Palmyra, Ill. It is not my intention to attack his theory, but to state some of my own observations in corroboration of the theory advanced by Dr. Upjohn. After applying the various theories advanced by many of the profession, I have concluded that the undertaking is hazardous when we attempt to inform the mother, however solicitous she may be, of the sex of her unborn child; still I believe that a reasonable solution of Dr. Upjohn's theory can be given, and if you will allow me a short space in your journal I will hazard an opinion. It is generally admitted that all females in the animal kingdom enjoy sexual intercourse just subsequent to menstruation to a greater degree, and that the pleasurableness of the act is diminished in proprotion to its removal from the period. I am now referring strictly to the act which is in obedience to physiological law, without reference to those unnatural indulgences acquired through prostitution.

Now, if this be true, it is not unlikely that the mother should transmit to her offspring her sexual peculiarities, and that, too, in proportion as her nervous forces are drawn upon in the sexual act; therefore the farther the act is removed from the menstrual period the more males will be born; and as the impression upon the mother's mind is diminished so are the chances in the production of a female lessened.

I have received the impression from some one, but am at a loss to give my author, that in dairy districts, from the light reflected by the above law, they are enabled to produce from eighty-five to ninety per cent. of a desired sex.

In breeding the foxhound, for which animal my love amounts almost to weakness, I have observed that the above law is the rule, and, to any one who is curious enough to investigate, he will find the following facts to be true, viz.: That if a male be born as an exception to the above rule or law, it will partake more of the peculiarities of its mother than that male which was conceived in obedience to the law. He is more likely to partake of the same color, his voice will be similar, and about eighty per cent. of this class of males will be provided with imperfectly developed mammæ and that conical protruberance commonly called nipple. It will be found that the female born as an exception to the rule will partake of the peculiarities of the sire.

There are two cases in natnre in which the offspring invariably partake of the peculiarities of the sire. I refer to the *mule* and *hinny;* but, believing as I do, I am convinced that they would by modified if particular attention were paid to the natural law.

I might add a great deal more, but fearing that it might require too much space, I close.

Respectfully yours,

Van S. Deaton, M.D.

Alcony, O., May 26, 1880.

GUNSHOT WOUNDS OF CHEST.

To the Editor of The Medical Record.

Sir:—I agree with your correspondent, Dr. Cowling, in the Record of May 8, 1880, in regard to perfect drainage in perforating gunshot wounds of the chest. Some years ago, while in Florida, I had a man shot down by my side, an ounce bullet having passed through his left lung. The ball entered one-half inch to the left of the cardiac boundary of the left ventricle, and passed out between the fifth and sixth ribs, three inches to the left of the vertebral column. I placed the man on his back, and kept both openings clear.

The hemorrhage was excessive, the mattress became saturated, and blood dripped through it and fell to the floor.

I made no effort to stop this hemorrhage, but kep the patient quiet upon his back without the use of anodynes.

Pieces of the coat and of the flannel shirt, and small pieces of a horn button were floated out by the hemorrhage through the exit in the back.

There was no suppuration, the wounds healed readily, and in three weeks the patient was ably performing his duty as a deck hand on board a schooner.

W. H. Smith, M.D.

San Francisco, Cal., May 20, 1880.

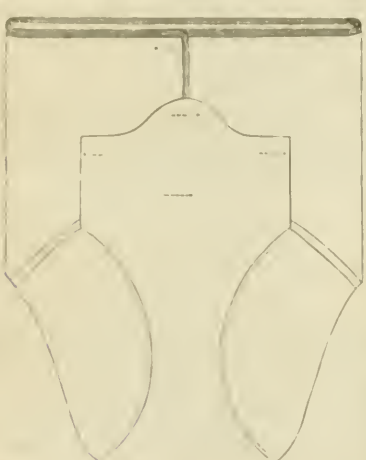
New Instruments.

AN IMPROVED OBSTETRICAL BANDAGE.

By W. B. REYNOLDS, M.D.

To make the lying in woman comfortable is no less the accoucheur's duty than to alleviate her suffering, or save her life. And while the improvement in the forceps, and the treatment of the parturient condition have received so much attention that they can now very well be considered perfect, yet there are minor matters, not unimportant, that to some extent have been neglected; and whoever improves them, however slight, so that they become more useful as appliances to the practical obstetrician, makes some advance in professional knowledge, and saves the sick much disagreeable annoyance.

It is only of the obstetrical bandage I wish to call attention; and in its present mode of application there are many difficulties constantly arising, which annoy the woman and embarrass the attendant. For, instead of giving, as intended, equitable pressure to the relaxed sub-abdominal muscles, and keeping them from remaining too voluminous, preventing the engorgement of, and afflux and stasis of the fluids of



the walls of the uterus, and the further advantage of obviating syncope, and of diminishing the after-pains: it is found generally, unless it is incessantly being rearranged, that these benefits are not obtained, but that it becomes doubled up, forming, as it were, a cord, not only interfering with the circulation and possibly causing hemorrhage, but invariably proving a very great discomfort.

The special advantages of this bandage, of which a cut is here given, are its cheapness, simplicity, the entire comfort to the patient, and the ease and satisfaction afforded by its use to the practitioner. It can be seen at a glance, that when properly made, how easily it can be kept in position, and what uniform support it gives to all the parts. Of its cleanliness I hardly think I can speak too highly, as it retains the napkins perfectly in position, from which they can, with no inconvenience, be changed as often as is necessary, thus preventing the soiling of the clothing or bedding. With little care two or three changes of the bandage will be sufficient to procure entire purity during the period required.

I am quite sure if a trial is given this bandage, it will prove highly satisfactory. For aught I know, one on this principle may have already been successfully used by different practitioners; however, it is more than likely there are some who have not used any of this pattern, and to those I would say a trial will well repay them. From the cut it can be readily seen how simple it is made, the manner in which it is applied, and the uses to which it can be employed. For common use it can be made of a double thickness of unbleached cotton, of a suitable size to fit the patient for whom it is intended; but for delicate ladies it is better to make the abdominal portion of two folds of soft linen, and the perineal, or lower portion, of two thicknesses of twilled cotton.

Marine Hospital, Washington, D. C.

A NOVEL FORM OF MEDICINE GLASS.

We have received an ingenious little medicine glass, invented by Mr. S. D. Mott, one of Edison's assistants at Menlo Park. It consists of a glass tube, the centre of which is enlarged, forming the receptacle for the dose. In the centre of this bulb is a small glass tube which is continuous with the lower part of the large

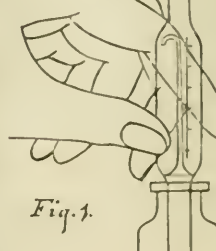


Fig. 1.

Fig. 2.

tube, forming the only means of entrance from the latter to the central bulb or receptacle. The bulb is made of various sizes, the smallest holding a teaspoonful. To use the instrument, the lower end is placed in the bottle and the upper end in the mouth. By suction the bulb is filled, all excess flowing back through the small central tube into the bottle. If the instrument is now reversed the dose can be swallowed without its coming in contact with the teeth. For travellers and for the administration of iron and other preparations liable to discolor the teeth, the instrument will prove particularly useful.

A NEW MICROTOME.

The instrument which for its simplicity, cheapness, and efficiency, is here presented to the microscopist, is a flat piece of steel, 12 inches long by 2–2½ inches wide, with a bevelled cutting edge, 6 inches long, and ⅛ to ¼ inch wide. As presented, the handle is simply smoothed and rounded off.

It has been in use at the School of Histology, at the Columbia Veterinary College, and has held its own against finer and much costlier knives. The design is original.

The mode of action is very simple. The object being mounted in wax, paraffine, or pith, the sections are made by a stroke of the knife, the straight forward motion. As will be readily seen, the larger the section to be made the wider the knife will have to be.

The knife is easily kept in order, and its peculiar shape serves to turn the cutting edge in the right direction for cutting, in the act of strapping.

The microtome is made of the best plate steel, and sold by J. Reynders & Co., of New York, for the low price of $3.

It is known as the "Vincent" microtome.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from May 30 to June 5, 1880.

Vollum, E. P., Major and Surgeon. Having reported in person at these hdqtrs., is assigned to duty at Fort Hamilton, N. Y. H. S. O. 84, Dept. of the East, June 1, 1880.

Irwin, B. J. D., Major and Surgeon. To be relieved from duty at Ft. Meade upon return to that post of Assist. Surg. Brechemin, and then to report in person to the comd'g officer Ft. Snelling, Minn., for duty as Post Surgeon. S. O. 63, Dept. of Dakota, May 27, 1880.

Happersett, J. C. G., Major and Surgeon. Granted leave of absence for three months, to take effect when relieved from duty in Dept. of the East. S. O. 118, A. G. O., May 28, 1880.

Weisel, D., Capt. and Asst. Surgeon. Granted leave of absence for four months. S. O. 122, A. G. O., June 3, 1880.

Byrne, C. B., Capt. and Asst. Surgeon. Assigned to duty at Fort Johnston, N. C., relieving Asst. Surgeon V. Havard, who will comply with S. O. 74 C. S., A. G. O., in his case. S. O. 65, Dept. of the South, June 1, 1880.

Hall, Wm. R., 1st Lieut. and Asst. Surgeon. To proceed to Fort Hays, Kans., and report to Major Noyes, 4th Cavy., for duty with troops ordered to New Mexico. S. O. 113, Dept. of the Missouri, May 26, 1880.

Dr. Keith's Operations for Ovariotomy.—Dr. Keith's success with his ovariotomy operations has been interrupted; when he had got up among the eighties a patient died. It was a very bad case, and was operated on only at the urgent solicitation of the relatives.

Medical Items and News.

Contagious Diseases — Weekly Statement. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending June 5, 1880.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
May 29, 1880.	0	6	58	7	86	31	1	0
June 5, 1880.	0	2	32	4	58	25	0	0

Measles.—After a recent epidemic of measles in Dartmouth College, the following facts were elicited: eighty per cent. of the students are from New England, the rest from all parts of the country. The average age of entrance is nineteen and a half. The number replying to questions was 258. Of these, 213 or 82 per cent. had measles before entering college; 39 or 15 per cent. had had it since entering; and 6 had wholly escaped, so far as they knew.

International Medical Congress.—At a meeting held in London, by delegates of the various universities and societies, to arrange for the next International Medical Congress, the following matters were decided:

The meeting will take place in London, from the 4th to the 15th of October, 1881. A general committee was appointed to make all necessary arrangements. This committee numbers fifteen, Mr. W. Bowman being chairman. Each member of the Congress is to be assessed one guinea.

The New York State Pharmaceutical Society, which met at Syracuse, May 19th, elected the following officers for the ensuing year: President, P. W. Belford, of New York; Vice-Presidents, G. M. Baker, of Brooklyn, Frank Hamilton, Syracuse, H. B. Napier, Oswego; Secretary, C. W. Holmes, Elmira; Treasurer, Wm. Blakie, Utica.

The New Jersey Pharmaceutical Association held its annual session at Jersey City, May 19th. W. N. Laird was elected President; Anselle Walker and A. G. Smith, Vice-Presidents; Wm. Rush, Treasurer; A. P. Brown and R. W. Vandervoort, Secretaries.

Presbyterian Hospital.—Drs. James L. Banks and S. T. Hubbard have been appointed consulting physicians to the Presbyterian Hospital.

Tannate of Quinine, which is becoming popular for use with children, is less reliable than the sulphate, slower in action, and about half as strong. It is soluble, however, in the stomach, and, if pure and carefully given, preferably with a little wine, it will generally act just as well as other preparations.

Case of Early Viability.—Dr. J. H. Moore reports a case, seemingly well-substantiated, of very early viability. The woman, at the time of delivery, was in the last of the fifth month of pregnancy. The child at birth was nine inches long and weighed one and a half pounds. It was nourished at first by dropping liquid food into its mouth. At the age of

fifteen months it was healthy and weighed nineteen pounds.—*Philadelphia Med. and Surg. Reporter.*

Examinations in Sanitary Science.—A new feature was introduced at the recent meeting of the Michigan State Board of Health, held at Lansing, April 14th. It consisted in holding examinations in sanitary science. Such candidates as passed a satisfactory examination were given a certificate of merit. This plan, though as yet imperfect, indicates an interest in sanitary education, and will doubtless give some impulse to the cause.

Four Cremations took place at the Milan crematory in March.

The Electrical Polyscope, invented by M. Trouvé, received a new use at the annual meeting of the Paris Physical Society on April 2d. M. Trouvé placed it in the stomach of a fish swimming in an aquarium, and, without its seeming to suffer any inconvenience, it radiated a light equal to one common candle.

The International Ophthalmological Congress will hold its sixth meeting at Milan, September 1st to 4th next.

Dr. Wm. B. Carpenter has resigned his position as representative of the London University in Firth College, Sheffield, on account of ill-health.

Bromide of Ethyl vs. Ethidene Dichloride.—Mr. J. T. Clover writes to the *British Medical Journal* concerning hydrobromic ether, that it stimulates and excites the patients quite as much as ether. It also often leaves the patients nauseated and giddy. He much prefers ethidene dichloride, because the after-effects are less unpleasant.

Dartmouth Medical School.—Prof. Edwin J. Bartlett, M.D., has been appointed Lecturer on Medical Chemistry at this school. A committee from the New Hampshire State Medical Society were present at its last examinations and warmly endorsed its educational work and methods. Examinations in anatomy, physiology, and chemistry are given, if desired, at the end of two full courses.

On the Diuretic Properties of Antihydropine.—In Russia, cockroach in powder or infusion, has been for a long time a popular remedy for dropsy. The attention of the profession was called to it for the first time by Dr. Kuprianoff, in his dissertation for the degree of Doctor of Medicine, his thesis being that the cockroach in one-grain doses is a reliable diuretic. Later on, Dr. Bogomoloff (*St. Petersburger Medicinische Wochenschrift*, 1876, No. 31) made experiments with antihydropine on six patients in Prof. Botkin's clinic, and three patients in Krasnoe Selo Hospital, all suffering from dropsy induced by various causes. The conclusions to which he arrived were as follows: antihydropine increases the amount of urine and diminishes the amount of albumen and structural elements, dropsical symptoms disappear, the weight of the body diminishes, perspiration in the majority of cases increases, and the digestion is not affected by it at all.

The article referred to above contained also the report of a case from Prof. Botkin's private practice—a lady suffering from cardiac dropsy, after every diuretic had been tried successively without giving relief, was put finally on this popular remedy, and in a short time all dropsical symptoms disappeared. Dr. Spulsky's case was one of the patients in Prof. Slawjansky's gynæcological and obstetric clinic at the St. Petersburg Medico-Surgical Academy. She suffered from a tumor in the peritoneal cavity, probably of a malignant nature, complicated by an ovarian cyst, and an extensive ascites. The average daily amount of urine for eight days, previous to the treatment by antihydropine, was 925 c.c. Then she was ordered to take three grains of the cockroach three times a day. For the first six days her average daily amount of urine increased by 172 c.c. (1097 c.c. per day). During the next five days she passed daily 951 c.c. of urine. At the same time the size of the abdomen and the ascites diminished considerably and her general condition became improved. For the purpose of a cross-test, antihydropine was withdrawn during the following thirteen days. Daily average fell to 610 c.c., ascites increased, abdomen became larger, and her general condition became worse. With the return to antihydropine, daily average of urine increased to 1038 c.c. per day, and the improvement was noticed again in the general and local symptoms. Dr. Spulsky states that both before and during the treatment the patient took approximately the same amount of fluid, that she did not suffer from diarrhœa, that the perspiration was not increased by the antihydropine, and there was no increase of salivation. Appetite, digestion, sleep, and other functions were not disturbed. Except for the appearance during the last few days of a trace of albumen, no qualitative changes in the urine were observed. The above facts are sufficient to indicate the value of antihydropine as a diuretic.—Dr. W. Spulsky in *St. Petersburg Vrachebn. Vedomosti*, February 28, 1880.

A Method of Preserving Rubber Instruments.—Various articles and instruments made of rubber are apt with time to become dry, to crack, grow brittle, and lose their elasticity. Dr. Pol (*St. Petersburg Vrachebn. Vedomosti*, March 6, 1880) recommends the following simple mixture—R. Water of ammonia one part, water two parts—in which the articles should be immersed for a length of time varying from a few minutes to one-half or one hour, until they resume their former elasticity, smoothness, and softness.

The Kansas State Medical Association met at Fort Leavenworth, Kansas, May 11th, 12th and 13th. A large number of members were present. Papers were read by Dr. Floyd, on antiseptic surgery, recommending in that connection eucalyptus globulus; by Dr. Shoyer, on puerperal eclampsia and hysteria; by Dr. Coons, on a case of neuroma of the sciatic, treated by excision; by Dr. D. G. Ross, on diphtheria. A number of other papers were read of much interest. A new tracheotomy instrument was presented by Dr. Shoyer.

The Society discussed the duties of the State Board of Examiners, and passed a resolution instructing the Board to use all proper measures towards carrying out the law regulating the practice of medicine.

A resolution was adopted to the effect that the Kansas State Medical Association would not recognize the diplomas of the St. Joseph Medical College.

The officers for the ensuing year are: President, Dr. E. B. Fryer; Vice-Presidents, Drs. F. M. Dailey and G. Grass; Secretary, Dr. F. M. Morse; Assistant Secretary, Dr. W. B. Gibson; Treasurer, Dr. W. W. Cochrane. A Board of five Censors was also elected. The Society adjourned to meet at Topeka, the second Tuesday of May, 1881.

Dr. William Ogle has been appointed Superintendent of Vital Statistics in the Registrar-General's Department, vice Dr. Wm. Farr, resigned.

Frequency and Cause of Stammering.—M. Chervin, of Paris, who has long devoted himself to the study and treatment of stammering, states that in France it occurs in five out of every thousand persons. It is found much more frequently in men than women, in the country than in the city, and among the ignorant than among the educated. In some savage tribes it is very common.

The most frequent cause is some sudden fright in childhood; but it may come on gradually or from an involuntary imitation of others.

M. Chervin states that 1,000 young men are exempted from military service annually on account of stammering. He urges the importance, therefore, of more attention being given to its cure. He has himself established several schools for this purpose.

In this country it is not very easy to find a reliable place where sufferers from stammering can be treated. There are, however, a few such in some of our large cities. The method of treatment adopted is essentially the same everywhere. The patient is told to take a deep inspiration at the beginning of each sentence. He is taught to speak very slowly and distinctly, and must daily go through a regular series of exercises.

Dr. E. Seguin, of this city, thinks that he has found muriate of ammonia beneficial.

A Case of Abdominal Pregnancy, with Development of Rudimentary Fallopian Tubes and Ovaries.—Dr. E. C. Bowen, of 86 Waltham Street, Boston, relates a peculiar case of extra-uterine fœtation which had come under his notice. The patient, a colored woman, aged 40, was in her second pregnancy when the doctor was called in. She stated that she believed herself pregnant, yet she had menstruated regularly. Examination showed that the uterus was empty, but there was a well-marked abdominal tumor, which led to the suspicion of extra-uterine pregnancy. The woman was suffering from a most persistent diarrhœa at the time. She died a few days later. A post-mortem examination revealed the following condition: A large cyst was found in the abdominal cavity, attached to the peritoneum about half way between the symphysis pubis and the umbilicus. There were no adhesions except at this point. On opening the cyst a fœtus was discovered, which seemed to be about eight months old. The funis was large; the placenta attached to the internal wall of the cyst, at a point opposite the attachment of the cyst to the peritoneum. Most remarkable of all, there existed on each side of the upper part of the cyst a small cord, about four inches long, and the size of a knitting-needle. At the free ends of these cords were small bodies like rudimentary ovaries, about the size of a bean. The whole arrangement looked like an effort on the part of the cyst to transform itself into a uterus and develop the proper appendages.

Small-pox and Cow-pox.—A recent article by Mr. George Fleming, in the *Lancet*, discusses the relations between these two diseases. Since the time of Jenner, the opinions as to whether they were identical or distinct diseases have varied from one side to the other. Mr. Fleming quotes the conclusions of the Commissioners of the Academy of Sciences in 1865, and of those of the Italian Medical Commission in 1871 and 1874. From these and other data, the opinion is expressed that small-pox is a different disease from cow-pox. Furthermore, that they are mutually exclusive, and that the occurrence of one in a cow, as in a man, prevents the other.

There are still a good many authorities who do not accept these views of Mr. Fleming.

Muscle-Beating, by C. Klemm, with illustrations, is the title of a little pamphlet giving full directions for carrying out this form of exercise. There has been considerable attention paid to this subject lately, and this pamphlet will prove of general interest. Published by M. L. Holbrook & Co., New York.

The Transactions of the Society of the Alumni of the Medical College of Ohio contain a record of the organization of the Society, and of its annual meetings since 1875. A number of addresses upon various topics, the constitution of the Society, and a minute of the proceedings, make up a volume that will be of much interest to the members of the Association.

Proceedings of the Oregon State Medical Society, Portland, June 12 and 13, 1879.—The Oregon State Society publish a small volume of transactions, but this indicates no lack of energy or interest on its part. The Society appointed a number of standing committees on various medical subjects. It also passed a resolution recommending the adoption of the decimal system. A number of interesting cases were reported and discussed. An elaborate paper on medical education, by Dr. C. H. Merrick, showed an appreciation of the educational deficiencies of our schools, and the need of higher standards was strongly urged by the writer and the Society. The permanent secretary of the Society is Dr. Curtis C. Strong, of Portland.

The County Hospital of Sacramento got into the hands of the homœopaths some time ago. According to the *Pacific Medical and Surgical Journal*, it has been recently taken from them, in part because so much money was spent for drugs, and among the items were three pounds of salicylic acid, and 4,000 grains of quinine.

Acute Rheumatism in a Baby.—A case of rheumatic fever affecting a child nine months old is reported by Dr. Barton Dozier in the *Independent Practitioner*. The knee- and hip-joints were affected. The baby died in three days from cardiac complications.

The Providence Medical Association has been at work for two years, trying to establish a medical library. Through the energy largely of Dr. G. D. Hersey, it has made considerable progress. At the March meeting of the Association all the journals and books so far collected were turned over to the State Medical Society to form the nucleus of a State Library.—*Bost. Med. and Surg. Journ.*

Prescription for Artificial Carlsbad Salts.—The artificial, and especially the natural Carlsbad salts, as sold by druggists, are quite expensive. The following represents the ingredients as given by the *Cincinnati Lancet and Clinic:*

℞ Sodii sulph..... ʒ vi.
Sodii carb. cryst..... ʒ vij.
Sodii chlorid..... ʒ i.
M.

A Case of Fatal Tetanus following enucleation of the eyeball was reported by Dr. J. J. Chisholm in the *Archives of Ophthalmology*, and we have a reprint of it now before us. The peculiar points of interest

were the extreme rarity of tetanus following the usually safe operation of enucleation, the fact that the patient was seventy one years old, and that the symptoms did not appear until the fifteenth day after the operation.

Charlatanist Doctors in Pennsylvania.—We have it on the authority of the *Medical Press and Circular*, that there are 1,500 "magnetic healers" in the State of Pennsylvania. Of these, only 96 have medical diplomas of any kind.

The Air Breathed in Leadville, 10,500 Feet Above the Level of the Sea.—Dr. H Steiman, of Leadville, Col., sends us an interesting article upon the above subject. It has been asserted that the atmosphere of Leadville is poisoned by the smoke and gases from the numerous smelters, of which there are about twenty, in the neighborhood of the city. Dr. Steiman has examined into the question, and comes to the conclusion that the amount of deleterious vapor, though large, is quantitatively insufficient to produce any poisonous effects. The gases from which danger is to be apprehended are those containing lead, sulphur, chlorine, and arsenic. Estimating that each of the twenty furnaces around the city consumes thirty tons of ore per day, he finds that about ten ounces of chlorine, eighty pounds of sulphurous acid, and eighty ounces of arsenious acid would be given off every minute of the twenty-four hours. Most of the chlorine, however, unites to form solid chlorides; more than half of the arsenious acid fails to escape into the air, but is found in a solid condition in the spelss. The sulphurous acid is so diluted by the air that its presence is scarcely noticeable. The lead vapors are the most harmful, but their amount is small, and they can easily be prevented from escaping into the air. The conclusion, then, is that the furnaces are not sources of danger from their poisonous emanations. This conclusion is confirmed by practical experience, as no cases of lead or arsenic poisoning have been found.

Dr. Steiman is of opinion that Leadville is in much greater danger from its neglect to care for the drainage of the city, and the disposal of filth. Nothing, he thinks, but the great natural salubrity of the place, with the high percentage of ozone in the air, has prevented an epidemic from occurring already.

Lectures on Cataract, with a tabulated report of 100 cases, by Dr. G. E. Frothingham, of Michigan University, is a reprint of fifty pages, which can be read with much profit by the student. It is a series of clear and practical clinical remarks upon the subject chosen. Dr. Frothingham employs Von Graefe's modified linear extraction in operating for cataracts.

We regret to see that he never uses electricity to dissolve cataracts; and it must be inferred that he fails in the first duty of the ophthalmologist—that of reading *The Churchman*.

The Duchess Pauline, of Württemberg, has just married a Breslau physician. The lady is twenty-six years old. She has renounced the title and position of a princess of the royal house and has assumed the name of "Von Kiebach." She is the youngest daughter of the late Duke Eugene.

Glycerine was introduced some time ago as a substitute for cod-liver oil, but failed to gain favor. Dr. Larmande now recommends it again in a form which he calls tonic-glycerine. It consists of glycerine 300 grammes (℥ x.), tincture of iodine, 30 drops, and iodide of potassium, 3 grammes (gr. v); the dose being f ʒ ss. This is claimed to restore the appetite and regulate the bowels. Experiments recently made by Munk show that glycerine is not a food in the usual acceptation of the word. Practical experience, however, may show it to have some medicinal value.

Answers to Correspondents.

Benzoate of Sodium.—So many correspondents have asked regarding the use of this salt in the treatment of phthisis pulmonalis that we give a general answer as follows.

Letulerich recommends the following for internal administration:

℞.

Sod. benzoat.	gr. 80 (5.0 grms.).
Aq. dest.,	
Aq. menth. pip. ää	ʒ iss.
Syr. cort. aurant.	ʒ ijss.

M. Sig.—One tablespoonful every hour for adults; a teaspoonful every hour for children less than two years old, and a dessertspoonful for children three to five years old.

Klebs advises the inhalation of ʒ ijss. per day at two or three sittings, conjointly with the benz. magnes. (internally), in doses varying from ʒ i. to ʒ ij. per day.

Schüller uses ʒ i. to ʒ ij. benz. sod. per day, taken by the mouth in doses of ʒ ss. to ʒ i.

Kraczuk employs inhalations of a 5 per cent. aqueous solution.

Others have used and recommended a 2 per cent. watery solution, the sittings lasting at times over an hour.

The dose administered by inhalation is ʒ ss. at starting, with a gradual increase up to and above ʒ iss. daily. Two to three inhalations are practised each day, the sittings in some instances lasting two hours (counting pauses for rest).

The minimum dose appears to be about 10 grains; the maximum ʒ ss. and even ʒ i.—Ed.

Expulsion from Medical Societies.—An Old Subscriber of Covington, Ky., asks if a medical society under the jurisdiction of the State and National Medical Association expels a member for violation of its rules, and other local societies are duly notified of the fact, is it, or not, proper for such societies (duly notified) to have professional intercourse with the expelled member?

[This will depend partly on the nature of the offense and partly on the status of the society. If the member be legally expelled by a local chartered society for breach of the code of ethics of the A. M. A., the members of other similar societies should refrain from professional intercourse with the expelled person. If, however, the expulsion be for breach of some local rule or by-law, as for non-payment of dues, etc., or for indecorous behavior at a meeting, other societies are not bound to take notice of it. On the other hand, if the expelling society be a voluntary or unchartered one there is no obligation on the part of other societies to govern themselves by its action in the premises, for the reason that a member may be unjustly expelled and be left entirely without redress, while, if unjustly or illegally expelled from a chartered society, he can, by due process at law, compel it to reinstate him.—Ed.]

Original Lectures.

ETIOLOGY AND TREATMENT OF UTERINE DISPLACEMENTS.

By MONTROSE A. PALLEN, M.D., LL.D.,

PROFESSOR OF GYNÆCOLOGY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.

PART II.—TREATMENT.

GENTLEMEN:—You will probably recollect, when speaking of the conditions which bring on uterine displacements, I mentioned that at the period of menstruation, and at the period of erotic excitement, there was an erection of the entire contents of the pelvis, of the uterus and ovaries, and I now tell you there is also an increase in the size of the blood-vessels themselves. The causes of uterine displacements are principally vascular, and this vascular condition may be either uterine, or extra-uterine, and the extra-uterine vascular disturbances may be due either to pressure, dragging, or absence of support. I give you a schedule of the causes of displacements:

Etiology of Uterine Displacements.	Vascular. (Uterine and Periuterine.)	Extra-Vascular.	Pressure. Dragging. Absence of support.

The vascular conditions I have already described. I have told you why, from the retention of blood, the uterus becomes erect and increased in size; that an increase in the quantity of blood determined not only the erection, but the increase in the weight of the parts; and, under this head, we would class the great causative of uterine displacements, as vascular. A plus quantity of blood makes the uterine structure, the periuterine, and the connective-tissue spaces larger than normal.

For the purpose of illustration, suppose we have an india-rubber band, and we attach to it an ounce weight, and that by pulling down upon the weight, the elasticity of the rubber is just sufficient to make it rise and fall rapidly. If we add half an ounce, thus increasing the weight to an ounce and a half, we find the elasticity diminished, and if we add another half ounce, thus increasing the weight to two ounces, we find that the resistance represented by the elasticity of the rubber string is entirely overcome. Thus we have demonstrated that too much weight has overcome the normal elasticity of the rubber string. Now, suppose we have a uterus that weighs two ounces, which is held and supported normally by connective tissue. If its weight be increased to three ounces, the power represented by the connective tissue is decreased by the weight of the uterus; therefore the elasticity of the normal supports become lessened, because the weight is greater, and, as a consequence, the uterus sinks in the pelvis. Now what is the rationale of this condition. The cause is chiefly vascular, an increase in the weight of the organ, due to the presence of an increased quantity of blood. This increased quantity of blood may be inside or outside of the uterus. In ninety-four per cent. of the cases, you may say it is due to the condition of the vascular parts. In the other six per cent., its increase is due to other causes. One of these factors is pressure. Again, we may find that above or below the uterus there is something which may be dragging or pushing it out of the way. This may be attached to the uterine wall, anteriorly, posteriorly, or inferiorly. Again, we have a very large number of cases where there is absence of support, and the uterus sinks in consequence thereof and becomes displaced. Therefore, in the treatment we must never forget to consider the cause of the displacement. Would you think it proper to treat a displacement due to laceration of the perineum the same as if the cause were superincumbent pressure? Certainly not; and yet, if you will consult a large number of the works upon gynæcology, you will find directions for treating these cases by the introduction of a proper pessary. Hitherto, this has been the accepted plan of treatment, and there are many gynæcologists of the present time who recommend the pessary as a means of curing displacement. However, a few men are beginning to pick out of this chaotic class of uterine displacements, various causes for certain conditions, and they are beginning to tell you to treat the cause. Another fact. We must recollect that when the uterus is displaced (and under the head of displacements I mean versions, flexions, and prolapsus generally), you will always find the integrity of the uterine structure deranged. Thus, if the displacement be an anterior version, you will find the anterior wall thickened, and generally hardened; and you will also find that here there is usually some anteflexion. In a large number of cases of retroversion, there is also retroflexion, and the posterior wall is thickened. Where the uterus is prolapsed—that is, when the body of the uterus is lower in the plane of the pelvis than it should be—it gets into a state of retroversion, except in those very rare cases where there is a dragging down from thickening or adhesions of the uterus, or in consequence of a folding forward of the vaginal wall from dislocation of the bladder.

Are we to treat a case of this kind as we would treat a displacement due to the loss of the perineal body? By no manner of means. Now, suppose we have a case of anteversion of the uterus; primarily, this anteversion is produced by what? It is produced by vascular causes, and these are not only uterine, but extra-uterine, or, in other words, there is primarily an increased quantity of blood in the uterine tissues and periuterine spaces, and the weight of the uterus is perhaps three times as heavy as it should be. From some peculiarity of a woman's pelvis, whether from an overloaded rectum, or from the inclination of the pelvic cavity, or from the attachment of the vaginal structure toward the bladder, the tendency of the uterus is to fall forward; and this is the normal tendency of the uterus. The frozen sections of virginal bodies, made by Winckel, Breisky, and Aeby, have demonstrated that the axis of the uterus should be on a line above the bladder. Now, let any weight come upon the uterus, and if it overcomes the resistance of the normal supports, the uterus drops forward most frequently in the nonparous woman, oftener backward in the parous woman. In addition to this, suppose that the woman has a mass of fat in her omentum, or she has a tumor, ovarian, or a subserous fibroid of the uterus; or there may have been an exudation anteriorly, and above the bladder, in consequence of a cellulitis, and the uterus is bound down at that point—it is fixed. Now, I ask you, in the name of common sense, is the wearing of an anteversion pessary going to cure such a case? Suppose the same thing obtains in the converse, that the uterus is drawn backward, then, according to the lights before us, and according to the

teachings of many, we must use a retroversion pessary.

Now, if version is produced from either of the several causes I have mentioned, be it due to uterine or extra-uterine influences, be it due either to pressure, dragging, or absence of support, what are we to do? The first great rule in surgery, where a dislocation exists, is primarily to reduce the dislocation, whether that dislocation be due either to traumatic or pathological causes. The next great rule after the reduction has been accomplished is to retain the part in its rectified position, therefore it is well to give the patient some means by which this may be accomplished. Now, these means are varied. What are they? Primarily rest; secondarily, the change of the pathological into a physiological status by means of adjuvants, and the association of medicaments, diet, and hygiene. Thirdly, after having done this, maintain or retain the dislocated organ in position; and frequently we have to do this by direct surgical interference. Thus, if dislocation be due to pressure, we may be required to remove a tumor; sometimes we cannot remove a tumor without great danger to the woman's life. The tumor, however, may be moved out of the pelvis into the abdominal cavity, and held there by an abdominal bandage. In cases of congestion of the liver, spleen, intestines, or kidneys, we frequently find uterine displacement. The communication between the uterus and liver is such, that if the circulation of the latter be interfered with, the former will necessarily suffer. Hence I say, that the man who tries to treat chronic congestion of the uterus, without paying attention to the circulation of the abdomen, is behind the age. I have frequently tried to impress this important matter upon your minds, and when you get into practice, and have an opportunity of demonstrating this fact in the cases which come to you for treatment, and learn how little attention is paid to it by those about you, you will be surprised at the want of practical adaptation of anatomical and physiological facts, to a proper therapeutical advantage.

Now, suppose that we find dislocation of the uterus, due to dragging downward from a want of support, and that dragging may be what? The bladder being attached to the uterus, and from some cause the connective tissue of the bladder and vagina is defective, it falls down and pulls the uterus after it. Now, of what use is a pessary in that condition? A pessary would merely flatten the bladder upon the vagina, and let it remain where it was. But if a pessary will not act properly, how are we to overcome it? It is a condition partially removable by art; we can overcome the cause, in cases of cystocele, by various surgical procedures, as in a removal of a portion of the relaxed, flabby, vaginal tissue, which lets the uterus fall by failure to support. In the vast majority of cases where the uterus has fallen from cystocele, the lesion does not come so much from the relaxed condition of the bladder, as from that other very frequent cause, namely, laceration of the perineum. You recollect, I told you the uterus and vagina in totality represented an arch. The strongest support known in mechanics is the arch, and nature has adopted this for the holding up of the contents of the pelvic cavity, and the base, not the key-stone, of that arch is the perineum, or, in other words, the genital tract is a horse-shoe-shaped canal, the uterus representing the upper anterior end, the perineum the lower anterior support.

The inferior end of the horse-shoe arch is destroyed when the perineum is torn, the uterus drops down, and dragging the bladder with it makes a cystocele; therefore, in any form of retroversion, anteversion, or prolapsus, dependent upon absence of support, as laceration of the perineum, where you find rectocele, or cystocele, the treatment is nothing more nor less than a radical operation for the repair of the broken perineal structure. Take my word for it, gentlemen, all the pessaries ever invented are of no use in cases of laceration of the perineum. I have studied these classes of cases many years and I have come to the conclusion that the proper way to teach young men how to treat them is to describe only the proper method of procedure, and nothing else. If we find that the tissue is flabby and flaccid, and that a plus quantity of weight has overcome the elasticity of the normal supports, then the damage done should be repaired by a surgical operation. If we find, after we have made a new perineum, that the uterus is still anteverted or retroverted, then we can give the patient a pessary, because the pessary has now a base upon which to rest; but rest ignored, where there is a laceration of the perineum, there is no base for the pessary to rest upon. I have operated within the last three weeks upon three ladies who had what I called many years ago "*perineal wanderong*," that is, a division or a separation under the mucous membrane of the conjoined perineal structures. I found that these muscles were sundered at labor, and the result was a thin patulous band in the inferior segment of the vagina, where the pyramidal perineal body ought to be found. As a consequence, all these ladies had passed through a prolonged course of the usual treatment by various forms of large pessaries, but without any benefit whatever. These pessaries interfered with the circulation of parts in the vicinity of the bladder anteriorly, the rectum posteriorly, and the vaginal walls laterally. The obstructed veins became turgid, the capillaries partook of this turgidity, as did the lymphatics in the pelvic cavities, which are scarcely more than five inches in breadth from behind forward, and instruments were worn measuring nearly four inches in their antero-posterior diameters. Of course, defecation and urination were difficult, and there was likewise a copious leucorrheal discharge.

How are you going to cure such cases as these? I reply, there is but one method: by removing the cause. One of these ladies had borne nineteen years ago a child, at which time a laceration of the cervix and perineum had occurred. The involution that the uterus should undergo after labor had been suspended, and for years the uterus remained larger than normal. In another case involution never took place; hypertrophy of the organ remained for fifteen years, and, on account of absence of support, the necessary result was, dropping in the pelvic cavity of its entire contents. If there be a laceration of the perineum, then excessive weight, or non-shrinking of the connective tissue, will let the uterus drop down, and, as a result, there will be an engorged pelvis and obstructed rectum. This will beget constipation of the bowels as well as vaginal leucorrheal discharge, as a result of interference with the circulation. Then there will be the usual reflex symptoms found under such circumstances, such as supra-orbital neuralgias, pain in the left iliac fossa, sciatic pains, sleeplessness, etc.

In one of the cases to which I have referred, the patient thinks she has taken enough bromide to fill a well-bucket. She had taken large quantities of chloral to make her sleep, and had worn every conceivable form of pessary, and, I am sorry to say, to no

purpose whatever. Now, when we have a case like this, what are we to do? We must get rid of the cause; we must reduce the dislocated organ, particularly if the dislocation is producing a painful condition. If the dislocation interferes with defecation, if the contents of the bowels cannot be cast off properly in consequence thereof, then the organ should be placed at once in as nearly a normal position as possible. But, if we find that the dislocation has existed a long time and the parts have become tolerant of manipulation, we must gradually place the organ in such a position, that when it is reduced, it can be ultimately retained in position. The first step in the proper procedure is to make a surgical operation for its relief, be that operation greater or less, for the restoration of loosened or lacerated tissues.

To illustrate: if we take a rope that is made of a large number of strands of hemp, it represents, in its unity and entirety, a certain resistant power—a certain strength. Suppose a rope containing ten thousand strands is just capable of sustaining five tons. If these strands be separated, it will be found that one of them will not sustain one ten-thousandth part of five tons; or, in other words, the union of many strands increases the strength of the individual strands. So it is with the connective tissue around the uterus. If each shred is properly woven and interwoven to make a proper woof, combined they retain the parts *in situ*. But let us have some of these strands of connective tissue broken, some flabby, some relaxed, and what is the result? We have at that point where they are broken a tendency to dislocation. Now, if there be a pathological condition which increases the weight of the organ, that increase of weight is in inverse ratio; or, in illustration, if my finger represents a series of strands of connective tissue, and my other hand represents ten pounds, the normal resistant power of these strands will bend or give way by letting my hand represent twenty pounds. Suppose the connective tissue is broken in some place, that it is destroyed in others, and atrophied in others; then a weight of ten pounds, which represents the normal resistance of these tissues, will cause a separation at the point where the diseased strands exist. How are we to overcome this and find out that these diseased strands, or this non-resistant tissue, exist?

If you will recall what I gave you on the circulation of the parts as productive of uterine displacements, you can understand how it is, that an increased weight of blood in the connective tissue, constantly recurring, will reduce the strength of the strands that hold the uterus in position: the weight is increased and the elasticity is diminished, and in proportion to the diminution of the elasticity do we have these displacements. Perhaps I can make this plainer. Say we have a woman who presents with prolapsus, that is, a sinking of the uterus in the pelvic cavity. We examine this woman and find, that, according to all known methods of examination, the uterus is normal in size, that the sound goes in two and a half inches into the cavity, that with the finger in the vagina and the hand upon the abdomen conjoined manipulation fails to reveal any increase in the length, size, or lateral dimensions of the organ. We find out its thickness anteriorly and posteriorly, by introducing the sound into the bladder, or finger in the rectum, while the other finger is in the vagina; no abnormal thickness is discovered. But now if we have measured this prolapsed uterus, and find it normal in length, breadth, and thickness, but that it has dropped down in the vagina and the neck rests upon the perineal structure, there certainly must be a cause for it. We eliminate the cause pressure, we ascertain that nothing drags it down, and that there is no want of support. We then know what? That the cause of the procidentia is want of strength in the connective tissue that holds the uterus in place. How are we to rectify this? Primarily, by reduction of the dislocated organ, and secondarily, by its retention in the improved or rectified position. Now are we to do all this by the sole means of a pessary? Not at all; the pessary simply acts as a splint to hold the organ in position long enough to give the overtaxed tissues rest, to permit them to re-establish their elasticity.

Of late years I have been using pessaries very much less than formerly, although I have added three more instruments to the already formidable array, viz.: a retroflexion, an anteflexion, and the general soft-clay pessary.

There are cases where the anteflexed or retroflexed organ cannot be made to stay *in situ*, without the assistance of a pessary—a splint—to hold it. To meet some of these emergencies, I have devised these pessaries and find them better than some others used for similar purposes. Yet they do not get rid of the cause—they simply palliate the effect by lifting the organ into its normal plane, thereby giving the overstrained, stretched, and altered (hypertrophy and sometimes atrophy) connective tissues an opportunity to resume their healthy elasticity. Should there be, however, a varicose condition of the subovarian or periuterine venous plexus, or a separation of alar, ovarian, or periuterine connective tissues, then it is hardly probable that any known instrument, any pessary modification, will radically cure the condition, as it will fail to give equable and generally diffused support.

Pessaries are usually constructed in some form of a ring, bent to be adapted to the vaginal curves, and they necessarily press more in the antero-posterior spaces than elsewhere, that is, they usually rest upon the subpubic ligament and lift the posterior vaginal fornix, in retroversion; and they act, in a measure, just the reverse in anteversion.

If you had a varicose leg to treat by bandaging, you would not bind the instep and the popliteal space with a roller bandage, and leave the rest of the foot and leg uncovered. It is just as philosophical as to treat the majority of uterine displacements with a pessary that will not make equable pressure as well as maintain uniform support.

Years ago I made up my mind that the pathology of uterine disease had been studied in the wrong way, that the philosophy and rationale of so-called ulceration, induration, and displacement were incorrect and unscientific. Reasoning by analogy, I soon discovered that cauterizing the uterine neck, or leeching it, or blistering it, or swinging it in a pessary, was the purest species of empirical treatment. The surgeons, I observed, didn't direct their attention entirely to the ulcer under the skin, but sought to re-establish a more healthy afferent and efferent blood supply, by curing varicose veins or caries of the bone, or even necrosis, or building up a shattered scorbutic constitution. I likewise noticed that these same surgeons kept the inflamed parts, the ulcerated surfaces, the swollen tissues, as quiet and as clean as possible. Here then was a key to unlock the hidden uncertainties of uterine therapeutics. Undoubtedly, almost all uterine disease (save, of course, the specific affections, such as cancer, syphilis, etc.) is begotten

of faulty pelvic vascularization, derangements of the portal, renal, splenic, and mesenteric blood vessels, which in turn engorged the uterine, ovarian, cervical and hemorrhoidal veins, or diminished the supply from a corresponding set of nutrient arterial systems.

Much, very much is to be done to uproot the faulty pathology governing the therapeutics of the diseased female pelvis, but I must omit its discussion to-day, reserving its consideration for a later lecture.

To resume, how are we to imitate the surgeon in his treatment of ulcerated leg, or swollen testicle, or dislocated hip? If the latter should come from a traumatism, reduce the luxation, and maintain the head of the bone by a properly adjusted splint until the lacerated capsule heals; but if the head of the femur be forced from the acetabulum by destruction of the rim of the cup, or in consequence of some effusion or growth in the joint cavities, most assuredly the reduction of the luxation could not be maintained by any form of splint, however ingeniously constructed.

Just so with a displaced uterus. It is an invariable rule with me to first reduce a displaced womb, one that you have always heard me insist upon, one that my assistant, Dr. Von Ramdohr, has seen me practice for six years, one that I have taught for fifteen years, to always place the patient in the knee-chest position, with the femora at right angles to the spinal column, which is at an angle of full forty-five degrees to the plane of the table, and then to lift the perineum either with the fingers or a Sims speculum until the vagina is thoroughly inflated with air. This "ballooning" of the vagina is all-important, because it is a *vis-a-tergo*, a force from behind to facilitate the rolling of the uterus into its normal plane, more particularly when the intestines roll *under* by gravitating toward the diaphragm. This being accomplished, a gentle manipulation of the uterine structure (when in retroversion) will start it downward and forward; or, failing to do it through the vaginal wall, a similar manœuvre through the dilated (ballooned) rectum will accomplish the result. In anteversion the organ drops of its own accord. I never use a repositor to replace the uterus. It is, next to Simpson's sound, the most dangerous instrument a young gynæcologist can use. In the skilled hands of those great masters of uterine surgery, Sims, Emmet, and Thomas, it is used excellently well, yet I would warn you against it, because a uterus not bound down by adhesions can be easily thrown into place by the postural method, and one that is even partly movable, but held by more or less of adhesion, will indubitably drop back as soon as the repositor is withdrawn. After the uterus is in its place we can adapt the pessary, be it Hodge's or any other modification, holding it in place until the air is expelled from the vagina. I have so often given you positive rules about the adaptation of a properly shaped and sized pessary, I mean those ordinarily recommended by the authors in gynæcology, that I shall omit their repetition. At the next lecture I hope to illustrate the practical application of the best of all pessaries, the "utero-vaginal rest" as constructed of soft clay, and at the same time say something *in extenso* about the constitutional treatment of displacements. I claim for the clay pessary uniformity of support, equable pressure in and around the vagina, a perfect antisepsis, and consequently, the most cleanly of materials to use in a woman's vagina, which is certainly very seldom as free from impurities of secretion as nature designed it.

Original Communications.

THE THERAPEUTIC VALUE OF THE IODIDE OF ETHYL.

By ROBERT M. LAWRENCE, M.D.,

BOSTON, MASS.

The iodide of ethyl, or hydriodic ether, $C_4 H_5 I$, may be prepared by careful distillation of a mixture containing ten parts of iodine, five parts of absolute alcohol, and one part of phosphorus.* It is normally colorless, but, on exposure to light, becomes a reddish brown, owing to the separation of the iodine and ethyl, the decomposition taking place slowly in diffused daylight, quickly in sunshine.† Its odor is like that of chloroform, its taste sweetish. It is soluble in alcohol, but not in water. It has no acid reaction, is non-inflammable, and boils at 158° F. (70° C.). Its specific gravity is 1.93 at 59° F. (15° C.).‡ Although discovered by Gay Lussac in 1815, it does not appear to have been proposed as a medicinal agent until 1849, when M. Duette made some experiments, with the object of determining its value as a remedy in phthisical dyspnœa.

Influenced by his favorable report, Dr. Turnbull, of Liverpool, employed it in chronic pulmonary affections. In an address§ before the British Medical Association, he remarked that iodine had often been tried in this class of diseases, but that its use had been abandoned on account of its irritating effects. In order to give it by inhalation, it was desirable to find a compound possessing the requisite volatility and absence of irritating qualities, and he considered the iodide of ethyl to be such a compound.

However, the drug was soon forgotten, and was unheard of for nearly twenty-five years, until attention was directed to it by Professor Sée,‖ of Paris, who after employing it in a number of cases attended with dyspnœa, reported that he had found it very efficient in relieving that symptom. In 1879, Dr. Thorowgood¶ made use of it in several cases of asthma, at the Victoria Park Hospital in London, with good results. The writer has carefully studied its effects, having employed it systematically during the past fifteen months.**

The drug may be *administered* as follows: Having moistened a handkerchief with eight or ten drops, the patient may be directed to inhale the vapor therefrom. As soon as he shall have acquired confidence, let the inhalations be made directly from a small vial, containing half a drachm of the drug, and applied to the nostrils. Let the inhalations be continued for ten minutes at a time, thrice daily, or oftener. Should slight nervous symptoms, due to the primary exhilarating effects of the ether, supervene, the inhalations may be discontinued for some seconds, and then resumed. By this method the system is kept constantly impregnated with iodine.

After frequent personal experiments and observation of its effects on others, the writer feels warranted in making the following statement: ethyl iodide has no depressing effect on any of the functions. It

is a mild invigorant, and its primary action resembles that of sulphuric ether, while it differs from the latter in that it has no anæsthetic properties.

A very brief time is required for its *absorption*. The iodine is taken up by the respiratory mucous membrane, and is conveyed, by the bronchial and pulmonary veins, directly to the left auricle, and thence into the arterial circulation. It has been detected in the urine in ten minutes after the inhalations. The writer has found it in urine voided at the following intervals: forty-five minutes, one, seven, eighteen, twenty-four, thirty hours.

Its *physiological action* is thus described by M. Huette:* "After some inhalations, an impression of calmness and satisfaction announces that the hydriodic ether acts at first in conformity with the other ethers employed in medicine.

"The respiratory motions are carried on with a readiness and fulness advantageous to the circulation. But the antispasmodic action of the ethereal vapor, which favors the absorption of the remedy, is soon followed by the influence of the absorbed iodine. The increase of vigor, ceasing to be limited to the thoracic muscles, extends to the whole muscular system. The appetite is developed, the secretions are increased, the pulse acquires fulness, and the vivacity of the feelings and the activity of the intellect prove that the impulse given to the other organs extends to the brain also."

Later observers have not fully corroborated all of the above statements, though they are in the main correct. The action of the drug on the animal economy in a state of health, is that of an agreeable exhilarant, and is modified by the circumstances of age, sex, and idiosyncrasy.

Professor Sée's opinion on this point is expressed as follows: "After a few inhalations, there is observed a greater facility of respiration, and this phenomenon persists for several hours. There is no anæsthetic nor soporific effect. Frequently a fit of coughing occurs at the beginning of the inhalation."

It appears, therefore—and we may be pardoned for dwelling on this important point, which can be verified by any one who will himself experiment with the drug—that ethyl iodide exerts a special influence over the respiratory function. It has, moreover, been proved that this agent, when inhaled, is capable of relieving certain forms of dyspnœa. How does it accomplish this? What is its *mode of action?*

We know that when from any cause the proportion of carbonic acid gas in the blood is increased, a centripetal influence is conveyed, chiefly by the pneumogastric nerves to the respiratory nervous centre. An undue excitation of this centre results, whereby energetic reflex influences are transmitted by motor nerves to the respiratory muscles. In a word, dyspnœa is produced in the paroxysms of *spasmodic asthma*, and in other forms of nervous dyspnœa ethyl iodide appears to act as an antispasmodic, by relaxing the muscular contraction of the bronchial tubes. Their calibre being widened, more air finds access to the pulmonary vesicles. The blood becoming once more properly oxygenated, the phenomena of dyspnœa are replaced by freer respiration. Hence the drug may also be said to act by lessening excito-motor action.

In the dyspnœa incident to *bronchitis*, and to chronic affections of the air-passages, it promotes a free mucous secretion. Since this secretion becomes, at the same time, of a more fluid consistency, air is more readily admitted to the lungs. The action of the drug is here partly expectorant, and resembles that of the alkalies.* But since in bronchitic dyspnœa, there exists usually, if not always, a reflex contraction of the bronchi, the antispasmodic quality of the drug is also of value in these cases.

If we admit that a frequent cause of dyspnœa is an acute tumefaction of the bronchial mucous membrane,† owing to a dilatation of its blood-vessels, through vaso-motor influence, we may infer that ethyl iodide gives relief by causing a contraction of the capillary vessels.‡

When a difficulty of respiration is caused by pressure on the air-tubes of enlarged and indurated bronchial glands, it is reasonable to expect benefit from the continued use of iodide, administered by this method.

When embarrassed breathing is caused by a *passive congestion* § of the bronchial mucous membrane, which, in turn, is due to an impeded circulation through the lungs or heart, in organic affections of those organs, marked benefit can hardly be expected from the drug in question. Yet in cardiac dyspnœa, good effects have been observed from its use.‖

In general, ethyl iodide appears, in some way, to favor the oxygenation of the blood, and thus stimulate, in a reflex manner, the respiratory muscles. Thus the increased buoyancy of the act of breathing, experienced in widely-different pathological conditions, as a primary result of the inhalation of this drug, may be intelligently explained.

In conclusion, if this agent has, as the writer believes, a very positive therapeutic value, and is a prompt, safe, and efficient remedy in many forms of dyspnœa, it deserves the serious attention of the profession.

May it have a thorough trial at their hands and be judged on its merits.

A few typical cases are appended, illustrating the effects of the drug.

Case I.—Katharine N., aged fifty, short, and of slender build, first came under the writer's care at the Boston Dispensary, in October, 1876. She had been a martyr to asthma and chronic bronchitis for twelve years. Frequent paroxysms of dyspnœa had greatly reduced her strength, and her sufferings were unusually severe. During the next two years trial was made of nearly every known remedy, but without much benefit. Tonics and alteratives seemed of no avail. The nitrite of amyl gave some relief, but was dreaded by the patient on account of its disagreeable physiological effects. In February, 1879, trial was made of ethyl iodide. The result was remarkable. Not only was the dyspnœa relieved, but there was no recurrence of it for several hours, and a good night's rest was obtained. Similar favorable results have followed each inhalation. At the present time, May, 1880, the attacks of dyspnœa are few and far between, and much less severe than formerly.

Case II.—James B., aged fifty-six, slender-built indoor man, contracted spasmodic asthma in the army in 1865, and has been subject to it ever since. He had attacks of dyspnœa frequently in the early morning. Had tried most of the usual remedies. In February, 1879, began inhaling ethyl iodide, and found that it gave positive relief. When used at the

‖ Professor Sée. Op. cit.

commencement of a paroxysm, it had the effect of rendering the latter abortive. A decided anæsthesia of symptoms followed its continued use.

Case III.—Thomas A., aged fifty-seven, has had nervous asthma for sixteen years. It first supervened on an attack of bronchitis. Paroxysms of dyspnœa were frequent and lasted some hours. Was obliged to sit up at night. After trial of different remedies, began inhaling ethyl iodide, February 14, 1879. Marked relief followed. After several weeks of this treatment, the paroxysms, which had steadily diminished in number, at length ceased altogether, April 16, 1880. Patient has been free from dyspnœa for a year past, though his respiration is still wheezy.

Case IV.—Mary M., aged forty-five, married, dark-complexioned, rather stout, contracted asthma in the following manner. Sixteen years ago, while engaged in frying salt pork, the patient, through some mishap, was nearly suffocated by smoke. An attack of asthma ensued, and she has since been subject to that affection. Paroxysms, on an average, three times weekly. Had tried the ordinary remedies.

April 14, 1880. Half a drachm of the drug was put into a little vial, and the patient inhaled the vapor. After three minutes, the breathing was easier, and this condition lasted for three hours.

May 4th. Has continued to practice three daily inhalations of ten minutes, and had no attack last week.

May 22d. She states that the medicine has given more relief than any previous treatment.

Case V.—Elizabeth P., married, aged forty-four years, of nervous temperament, has been subject to a difficulty in breathing for eight years past, which is much aggravated by frequent attacks of bronchitis.

May 19, 1880. After five minutes' inhalation of ethyl iodide, there was marked exhilaration of spirits and some hysterical laughter. This phase was shortly succeeded by a feeling of invigoration. This condition, with a sensation of calmness and well-being, lasted for some hours.

May 24th. The same effects have followed systematic daily inhalations.

AN INTERESTING CASE.

By HORATIO R. BIGELOW, M.D.,

WASHINGTON, D. C.

Dr. ———, late an acting assistant surgeon, U.S.N., came to me for treatment about four weeks since. As his case was a really interesting one to the neurologist, he very courteously gave me permission to publish it in detail. His service in the United States Navy has been, for many years, in iron-clads which have been stationed along the Atlantic coast from Maine to Florida. As an applicant for a position upon the retired list he was furnished with the following certificates:

"Washington, May 21, 1879.

"*To the President and Members of the Naval Medical Board:*

"Gentlemen:—I have known Dr. ———, U.S. Navy, for several years past, and during that time have observed that he was an almost constant sufferer from a severe and complicated form of neuralgia. He long ago consulted me in regard to his malady. It is of an obscure and unusual nature, and I have always classed it among the anomalous neuroses resulting from long residence in iron-clad ships, with a paralytical character impressed on it by exposure to malarial influences. Very respectfully,

"Richard C. Dean,
"*Medical Inspector, U.S.N.*"

Naval Dispensary, Washington, D.C.
May 21, 1879.

"I hereby certify that ———, acting assistant surgeon, U.S. Navy, has been under my professional care several times during the past two years for treatment. He suffered from the effects of malarious influences, manifested by neuralgia, conjunctivitis, and vascular and divers nervous phenomena.

"Philip S. Wales,
"*Medical Inspector, U.S.N.*"

Extract from sick report of U.S. iron-clad "Terror," 1874, at Key West, Florida:

"———, acting assistant surgeon, admitted to sick-list February 3, 1873, with neuralgia, superior branch, fifth pair. Discharged to duty Feb. 8, 1873. Origin, in the line of duty, from climatic influences."

The Naval Examining Board reported as follows: The Board find that he is affected with neuralgia and headache, and that he is not, at present, physically qualified to proceed with his examination. From his own statement and certificate of medical inspectors R. C. Dean and P. S. Wales, U.S. Navy, the Board is of the opinion that his disability originated from exposure to climatic influences in the line of duty in the navy.

Subsequently the Board reported that "after mature deliberation upon all the evidence in the case, we find that Acting Assistant Surgeon ———, U.S. Navy, is at present unfit for active service, but he is not incapacitated within the meaning of the law, and therefore we do not recommend that said O—— be placed on the retired list." The Board held that the disability was a temporary and not a permanent one.

History of the case.—The patient is a man forty-three years of age, six feet in height, of full habit, weighing about two hundred and fifteen pounds. The complexion is of a dark, muddy hue, becoming red, or striated with reddish streaks when suffering with an attack. The brow is furrowed, and the moustache whitened, which effects are due, he thinks, to the severity of the pain. He has an anxious, dejected caste of countenance. The neck is short and thick. The cheeks and chin heavy and flabby. He has suffered in times past from attacks of intermittent fever, and, during the past five years, a peculiar neuralgic attack has developed very regularly every Friday night, extending over Sunday. These are not preceded by a chill, neither is fever a predominant symptom. The premonitory symptoms are a peculiar congestion of the whole conjunctiva of the right eye, which commences as little streaks radiating from the inner canthus to the iris; the left eye subsequently participating. The lids are somewhat swollen and puffy. The pain, which is of an excruciating character, shoots over the supraorbital region of the right side to the helix of the ear on the same side, then down to the angle of the jaw. He was examined by Dr Baxter, of the U.S. Army, for disease of the alimentary track, but nothing abnormal was developed. Dr. Marmion found the fundus oculi normal. He has had a transient attack of aphasia, and once became unconscious while at

stool, and cannot remember being removed to his bed. He has wandering pains in the limbs, with tingling sensations at the fingers' ends and formication up and down both arms. He has been much dejected, as one that suffers from a dread of some impending danger. Is unable to engage in any connected conversation, has difficulty in expressing his ideas, uses words incorrectly, and has much hesitancy of speech. He finds it impossible to concentrate his mind upon any given subject. Suffered a year ago from loss of virility. He has muscæ volitantes, and sometimes when walking feels as if rubber heels were on his shoes. Has had several severe attacks of vertigo. At one time he apprehended angina pectoris, as he had intermittent stabbing pains around the heart. Has tried a change of climate without avail. These symptoms have been more or less prominent since 1873. He states as a peculiarity that he is prone to assume that especial type of disease which may obtain in the place wherein he may take up his residence for the time.

Present condition.—There are no anomalies of temperature of the head or trunk. The central artery of each eye is somewhat congested. The temporal arteries are not tortuous and there are no indications of atheroma. The carotids are prominent and pulsate heavily. The heart's action is somewhat weak, but the pulse tracing defines no especial characteristic of any abnormality in the arterial tension. There are neither casts nor albumen in the urine. The liver is somewhat enlarged, and the manifest tendency is, I think, to fatty heart. None of the paræsthesiæ are present, and the muscles respond perfectly to the battery. His respiration is billowy and uneven, as often occurs to one who has just eaten heartily. The lungs are normal. He has an uncertain, faltering manner of speech, and expresses himself with difficulty. The protruded tongue shows no deviation to either side. He can easily send the needle of the dynamometer around the arc. His operations are regular, the dejections being plastic. Eight days ago, a small papule made its appearance upon the nose, which was followed by an exanthem over the eyes, upon the day in which the neuralgic attack ordinarily appears; on Saturday he noticed a marked diminution in the pain.

In the treatment of his disease he has exhausted the materia medica—at one time, he followed Dr. Seguin's suggestion, and took increasing doses of cannabis indica. This, however, while it restored his virility, did not diminish his suffering. I wrote a synopsis of the case and forwarded it to Dr. Seguin, requesting his opinion, and while his response was not intended for publication, I am sure that he will not object to my quoting from it. "The attacks in the head are like migraine of vaso-motor nature, and I would advise for them, quinia, and ergotin, and arsenic regularly; an extra dose of quinia to be given just before the expected attack. Perhaps citrate of caffein may relieve the attack itself, fifteen every half-hour for two hours."

I had determined upon this line of treatment before writing to Dr. Seguin, except that I had proposed to use the monobromide of camphor, instead of the caffein, but as my patient from constitutional idiosyncrasy is unable to take quinia in any form, I was obliged to substitute for it, salicin, and, just here, I may add, that the caffein has worked admirably in arresting the severity of the neuralgic attack, three doses proving sufficient.

The conclusion that I had reached was that I had to deal with a case of general plethora, with decided cerebral hyperæmia, and that if I could succeed in conquering this condition, other symptoms would disappear as the general health became better. The periodicity of the neuralgic attacks, together with the nature of the attacks themselves, seemed to indicate a condition of malaria, so far as the regular return of the seizures is concerned, and one of vaso-motor disturbance due to nervous irritability in relation to their character. For these latter arsenious acid and salicin were given, with sufficient ergotin to reduce the cerebral blood pressure. I am unable to account for the exanthem, whose appearance was coincident with a cessation of the pain, and perhaps no less difficult is it to find a logical explanation of the aphasia and loss of consciousness, which were unattended by motor or sensory phenomena or by any subsequent bad effects. The chief difficulty now is ideo-motor—is it due to a limited, circumscribed congestion?

1502 Fourteenth Street, March 25, 1880.

INFRA-HYOID BRONCHOTOMY.

By T. H. MANLEY, M.D.,

LAWRENCE, MASS.

On the morning of the first day of April of this year, at an early hour, I was called to see a man who, the messenger said, was dying. Without inquiring what the circumstances were that led to this condition, whether they were from accident or disease, I started off with all possible haste. Reaching the man's bedside I found him vomiting with violent expulsive effort, and without the power of uttering a single audible syllable, so great was the difficulty in breathing; and what particularly struck me was, that as the retching continued between every short interval of rest, the stridor was increased. Every expiration produced a loud whistling sound, with the ring of true croup.

I was told that he drank, through mistake, about twelve ounces of lime-water. It appeared that, having some stomach derangement, he was in the habit of drinking an infusion of oatmeal and water every night, and that he would commonly rise during the night and allay his thirst with a large draught of this mixture. On the occasion under consideration, it seems that the previous evening some one placed in this pint-pitcher a lump of unslaked lime about the size of a duck's egg, without his knowledge, and after giving the vessel a few turns with his hand, to mix the supposed meal well, he swallowed nearly the whole, when he discovered his mistake; then commenced the vomiting and suffocation.

After the history of the case being hastily given me, I quickly left the room for another, to prepare an antidote to meet the alkali. Milk and sweet-oil being near at hand, in the want of anything better I prepared a cupful, equal parts of these two liquids. In a moment I returned with this to the patient, but it was of no avail; he could not swallow a drop. Finding my efforts futile in this direction, I returned to the kitchen for ice, intending to fill the mouth and envelop the neck with it, hoping by this means to control the violent congestion caused by the corrosive action of the lime.

I was scarcely five paces from the bedside, when the frightened attendant (a female) called me back, and here comes the tragic part of the accident. To my surprise and horror, I found the man on the

floor. In as it seemed, the agony of death from suffocation. Such a terrible sight I never before witnessed. There he lay, the tongue protruding through a thick foam that filled the mouth, the eyeballs bulging from their sockets, the face distorted, swollen, and discolored, the pulse gone at the wrists, the hands cold, and the expression that of a man struggling desperately for life.

I took the whole in at a glance, believing that it would be all up with him if immediate relief were not rendered. Antidotes were not to be thought of for the time, and the only thing offering any gleam of hope was the keen-edged scalpel. But where was my assistant? The only man about—the one who came for me—had disappeared. The woman, in trepidation and terror, had left the chamber, and to call a surgeon with a view of assisting me at that hour (3 A.M.) was absurd to think of. Realizing the critical situation in which I was placed, I decided to make a bold move that would at least ease the patient's suffering, if it did not save his life.

With this determination, I placed the lamp on a chair, laid the man squarely on his back, and gave him to understand that the slightest move on his part would interfere with my efforts to give relief. Then picking up a common strong scalpel, I entered the larynx with two free strokes of its blade, making an incision about two inches wide.

The change that followed was no more sudden than amazing. All consternation on the patient's part passed off. The dusky hue left the cheeks, the tongue was returned to the mouth, and the pulse again beat in the radial arteries. The features assumed an aspect of ease, and the breathing, though through an artificial opening, was not embarrassed. However, the danger was not yet over; bleeding commenced in earnest, and I knew that danger lay in prostration from excessive hemorrhage, and from quantities escaping into the air passages from the divided vessels and interfering with respiration. After all immediate danger was past, I sent for a surgeon with the experience obtained from a long period of military service in the late war of the rebellion—Dr. C. N. Chamberlain—to assist me in controlling the hemorrhage, etc. The doctor, very kindly, immediately responded to my call.

With his skilful aid the bleeding was soon completely checked. We inserted a silver tube, through which the patient breathed, packing the space between it and the edges of the wound with fine, moist sponge to prevent any oozing of blood or mucous. At 8 A.M., alarming collapse set in; however, after an injection of six ounces of whiskey it gradually passed away. No trouble was encountered after this, with hemorrhage. The great difficulty was in nourishing the patient, who did not retain injections well. After the operation for the supply of air, we had to keep in mind the inflamed state of the œsophagus and stomach. Accordingly, after subduing the facial or throat congestion by the liberal use of ice, we closed the opening in the metallic tube and caused the patient to swallow a large quantity of milk and castor oil.

Four hours after the operation by closing the tube, sufficient air passed through the mouth to the lungs to supply the man's wants, showing conclusively that the inflammation and tumefaction of the glottis and surrounding parts had subsided, and that the tube was no longer needed, and the surgeon had only to sustain the strength and heal the opening.

The points which I regarded in this case as of sufficient interest and importance to be placed before the profession are: first the situation; secondly the direction of the incision; and lastly, the harmless effects in the intestines of the large quantity of lime drunk.

Remembering the urgency of the case, that there was no assistant of any description at hand, it became necessary that the opening should be made where it could be done with the most celerity, and where there was not the least liability to dangerous bleeding. The man being of a short build, with a thick, fat neck, it would be useless, without any assistance nor tracheotomy-tube, to open the windpipe low down. Again, in this section the carotids pass dangerously near the trachea on their way to the cranium, so that to hazard an incision in this locality in a dimly-lighted room, and alone, would be hardly justifiable.

The man being forty-five years old, to open his well-ossified larynx with an ordinary scalpel was impossible. Accordingly, acting on the judgment acquired while interne in the Park Hospital, New York, in the treatment of wounds of the neck, inflicted with suicidal intention, I quickly made a *transverse incision between the hyoid bone and the thyroid cartilage of the larynx*. This brought me down below the obstruction in the pharynx, and, by the contraction of the divided muscular fibres, secured a permanent opening without the necessity of using retractors; besides, it allowed of the opening with the least hemorrhage. There was little, except from the small transverse branches of the superior thyroid artery. No tissues to divide except the skin, fat, one ribbon-like muscle, the platysma, and the fibrous membrane that connects anteriorly the hyoid bone with the thyroid cartilage of the larynx. The margin of the muscles, passing nearly vertically close to the median line, were necessarily wounded.

After the introduction of the tube, all bleeding ceased, but it having to be passed down between the vocal cords caused great pain, so, though contrary to the suggestion of my consultant, I removed it as soon as it appeared possible to me to dispense with it with safety. This early removal likewise contributed to accelerate the healing of the wound. While in, it was continually filling with mucus and impeding respiration, so much as to require one to stand by all the time and keep it swabbed out.

On account of the opening being so high up, during the act of deglutition it became necessary to press the edges of the wound together, else the liquids would leak through. I am not able to explain the exact phenomenon of this occurrence, but I suppose it was due to a derangement of the suction apparatus of the pharynx. I have seen the same thing occur where the wounds were self-inflicted.

After the first week, when the wound began to close, this disagreeable leakage ceased. After five weeks' treatment the wound was completely healed (no antiseptics used or disinfectants, except pure water, pure air, and clean linen), and there is nothing to be seen on the neck to indicate a previous mutilation of tissues, except a small scar about the circumference of a pea. He says he can breathe and swallow as easily as ever, and from appearances, certainly, there is nothing to indicate that he is telling an untruth.

In the evening following the accident, he passed by the rectum large quantities of lime in small lumps. Why this should have excited such violent inflammation at the primary orifice of the alimentary canal and none at its middle and lower parts, I cannot understand, unless that it spent its strength at the ont-

set on the first mucous membrane it came in contact with. Had this case terminated fatally, I have reason to believe that I should have had to submit to a judicial investigation—in other words, would have been sued for malpractice. A neighboring practitioner, either through unpardonable indiscretion, or a desire to advertise his name, criticised me in the presence of several spectators, who had assembled by the time he arrived, for making a "transverse incision," stating, in a tone of censure, that it should have been vertical. It is hardly necessary to state that this remark gave fresh alarm to the already terrified friends and relatives.

As soon as I reached home, after leaving the patient, I examined my text-books and could find no description of an operation for bronchotomy done in this region.

I was about to give up the search, in despair, for an author to support my course, when I found a paragraph in "Malgaigne's Surgery" wherein the author "proposes" the operation of "infrahyoid bronchotomy" in cases of grave diseases or foreign bodies in the larynx.

In describing the different stages of the operation, he says: "It has not yet been performed on the living subject."

Though I found little or nothing published to justify my course, still I was and am now convinced that the circumstances were such as allowed of no other means of immediate relief.

Why, I thought to myself, will not my patient recover, when in many suicidal cases I have seen the trachea and œsophagus completely severed, and the patients survive?

Here it will be observed, that, without any previous acquaintance with the particular operation, I did it successfully, acting on the dictates of common sense, without which, time proves that books and blades are of little use.

I am positive, in this case, nothing could have been done that offered my patient so good a chance of life, and me so ready a method of entering the air-passages.

I offer this article for publication, with the hope of getting some light on its literature, and to inform the profession of a method of opening the larynx seldom heretofore performed by surgeons.

I hope also that it will serve as a reminder to some practitioners to beware how they trifle with their neighbor, in needlessly and publicly criticising his practice.

A Case of Double Colon is related by Dr. John M. Alexander, of Clifty, Ind., in the *Cincinnati Lancet and Gazette*. It occurred in a boy who at the time of death was eight years old. He had a very protuberant abdomen, and had always suffered either from diarrhœa or constipation. Sometimes he had no passage for thirty or forty days. At these times he had fever and great tympanitis. The post-mortem showed the colon taking its usual course until it reached the left iliac fossa. It then doubled upon itself and retraced its course, finally descending along the ascending colon and connecting itself with the rectum. Its size was enormous, being eight inches in diameter at the lower part, where it was distended with nearly three gallons of fæces. The total length of the colon was six feet. Tubercles were found in the lungs, but the other organs were healthy.

Reports of Hospitals.

ST. FRANCIS' HOSPITAL, N. Y.

Reports of Practice and Peculiarities of Treatment.

Service of Dr. GEORGE F. SHRADY.

THE TREATMENT OF BURNS.

A number of cases of more or less severe burns have been treated, very successfully, by an application of a gum dressing, which consists of a paste composed of gum acacia, ℥ iij.; gum tragacanth, ℥ i.; carbolized water (1-60), 1 pint; and molasses, ℥ ij. It is applied to the burned surface with a broad flat camel's-hair brush immediately on admission to the hospital, and dries in the course of an hour or two. The dressing is then renewed at suitable intervals, until a firm and unyielding scab is formed. Generally four applications are sufficient for this purpose. The molasses appears to prevent the contraction of the covering, while the carbolized water destroys any odor. The application is not attended with any pain to the patient, and effectually excludes all air to the burned surface, thus avoiding subsequent smarting. The scab cracks and peels off in the course of a fortnight, either leaving a mere rubefaction or a healthy granulating surface. If pus accumulates in the meantime under the scab, the latter is either punctured or gently lifted, giving exit to the discharge. No other dressing is required. Although forming a rather unsightly scab, the dressing is really a cleanly one. This plan of treatment is substantially the same as that advocated by the late Dr. Gurdon Buck, and, all other things being equal, is considered to give the best results. Its special advantages are its ease of application, the small amount of subsequent dressing required, and the freedom from pain. The granulating surfaces are treated with either simple cerate or the white oxide of zinc ointment, according to indications.

TREATMENT OF FRACTURED PATELLA BY THE WEIGHT AND PULLEY.

Two cases of fractured patella were admitted about the same time. Both were male adults. In each case the fracture was transverse, was occasioned by muscular violence, and the amount of separation was respectively two inches and an inch and a quarter. Both cases were dressed after the following plan. The lower extremity was placed on a single inclined plane and extension made by the weight and pulley upon the quadriceps extensor muscle. A broad strip of adhesive plaster was applied to either side of the thigh in such a manner that the lower ends of the plaster crossed each other just above the patella, and terminated in loops at either side of the knee. To these loops parallel cords were attached, and were joined to a stirrup beyond the foot; to the whole a weight of fifteen to twenty pounds was suspended in a line with the inclined plane, and over the foot of the bed.

In order to obtain a well-distributed bearing along the upper margin of the patella, the triangular space left by the crossing of the strips is covered by a brace of plaster. By such means extension is made not only upon the quadriceps muscle throughout its whole extent, but directly upon the upper fragment

of the patella, whose superior border is completely surrounded. The lower fragment is merely steadied by a pad below its lower border, and secured diagonally, upward and backward, to the splint.

In some cases Dr. Shrady advises that a suitable graduated pad be applied to the upper margin of the upper fragment before applying the cross-piece of plaster. By this means an extra purchase is obtained.

In the two cases mentioned, the fragments were gradually brought into perfect apposition and easily maintained there. Passive motion was cautiously commenced at the end of the third week. Although the fragments remained in contact after the patients were walking about the ward, it was fair to presume that the union, firm as it was, was not osseous.

INFLAMED CONGENITAL HYDROCELE OF CORD RESEMBLING INFLAMED IRREDUCIBLE HERNIA.

A German boy, aged ten years, from Kingston, N. Y., was admitted to the hospital with the statement that he had a "rupture which would not go back," and that "there was a bad swelling there, and great pain;" furthermore, that this condition had existed for more than a week, and that the patient was able to be only in one position—upon his back. On examination, a tense, painful, angry-looking, inflammatory tumor was discovered occupying the inguinal canal, and extending into the cavity of the scrotum. The general appearances of the swelling were precisely those of an inflamed strangulated hernia. On a careful examination into the history of the case, it was ascertained that the patient had not suffered from any symptoms of strangulation at any time; that there had always been more or less of a swelling on that side of the scrotum, and that his last trouble came on after an injury to the part. The tumor was dull on percussion, and contained fluid. On the introduction of a hypodermic needle, this fluid was found to be pus. All further manipulation of the tumor, for obvious reasons, was carefully avoided, and the patient was etherized without delay. The diagnosis lay between an inflamed congenital hydrocele of the cord and an inflamed incarcerated congenital hernia. The former was considered more probable, but, in view of the possibility of the existence of the latter, the operation was performed, with the assistance of Dr. Ripley, as for strangulated hernia. As soon, however, as the sac was opened, it was found to contain nothing but pus. The sac was continuous with the testicle below, and extended along the cord to the internal ring, proving the previous existence of a congenital hydrocele of the cord. After emptying the sac and injecting it with carbolized water (1 to 60), a free depending outlet was provided by a counter-opening in the lower part of the scrotum, through which a drainage-tube was introduced. The wound was then left open, dressed with carbolized lotion, and allowed to heal by granulation. The patient made a good recovery.

EPITHELIOMA OF LOWER LIP—CHEILOPLASTY.

A man aged fifty six was admitted with an epithelioma of the lower lip, commencing at the right commissure, involving three-quarters of the vermilion border and two-thirds of the substance of the lip, tapering to a point upon the tip of the chin. The disease was removed by a V-shaped incision, and the gap supplied by splitting the right cheek to the anterior edge of the masseter muscle, and the left cheek for half that distance, dissecting the flaps and sliding their upper corners into contact. Dr. Shrady thought at first it would be necessary to make a curved pedunculated flap, but the parts came readily into position without it. The wanting vermilion border to the new lip was supplied by stitching the mucous membrane to the edge of the flaps. It was found on bringing the lip into place that there was an undue wrinkling redundancy of the upper segment of the cheeks, especially the right. In order to correct this, the upper lip was enlarged somewhat by extending its vermilion border. The edges of the lower lip were carefully brought together at the junction of the vermilion border by hare-lip pins, as were also the corners of the new mouth. The remaining portions were stitched with fine silken sutures. The alternate sutures were removed on the third day, the pins on the fourth day, and the remaining sutures on the eighth day. The parts were firmly united throughout their entire extent, except a small portion of the right angle of the mouth, which healed by granulation.

Progress of Medical Science.

RESULTS OF SURGICAL TREATMENT WITHOUT ANTISEPTICS IN THE KILMARNOCK INFIRMARY.—Coming so soon after the delivery of the address on surgery by Mr. Savory before the British Medical Association, in which he claimed that equally good results may be obtained in surgery without a strict adherence to the principles laid down by Lister, the statistics collected by Dr. McVail from the practice of Dr. Borland at the Kilmarnock Infirmary are worthy of careful consideration. It may be of interest to state that the Kilmarnock Infirmary contains one hundred and twenty beds, and consists of three stories. On the ground floor are the surgical wards, on the middle the medical cases are treated, and on the top floor the fever patients are placed. There are 800 cubic feet to each bed, and from six to ten of the latter in each surgical ward. Of the 513 cases analyzed, thirteen died, seven within thirteen hours after admission, and on this account they are excluded, leaving only six, which is a percentage of 1.1 on the whole. In 107 operations performed there were three deaths, or 2.8 per cent. In comparing this with Mr. Lister's statistics, extending over a period of five years and nine months, the mortality amongst the patients of the latter is found to be 4.4 per cent. In 61 cases in which amputation for disease was performed by Mr. Lister there were 3 deaths, or 4.8 per cent. In Dr. Borland's practice, 1 death in 26 cases, or 3.8 per cent. Mr. Lister had 72 cases of injury with 4 deaths, or 5.7 per cent. In 50 similar cases Dr. Borland had 1 death, or 2 per cent. Mr. Lister reports 6 deaths from hospital diseases in 917 cases, or .65 per cent. Dr. Borland, 1 death in 161 cases from the same causes, or, if 61 cases of abscesses treated were added, the mortality would be reduced to .45 per cent. In conclusion, Dr. McVail properly says that, in order to sustain the views of believers in antiseptic surgery, it will be necessary to show better results than those reported by Mr. Lister.—*Brit. Med. Jour.*, March 20, 1880.

COMPLETE GENERAL ALOPECIA DUE TO A FRIGHT.—A young girl, 17 years of age, of robust constitution, had very thick blond hair, which measured over three feet in length. On March 30, 1875, she received a violent fright from the fall of a flooring, under which

she barely escaped being crushed. That night she complained of pain in the head, with a sensation of general chilliness. On the following day she was unusually restless, and complained of pruritus of the head. On April 1st she was much better, but the itching of the head persisted, and she noticed that her hair came out very freely in the process of combing. On the 2d her hair fell out *en masse;* she dragged out at one time an entire tuft from the vertex, leaving bare a circular spot as large as the palm of the hand. In three days there was not a single hair left on her head, and two days later all other regions of the body were also completely despoiled of hair. The general health, meanwhile, was perfectly satisfactory. One month afterward she consulted Dr. Fredet, and was placed on general and local treatment, consisting of chalybeates, bitters, strychnine, sulphur-baths, lotions, and stimulating applications of all kinds. Nothing, however, proved of the slightest benefit. Two years later the alopecia was still absolutely general.—*Gazette obstétricale.*

An Improved Surgical Needle.—Prof. von Bruns, of Tübingen, has altered his surgical needle so as to do away with the two objections to his old model, viz.: the tendency to catch in the skin while withdrawing it, and the difficulty of cleansing the tube. The needle, as now manufactured, consists of a thin-walled steel tube, 1½ mm. thick and 7 ctms. long, which terminates at one end in a solid, lance-shaped point; the other end is imbedded in a wooden handle. A thin steel wire runs through the tube, ending, toward the point of the needle, in a small hook, and attached at the other end to a button which works in a slit in the handle. When the needle is passed through the flesh, the button is pressed forward, and the hook end of the wire projects through a small opening just below the lance-shaped head of the needle. The thread to be used is then passed over the hook and drawn with it back into the tube, and the needle is then drawn out, carrying the thread with it. The tube can be readily cleansed by drawing through it, by means of the same hook, a thread of thick, soft worsted, which can be moistened with any desired lubricant.—*Centralblatt für Chirurgie,* February 7, 1880.

Polypoid Excrescences of the Female Urethra.—Dr. Terrillon, of Paris, asserts that there are two distinct varieties of polypoid excrescences of the urethral orifice in women. One variety is idiopathic, and due to some slight irritation. The prognosis of this variety, which is the more common of the two, is good. Simple removal of the growths produces a rapid cure. The other variety, on the contrary, although it possesses the same external characters as the preceding, accompanies or precedes tubercular urethritis or cystitis, of which it constitutes an important symptom. The prognosis is grave, on account of the general affection. The growths in this case may be of service in establishing the diagnosis of tuberculosis of the urinary organs, which is often a question of great difficulty in women. Treatment is almost useless, as it, at most, gives only momentary relief.—*Le Progrès médical,* February 21, 1880.

On the Use of the Saponinated Coal-Tar of Le Bœuf in Uterine Therapeutics.—This preparation has been employed in France for many years in the treatment of various uterine affections. It is a preparation of coal-tar emulsified by saponine, the active principle of saponaria officinalis and of quillaya saponaria. It is considered by many to be superior to carbolic acid, because it is equally effective as a disinfectant, and at the same time does not act as a caustic even in its pure state. It is employed as an injection, diluted with water in the proportion of two or more teaspoonfuls to the half-pint, and is also applied in a state of purity by means of cotton tampons, which are soaked in it and left in the vagina or in contact with the cervix uteri for twenty-four hours. As an injection it is useful in leucorrhœa, whether of adults or of young girls; it is particularly serviceable in slight cases where it is either unnecessary or undesirable to use the speculum, and in cases of cancer, where the introduction of that instrument causes pain. It is also recommended for the so-called hygienic vaginal injections, because it possesses the disinfectant properties without the unpleasant smell of carbolic acid. In vaginitis, chronic cervical metritis, cancer of the cervix, etc., it is applied on the cotton tampon in a concentrated form. In a word, it is recommended in all cases of vaginal or uterine disease where an energetic detersive or a powerful disinfectant and antiseptic is called for.—*Le Progrès médical,* February 21, 1880.

Chicken-Cholera.—M. Pasteur recently reported to the *Académie de Médecine* the results of his investigations on the nature of the virus of chicken-cholera. He regards this virus as a microscopic parasite. When one of these parasites was placed under appropriate conditions for culture, as, for instance, in a chicken soup neutralized by potash and rendered sterile by a temperature of over 100° C., the fluid rapidly became cloudy, and in a few hours it was found to contain millions of minute organisms. When guinea-pigs were inoculated with this fluid, it merely produced simple abscesses, which opened spontaneously, and healed up without affecting in any way the general health of the animals. The pus from these abscesses, however, swarmed with the above minute organisms, and when inoculated on chickens, killed them rapidly. The virulence of the fluid obtained by successive culture-processes was so great, that the inoculation of even a small fraction of a drop was invariably followed by the death of the chicken in two or three days. This virulence could be diminished by retarding the development of the organisms, and the inoculation of this less virulent fluid in a diluted form caused symptoms of sickness, but the disease did not prove fatal. M. Pasteur also found that an attack of this milder form of the disease gave immunity from further attacks, subsequent inoculations even with the most infectious fluids producing only simple local lesions, without the slightest general symptoms.—*Le Courrier médical,* February 14, 1880.

Cirrhotic Contraction of the Stomach and Atrophy of the Gastric Glands, with the Clinical Symptoms of Pernicious Anæmia.—In a case that presented a well-marked clinical picture of progressive pernicious anæmia, Prof. Nothnagel, of Jena, assumed as the cause of the disease an atrophy of the gastric glands and mucous membrane. Besides the usual symptoms of pernicious anæmia—marked paleness, retinal hemorrhages, etc.—the chief gastric symptom was a feeling of fulness after the ingestion of a few mouthfuls of food. The autopsy revealed hemorrhages in various organs, and an enormous thickening of the walls of the stomach, which was at the same time so much reduced in size that its cavity would be filled by a large pear. The mucous membrane was replaced by a wavy fibrillar connec-

tive tissue, which was poorly supplied with blood-vessels, no glands could be found. The submucous connective tissue and the muscular coat were greatly thickened. With reference to the symptoms caused by the gastric process, and to the question of diagnosis, it must be borne in mind that there are said to be three varieties of the process: in one there is atrophy of the peptic glands without thickening of the walls of the stomach, and without reduction of its lumen; in the second, there are marked cirrhosis and reduction of size, without any noteworthy atrophy of the glands; in the third, both the above conditions are combined. A priori it may be assumed, that the first of these conditions must be accompanied by the symptoms of an impairment or cessation of stomach digestion, while the second would give rise to physical or mechanical symptoms; in the third, both classes of symptoms will be combined. In point of fact, however, the symptomatology of these individual varieties is not sharply defined, and practically the symptoms may be regarded as the results of the pernicious anæmia, as they can rarely be referred to a primary alteration of the stomach.—*Med.-chir. Rundschau*, February, 1880.

A Peculiar Case of Progressive Pernicious Anæmia.—Dr. Pfannkuch, of Cassel, reports this case. The patient, a girl, nineteen years of age, had been delicate as a child, and had suffered from chlorosis about the period of puberty, but had subsequently grown stout and strong. She complained for a few days of slight weakness and digestive disturbances, for which the doctor, on September 4th, ordered strict diet and the use of Carlsbad water. The treatment was at first perfectly successful, but on September 22d he was called again to see her, and found her pale, with a cool skin and a small, quick pulse. On the preceding day, after eating some apple-sauce, she had been seized with a diarrhœa, which was so violent that she fainted after the fifth passage. No blood was passed per anum. The paleness of the skin and mucous membranes rapidly increased, the skin assuming a waxy hue, and the mucous membrane of the mouth becoming as livid as that of a corpse. The face seemed somewhat bloated, but actual œdema was not observed on any part of the body, and the panniculus adiposus was preserved intact to the last. Any attempt to sit up in bed caused syncope. For some days at the end of the first week, the patient was restless, with much jactitation, nervous twitchings of the limbs, and loud groaning. She then became more and more apathetic, and complained only of headache, palpitation, and general weakness. The area of cardiac dulness was not increased; when the hand was laid over the heart, a strong whirring sensation was communicated to it. There was a loud systolic murmur. The carotids pulsated strongly, and a distinct venous hum was heard over the jugulars. The pulse was at first 100, and increased to 136, but fell in the agony to 90. The respiration was 20, but became more rapid toward the last. The lungs presented nothing abnormal. Bowels constipated from the time the patient took to her bed. Urine contained no albumen. Liver, spleen, and lymphatic glands presented nothing abnormal. The initial coolness of the skin gave place later to increased warmth, but there was little actual fever, the highest evening temperature being 100°. No hemorrhages occurred, and the blood consequently was not examined. Death took place on the fourteenth day. An autopsy was not permitted.

In this case the possibility of a hemorrhage into any of the cavities of the body could be excluded, and hence it was necessary to assume the existence of a hemoptysis, . . . of a rapid destruction of the red blood-corpuscles. The rapid course of the case, and the preservation of the panniculus adiposus, argued against the existence of any cachexia. A vitium cordis could be positively excluded. The symptoms were not those of an ulcus simplex, and, moreover, this would not explain the pernicious anæmia. The patient lived under favorable conditions, and the mother ascribed her illness to a disappointment in love.—*Medicin. Rundschau*, February, 1880.

Comparative Value of the various Antiseptic Dressings.—In the article on antiseptics in the new edition of his Handbook of Surgery, Prof. Bardeleben states that in point of efficiency the carbolic acid dressing takes the first place. The thymol dressing, however, is only second to it on account of the greater difficulty met with in the preparation of strong solutions. Both substances are very volatile; hence preparations made up with gum or fat become inert in course of time, and care should be taken to use only freshly prepared materials, or such as have been kept hermetically sealed. Moist thymol or carbolic acid dressings have the advantage of being readily improvised, but on account of their volatility they require to be moistened from time to time. When jute is used for the dressings, it is not necessary to moisten it oftener than once in twelve hours. Salicylic acid is inferior to carbolic acid and thymol, both because of its slight solubility and because it has less antiseptic power. It is not at all volatile, and hence the materials impregnated with it retain their antiseptic powers indefinitely, provided the small crystals are not mechanically shaken out of the dressings, which is especially apt to occur when jute is used. The acid has this advantage over thymol and carbolic acid, that it is much less irritating to the skin and the wound. Lister's dressing is especially irritating to the skin of the patient, on account of the large amount of paraffine it contains in addition to the carbolic acid, a fact that gives weight to Brun's suggestion to substitute a mild fat for the paraffine. Lister's dressing not only causes redness and pain, but it has even been known to produce pustular eruptions and superficial gangrene of the skin, particularly when the bandages have been drawn too tight. It is not correct to say that carbolic acid acts as an irritant to the skin; it really exerts a paralyzing action, especially on the small vessels. Hence the free hemorrhage from all fresh wounds, when they are douched or sprayed with carbolic acid. In strong solutions (over 3 : 100), moreover, it acts as a caustic. Whether the burning pain experienced when even a weak solution of the acid is left long in contact with the skin, be due to a direct injurious action on the nerves, or to the dilatation of the small vessels and the consecutive blood-stasis, is still an open question. Thymol, even in as dilute a solution as 1 : 1000, also causes severe burning pain in the skin, but it does not paralyze the vessels. With carbolic acid the painful burning gradually passes into anæsthesia, but not so with thymol. Benzoic acid dressings have not often been employed in severe injuries, but they answer well for slighter cases, and for the later stages of severe ones. Under similar circumstances, boracic acid dressings will also be serviceable; these can be kept on hand without difficulty for years, as boracic acid is not volatile. Chloride of zinc preparations should not be brought in direct contact with the

wounded surfaces, as they exert a caustic action. For the same reason, the surgeon must see that discharges that have come in contact with the dressings do not flow back into the wound, or collect about it. When this caution is attended to, a perfect antiseptic dressing can be prepared with the chloride of zinc and jute-cakes. In like manner, jute-cakes, impregnated with the salts of clay, can be used.

In considering the question of the danger arising from the absorption of antiseptic substances, carbolic acid is the only one of which it is necessary to speak, as it is the only one that can be absorbed from the dressings in sufficient quantity to cause serious disturbances of the general health. Carbolic acid is in fact a poison. That it is very often absorbed from the dressings, whether they be moist or dry, is evident from the characteristic and easily recognizable changes in the urine. This is of an olive-green color, becoming dark brown and at last black, after standing a long time in the light; the sulphates are converted into sulpho-carbolates. In spite of these remarkable changes, however, the general condition of the patient is usually unaffected, unless some other injurious agency be at work. Still, in some cases, without any other apparent cause, the appetite fails, and the patients feel weak and inert, and suffer from nausea and occasional vomiting. The intensity of these derangements does not by any means correspond with the intensity of the discoloration of the urine. The patients may feel perfectly well when the urine is exceedingly dark. Hence, although it cannot be said to be necessary to abandon the use of carbolic acid as soon as discoloration of the urine appears, it is advisable to do so, and to have recourse to other antiseptics whenever the discoloration is accompanied by symptoms of general derangement.—*Med.-chir. Rundschau*, February, 1880.

Summary of the Results of Fifteen Cases of Battey's Operation.—In a paper read before the British Medical Association last year (1879), Dr. Battey gives the results obtained in fifteen cases operated upon by him. In eight instances, in which extirpation was performed, there was ovaralgia, in three hystero-epilepsy; and one of each of the following diseases: amenorrhœa, with hystero-epilepsy; threatened insanity; occlusion of the vagina and uterus; and violent menstro-mania. All recovered except two, and in these both ovaries were removed. Of the remainder, seven had both of the organs extirpated, and in all the result was favorable, there being an alleviation of the previous symptoms, and a marked improvement in the health. Of the other six cases, there were three from whom one ovary was removed with benefit to the patient; those in whom there was incomplete extirpation of both organs, the number being three, the results were not good. In twelve of the fifteen cases, the écraseur was employed, in two the ligature, and the finger-nail was made use of in the remaining. There are two methods of operating recommended: either by means of a short incision through the linea alba, or by a shorter opening through the median line of the posterior vaginal cul-de-sac. Dr. Battey prefers the former mode of operating, as he has met with better success by doing so. When both ovaries have been removed, menstruation has entirely ceased; if there is but an incomplete removal of both, or if one organ only has been extirpated, there has been no change in menstruation.—*British Med. Jour.*, April 3, 1880.

Iodic Purpura.—It is a well-known fact that the alkaline iodides produce different forms of skin eruptions, the more common being the papular, which resembles acne, and the bullous or pemphigoid variety. Among the other forms are the eczematous, erythematous, and purpuric. Iodic purpura is comparatively rare, and is supposed by some to be due to the action of the free iodine on the already diseased blood-vessels, by which a diapedesis of the red corpuscles takes place, resulting in the formation of the peculiar staining seen in the disease. Dr. Duffey, of Dublin, in a paper communicated to the Medical Society of the College of Physicians, cites an example of this affection. The patient, aged twenty-five, and a wine-porter by occupation, had rheumatic fever a year previous to his admission to hospital. He never had syphilis, and was moderately temperate in his habits. On admission a mitral regurgitant murmur was discovered, and his knees and ankles were slightly swollen. He also presented an anæmic appearance. On October 6th, ten grains of iodide of potassium, in solution, was ordered to be given three times a day, and on October 29th, this was increased to fifteen grains thrice daily, tartrate of iron being added because of the anæmia. In a month after admission (November 6th), when he had taken about two ounces and a quarter of the iodide, he complained itching of the legs, and also a feeling of warmth in them. On examination the next day, the itching in the meantime having ceased, a distinctly marked small purpuric eruption was to be seen on the dorsal aspect of the feet and the lower four-fifths of the anterior and lateral surfaces of both legs. The spots did not disappear on pressure, nor were they elevated above the healthy tissues, being of a dark blood-red color, round, and of various sizes, from the head of a pin to that of a split pea. No eruption existed elsewhere on the body, except some few acne spots, probably also due to the drug, and which were to be seen over the shoulders. No other symptoms of iodism were present, such as coryza, languor, or weakness, nor was there albumen in the urine. The spots disappeared when he ceased taking the iodide, and no vestige of them could be seen eleven days afterward. November 19th, he was again given iodide of potassium, in fifteen-grain doses, and the next day, after having taken forty-five grains, the eruption reappeared. This time there was no itching, the petechia were not so numerous, were confluent, and were of a lighter hue than those of the previous attack. The spots again disappeared when the medicine was stopped. He was now given chlorate of potassa in fifteen-grain doses three times a day for two days. Iodide of sodium in ten-grain doses three times a day was now ordered, and after having taken about half an ounce it was discontinued, as he complained of severe rheumatic pains. Iodide of ammonium was now prescribed in ten-grain doses, to be given three times a day. The eruption again manifested itself, after having taken twenty grains of the drug; this time the spots were mostly confined to the right leg, and there was no itching. The eruption again disappeared on stopping the medicine.—*The Dublin Jour. of Med. Science*, April, 1880.

Assistant-Surgeons in the Army.—The following gentlemen having passed the examinations, have been appointed assistant-surgeons in the army: Rudolph G. Egbert, of Oregon; Robert J. Gibson, of Connecticut; Robert B. Denham, of Pennsylvania; W. C. Gorgas, of Alabama; Norton Strong, of Michigan; Arthur W. Taylor, of New York.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, June 19, 1880.

THE UNWRITTEN CODE OF GREAT BRITAIN.

GENERALLY when our English friends take us to task for wrongs which we have committed, or mistakes which we have made, they have so much the better of the argument from the high moral grounds they assume, that we have nothing to say in extenuation. The shortcomings of Americans so often point a useful moral for English critics, that we look upon it as a matter of course, and strive to profit by it accordingly; occasionally, however, we see sufficient light from under our sackcloth to look beyond the mere prejudice which we should naturally hold against ourselves, and to wonder whether there is not sometimes an exception to the general rule of our wrong doing. If we see dimly at first, it may be because our eyes are unfitted for the stronger lights to which our more favored brethren are accustomed. We venture this much by way of preliminary, in order to excuse ourselves for apparent presumption in calling attention to some inconsistencies in a leader on medical ethics in a late number of the *Medical Press and Circular* of London. Our learned contemporary, in his interesting, instructive, and suggestive article, commences with the statement that in Great Britain "there is an unwritten code which regulates the conduct of medical men in this country toward members of their own profession, toward patients, and toward the public," and, further on, "that the strong feeling of *esprit de corps*, the maintenance of professional dignity, and the strict adherence to definite lines of duty that characterize our class throughout the kingdom, have rendered any step to formulate rules of conduct purposeless." In other words, as the members of the profession were above the possibility of committing even the smaller crimes no laws for punishment were needed.

This idea so far accords with our own regarding what relations should exist between professional brethren, that we were ready not only to endorse the doctrine promulged, but to congratulate our English brethren upon the fact that they were so constituted morally as to need none but the golden rule for their government. It is certainly comforting to believe that when physicians are struggling for the top of the ladder, where there is always so much room for the younger men, that such strugglers are always actuated by a truly generous rivalry for distinction. This is as it should be, but except for the occasional show of the skeleton we might suppose that English medical men had no dark closet.

By an unfortunate coincidence in the same number in which the editor upholds the British profession as our model, there are two articles which bear in quite an opposite direction. In the first of these, our distinguished contemporary takes occasion to speak against the general bad effects of medical discussions in lay newspapers, and to deplore the fact that the London *Times* has not a responsible medical editor to whom questionable medical topics can be submitted. The particular subject under discussion was the "Insensibility to Anæsthetics," evidently presented by a sensational medical writer to detail some rather extraordinary personal experiences. The admission of the letter was a sequel for a flood of correspondence, which culminated as usual in a good deal of free advertising. In speaking of the disposition to bring medical matters before the public, the editor of the *Press* very justly, but somewhat inconsistently, says "The opportunity is, of course, eagerly seized upon by numerous surgeons practising dentistry to air their views [and to publish their names and addresses] in the *Times*, while pointing out that such failures as the patient relates never by any chance occur in their hands, etc." But then surgeons practising dentistry may not belong to what may be strictly called the regular profession, and may not, therefore, be considered proper exponents of the ethical doctrines so ably preached by our transatlantic friend.

Bearing, however, as an exception on the general rule of the uselessness of a code, and directly applicable to those in the higher walks of professional life, we refer to another item in the same journal. Under the heading of "Professional Touting," a circular is published "believed to have been extensively circulated among non-medical persons" in which the most shameless advertising is manifest. The way in which it is done is so peculiarly clever, so apparently innocent, so judiciously convincing, and proves so strongly that the better part of the profession of Great Britain are above the requirements of any code, that we give the circular in full:

"*Private and Confidential.*"

"DEAR SIR:—I take the liberty of informing you and my professional brethren in Ulster, who frequently send me country patients, that, after mature con-

sideration, I have decided to confine my practice for the future to skin diseases, in their various forms, and chest affections; and I have little choice in the matter, as the public consulted me only on cutaneous or lung complaints; moreover, by not taking any family practice there will be no risk, even if I should be so inclined, of gaining the connection.

"For fifteen years I have been attached to the Hospital for Skin Diseases, containing twenty beds and suite of baths, and was selected by Mr. Erasmus Wilson to carry on his *Journal of Cutaneous Medicine*, the fourth volume of which I edited before its final discontinuance. As for chest diseases, during the last ten years I have met with a large number in the Royal Hospital, and, as I generally lectured and gave clinical instruction chiefly on lung and heart cases, I suppose this circumstance must account for my present position in relation to these affections. Recently I have been appointed Consulting Physician to the Institution for Chest Diseases, Donegall Pass.

"I remain, dear sir, yours sincerely,

"* * * *"

But, stranger than all, our esteemed contemporary, in commenting upon the propriety of the proceeding, is free to say "that the issue of such a circular is a gross breach of professional propriety, and altogether discreditable to the gentleman whose name is appended to it."

The nearest that American practitioners come to this sort of advertising is the occasional publication in the daily prints of medical certificates for mineral waters and lager beer; the periodical mention of college advertisements, the unpreventable accounts of a remarkable operation, and the like. Still we would not undertake to say that there is not some reason for drawing a codal line by which to govern that exuberance of generous rivalry which, even in professional matters, here is an evidence of our progressive nature. Certain it is, if our code prevents the appearance of such circulars as we have quoted, our English cousin has the wrong side of the argument when he attempts to prove that his arm of the service is beyond the reach of petty regulations.

But these are not the only grievances in the body medical which require some equitable adjustment. The readers of the different medical journals of Great Britain have become familiar with all phases of unprofessional conduct. In fact, the heading of "medical etiquette" under which breaches of professional trust are discussed is almost a standard one, and would lead the innocent New Zealander or the wild American to suppose that the refined and cultivated English medical gentleman was quite a quarrelsome and tricky individual. A junior practitioner complains of the wiles of a senior consultant, which reminds us of some of the experiences of the practitioner of Pine Ridge; a country practitioner asks if it is proper that a consultant should continue attendance upon a patient sent to him merely for advice; another medical man feels justly aggrieved because a professional rival calls him an ignoramus in the presence of a patient. And yet there seems to be no need of any code or standard of morals by which the sheep can be separated from the goats. It is a great reflection upon the medical profession that any but gentlemen should be admitted to its ranks, but as far as we can see, exceptions to what we would wish to be the rule are quite as frequent in other countries as in ours; or, at least, we may be privileged to say that there are enough good men and true in the ranks of the American medical profession to save it from the pitying condemnation of our English cousins. It is true we have a code; we wish there was no necessity for it. At least, by opening our eyes to the wrong-doing around us, we are in that respect a step nearer to reform.

BROMIDE OF ETHYL IN FRANCE.

THE properties and value of this new anæsthetic were quite extendedly discussed at a recent meeting of the Paris Surgical Society. Half a dozen gentlemen related their experience, which, on the whole, gave a qualified endorsement of the drug. The same characteristics, good and bad, which have already been noted by American surgeons, were observed by the French. No fatal cases were reported however.

M. Verneuil was struck with the rapid and powerful action of the anæsthetic. One of his patients, a woman, to whom he gave it, was put to sleep almost in an instant. M. Berger was also impressed with its power; a rabbit put under a bell-glass, in which were placed ten grammes (ʒ iiss.) of bromide of ethyl, expired at once. He had never seen so rapid an action in the case of chloroform or ether. These illustrations may be remembered in connection with the general fact, asserted by Dr. Turnbull, that the danger of an anæsthetic is in proportion to its strength of action. We may state here also the fact that a death is reported to have recently occurred in the practice of Dr. Levis while using the bromide. We are not informed, however, that the anæsthetic was the direct or sole cause of the death.

The opinion was expressed, during the discussion referred to, that the bromide of ethyl did not easily produce complete muscular relaxation, and could not be used in operations where such a condition is essential. The opinions, as we have said, while not against its use, were by no means strongly in its favor. This refers to the ether when inhaled. As a local anæsthetic it was spoken of highly. It is the only anæsthetic of this kind which, owing to its non-inflammability, can be safely used in connection with the actual cautery; such was the opinion of M. Mi-

cain. Evidence of its value in this direction has been given by American surgeons, and the point was referred to by Dr Turnbull, at the recent meeting of the American Medical Association.

It seems that bromide of ethyl is rapidly finding its true place as an anæsthetic and that place is not a very high one.

THE HEALTH OF THE CITY THIS SUMMER.

The sudden rise in the mortality-rate during the last week in May is a sharp reminder that the summer, with its dangers to infant life, is upon us. The number of deaths during the week referred to, was 634. The average death rate for that week is 486; the increase was 141 upon the preceding week, and 238 more than in the corresponding week of last year. There is no epidemic in this city, and the cause of the sudden increase in deaths can only be ascribed to the high temperature at that time, and to our tenement-house system. Neither of these influences would have produced such a result alone, but there is a deadly certainty in their united action. Statistics abundantly corroborate this statement. Out of the 634 deaths, 561 were in tenement-houses, and nearly half were among children under five years of age.

Although the high death-rate of May has fallen somewhat during the present month, we naturally look with some anxiety to the future. As long as our tenement-house system exists as at present, we can only expect some alleviation from the increased sickness and mortality brought on by the heat of the summer. Such alleviation has been attempted for several summers past through a systematic visiting of the tenement-houses by inspectors and doctors, and by the establishment of country sanitaria and excursions for the children and their mothers. All this machinery will soon be put in motion again. The number of visiting physicians to the tenement-houses, appointed by the Board of Health, is increased to fifty. The St. John's Guild, which took out nearly thirty thousand people last year upon its excursions, will soon resume its work. If present efforts are successful, there will probably be three seaside sanitaria for the children established near the city.

The *Post* Fresh-air Fund does an admirable work in this same direction. The excursions which this fund supports take children away into country towns where they are left for a week or more in the families of farmers or other persons, who have volunteered to take a certain number of city children for a time. The expense is, therefore, chiefly that of travelling, and the arrangement is a most happy one for the children.

With these various agencies at work we can be confident that something will be done toward lessening the sickness and mortality among the children of the city. The statistics of past summers assure us of this, showing as they do, an actual decrease in mortality. But we were reminded last month how comparatively helpless we are when the sun begins to pour down its hottest rays. There is need of still more help.

Reviews and Notices of Books.

Headaches, their Nature, Causes, and Treatment. By Wm. Henry Day, M.D. Third edition, with illustrations. Philadelphia: Lindsay & Blakiston. 1880.

If a person, while studying the subject of headaches, wishes to gain at the same time considerable knowledge of the anatomy, physiology, and pathology of the nervous system, with a little general physiology and pathology and an essay on the education of children thrown in, we should recommend to him the present book. It is an excellent work in many respects. The analysis of the causes of headaches is complete to exhaustiveness. The therapeutical part is quite full, and the remarks on the care of children exceptionally good. We are inclined to resent, however, the unnecessary bulk of the book. Its classification is not scientifically made, and is too elaborate to be practical. To find that we may have twenty-one different kinds of headaches is enough to create a twenty-second. In the therapeutical formulas we miss such potent drugs as Hoffman's anodyne, guarana, caffein, croton, chloral, and aconitia.

We do not wish to be captious, however. The book is probably the best out on the subject discussed. At least, if it is no better than Dr. Wright's, it is twice as large, and is better printed.

The Pharmacopœia of the British Hospitals for Diseases of the Skin, London. Second edition. Edited by Balmanno Squire, M.B., London, Senior Surgeon to the Hospital. London: J. & A. Churchill. 1880. Small 8vo, pp. 62.

This little book contains many formulæ which will prove of service to those engaged in the treatment of diseases of the skin. Some discrepancies exist between this and the first edition, the most notable of which is the formula "Boleum Creosoti," in the first edition, being given as follows: creasote, two fluid drachms in thirty gallons of water, while in this edition the quantity of creasote is put down as two fluid ounces to thirty gallons of water. New formulæ are added, and old ones omitted. We would take exception to classing chloasma among parasitic diseases, as is done throughout the book.

Sea-Air and Sea-Bathing. By John H. Packard, M.D. Philadelphia: Presley Blakiston. 1880. 16mo, pp. 124. (American Health Primer Series.)

This work, the eleventh of the series, is fully as interesting and practical as those that have preceded it. A brief account of the different kinds of baths is given in the first chapter. Next comes a chapter on sea-side resorts, and the benefit accruing to those who go to the sea-shore. The portion of the book devoted to "Accidents in Bathing," and the methods of resuscitating those who are apparently drowned, is worthy of careful attention. The book will no doubt prove useful to the laity, for whom it is chiefly intended.

Reports of Societies.

THE NEW YORK SURGICAL SOCIETY.

Stated Meeting, February 24, 1880.

DR. H. B. SANDS, PRESIDENT, IN THE CHAIR.

MYXO-SARCOMA OF THE BACK—EXTIRPATION.

DR. FRED. LANGE presented a patient from whom he had removed a large fibro-sarcoma, accompanied by the following history:

Mr. R——, 60 years of age, had always enjoyed good general health, except several attacks of the gout and a chronic catarrh of the bronchi. He referred, as the cause of his disease, to a handstroke which he had received, in good, friendly intention, but, nevertheless, of great severity, about nine months ago, in the right interscapular space. From that time a certain feeling of uneasiness at that point never left him. After several months a slight prominence appeared there, which, by gradual, and finally rapid, growth, prevented free motions of the scapula, and at last caused incessant pain. When Dr. Lange saw the patient, in December, 1878, the tumor was about the size of a new-born child's head, filling up the whole right side of the interscapular space, dislocating the scapula in a lateral direction, was immovable, and evidently was seated in the lowest parts of the back. The operation was performed on the 21st of January, 1879, when a long incision was made through the trapezius muscle, and the whole space, from the vertebral column to the basis scapulæ, was laid open. On attempting to enucleate the tumor, which was closely attached to the surrounding parts, free hemorrhage occurred. It was removed rapidly by a few large cuts, in order that the principal vessels might be quickly secured, and so prevent a dangerous loss of blood.

In that way the rhomboid muscles, which seemed to be partly destroyed by the tumor, were removed, and the deepest layer of the dorsal muscles and the ribs laid bare. The growth, however, did not have limited boundaries. To a large extent, and that especially along the deep fascia, there existed a diffuse infiltration, apparently representing the spreading of the tumor. He therefore prolonged the incision upward and downward, and removed, as carefully as he could, all the suspicious tissues. For this purpose even the periosteum of several ribs and the superficial layers of the intercostal muscles had to be removed, and though, macroscopically, no diseased parts were left, he closed the wound, feeling convinced that a thorough removal had not been accomplished. The patient, by loss of blood, perhaps also in consequence of the loss of warmth from the enormous wound, and the poisoning influence of carbolic acid, fell into a state of alarming collapse. Dr. Lange washed the wound with a five per cent. solution of chloride of zinc, introduced several drainage-tubes, applied a number of sutures, and had the patient placed in bed after a large antiseptic dressing had been applied. To prevent secondary hemorrhage, pressure was effected by means of a large sponge, fixed over the wound by a tight rubber bandage. The patient, though much exhausted, had a speedy recovery, after he recovered from the first dangers attending the shock and loss of blood.

In this case, as in several others with great loss of blood, he made use, with good result, of ample injections of warm water with claret into the rectum. It seems to be rapidly absorbed, and, he thought, answered one important indication, namely, the quick restoration of the fluid parts of the blood. He usually injects one to two pints of water with one to two glasses of wine, under a low pressure, slowly, the patient being in Sims's position; and the injection was repeated every three to four hours, with about half of the quantity, according to the state of the patient. Of course the rectum has to be emptied before the operation. Very often it is impracticable to feed the patient by the mouth, on account of the tendency to vomiting, and the hypodermic method of giving excitants alone does not fully meet the urgent indications.

On microscopical examination the tumor was found to be a myxo-sarcoma, with a number of small mucous cysts. Dr. Lange thought it had developed principally by proliferation of the cells of vessels, especially those of the adventitia, a kind of tumor which has been described as angiosarcoma. He regards the case as specially interesting because there was yet no evidence of a recurrence of the tumor. The patient made a speedy recovery, and there was left a scar more than fourteen inches long, but the tissues surrounding it were everywhere soft and movable. More than thirteen months had elapsed since the operation, and Dr. Lange thought that there need be no further apprehension with reference to return of the growth.

THE PRESIDENT referred to a case in which he removed an extensive sarcoma of the parotid gland, in 1870. The skin was involved, and the tumor extended inward to the region of the styloid process. It became a question whether the operation should not be abandoned on account of unexpected extent of the growth, and the additional fact that microscopical examination, made by Dr. Delafield after it was begun, revealed an undoubted fibro-sarcoma with an abundance of small cells. The operation, however, was completed, and the wound closed, but considerable inflammation followed, and the flaps sloughed, and perhaps to that occurrence the man owed his exemption from recurrence of the sarcoma. At all events he recovered, and within the last year Dr. Sands had seen him and found him perfectly well, without any signs of recurrence.

NECROTOMY OF THE INFERIOR DENTAL NERVE.

THE PRESIDENT presented Mr. B——, a healthy-looking man, æt. 64, who was brought to him by Dr. Gay, Feb. 24, 1878, on account of neuralgia of the right inferior dental nerve, from which he had suffered severely during the last two years. Occasionally, but rarely, pain had been felt in the infraorbital region. All the usual remedies had been employed without effect. He had consulted a distinguished neurologist in the city, who told him that the disease was syphilitic, and upon being informed that he had never had syphilis, the physician said there was nothing to be done, except to give the treatment appropriate for that disease. On March 1st ether was administered, and Dr. Sands divided the nerve according to Paravacini's method. He found it quite impossible to see the nerve, but succeeded in dividing it after having passed beneath it a small blunt-hook made for the purpose. In rehearsing the operation on the cadaver he found it quite easy to mistake the internal lateral ligament for the nerve. By applying the tip of the forefinger, however, to the process of bone overhang-

ing the foramen at which the nerve enters the canal, the error was readily avoided. April 1st. Considerable inflammation followed the operation, and some sloughing of connective tissue occurred in the wound. Patient was then annoyed by an abscess in the cheek, about an inch in front of the masseter, which discharged imperfectly into the mouth. The neuralgia disappeared immediately after the operation and had not returned. It was noted on May 14th that several abscesses had formed in the cheek after last date, April 1st, but the patient had been well and had experienced no inconvenience, except a slight stiffness of the jaw. He remained absolutely free from neuralgia, and was healthier than he had been for several years. On December 15, 1879, the patient was well. On Feb. 24, 1880, he said he had slight twinges of pain in the cheek, and slight pain in the lower part of the jaw. It was simply spasmodic in character and was of only trifling severity. The pain was in nearly the same spot as it was before the operation, but gave him no special inconvenience, and he was of the opinion that it was less severe than it was two or three months ago when it was felt for the first time after the nerve was divided.

The President remarked that the case was interesting as showing that a good result might be obtained without excision of the nerve. There was nothing found in the jaw to account for the pain. When he divided the nerve he attempted to tuck it down into the tissues beneath; but whether the effort was successful or not he was unable to say.

EXSECTION OF THE THIRD DIVISION OF THE FIFTH PAIR.

Dr. Herman Guleke reported a case of exsection of the third division of the fifth pair of nerves. Jacob Hoffman, æt. forty-seven, twenty-three years in the United States, and a 'longshoreman, was admitted to the German Hospital, Oct. 28, 1873, suffering from neuralgia in the face. His health had been good, no evidence of syphilis could be found. About twelve years ago, without any cause known to the patient, pain began in the right side of his face, having at first all the characteristics of toothache. He, therefore, had several teeth extracted, but without obtaining any relief. The frequency of the paroxysms of pain increased, and at last prevented the man from following his trade. The pain was located in the upper part of the cheek, corresponding to the os zygomaticum, which was swollen, and pressure on that point at once caused an attack. The pain was very severe, lasted from three to five minutes, and the paroxysm was repeated every ten or fifteen minutes, especially at night. Oft-repeated examinations failed to show that any other branch was involved. The only relief which the patient obtained was from the hypodermic use of morphine, about ℥ xx. Magendie's solution, giving him rest for half an hour; given by the mouth rest could be obtained for an hour and a half. Finding that the patient was not improving under this treatment and the use of iodide of potassium, etc., he proceeded, on the 7th of November, to exsect the zygomatic nerve. The incision was made along the edge of the bone, around the external corner of the orbit, the periosteum raised by a spatula, and, together with the cellular tissue of the orbit, pushed inward and the nerve exposed. In order to exsect a larger piece of the nerve and its branches he removed the larger portion of the body of the zygomatic bone, with the adherent portion of the nerve, about an inch in length. The wound was closed with sutures and ice applied.

November 8th. Patient did not sleep. The wound and the tissues around it were swollen. Ordered morphia and quinia.

November 9th. Patient slept about two hours. Some of the sutures removed.

November 10th. The remaining sutures were removed. Wound in the skin has closed, except in two places where considerable pus discharged. Eye and cheek swollen to some extent.

November 11th. Patient complained of pain, but was not able to say whether it was neuralgia or due to the wound.

November 12th. The pain has increased and is more like the neuralgic pain from which he suffered before the operation. In the evening the first neuralgic attack took place, which lasted about fifteen minutes. In the night he had two more attacks, but slept considerably.

November 14th. No attack.

November 15th. Patient has a chill and fever, and erysipelas developed around the wound, reached the scalp in two days, and faded on the 25th of November. On the same day the neuralgia appeared again, and attacked the patient frequently. On the 27th and 28th no pain, and the erysipelas had disappeared, the wound had closed, and the patient was discharged on the 5th of December without a recurrence up to that date.

On the 27th of March, 1874, the patient was again admitted, suffering from neuralgia, which was situated in the temporal region upon the right side, following closely the course of the auriculo-temporal nerve. The pain appeared every fifteen minutes, and finally was caused by touching the affected part, or by mastication. On the same day Dr. Guleke exsected about three-fourths of an inch from the affected nerve, but as soon as the effect of the chloroform had passed off, the neuralgia returned so severely that injection of morphia was necessary to control the pain. The attacks were frequent. The operation did not give any relief, and the patient asked for another. A deep-seated pain persisted in the temporal region, and in front and above the right ear.

On the 28th of April he proceeded to resect the third division of the trigeminus in the sphenomaxillary fossa. A circular incision was made, reaching from near the external meatus of the ear downward about an inch and a half, and curving up toward the inner edge of the rest of the os zygomaticum. Some fibres of the masseter muscle were cut, the arch of the zygomatic bone was cut from its base by forceps, and with the integument was turned upward a part of the coronoid process, first having detached the insertion of the temporal muscle. Reaching the external pterygoid muscle, he found it necessary to incise it, and caused thereby a severe venous hemorrhage, which, however, was finally controlled by the use of cold sponges. Following the base of the skull in the direction of the foramen ovale, at last the nerve was found, and a piece about one-fourth of an inch removed. The wound was closed by sutures. About 9 o'clock the patient had fever and a chill. The next morning the right side of the face and the wound were swollen. Ordered thirty grains of quinia.

On the 30th of April he had another attack of neuralgia. The pain was not quite so severe as before the operation, but had been changed to the frontal tubes, and could be caused by touching the upper lips and this part of the face—parts that never before seemed to be involved by the neuralgia—and the paroxysms were severe and frequent.

On the second day the attacks were less severe. On the fourth day severe attacks again, and deep in the temporal region. On the seventh day neuralgia in the frontal tubes. On the eighth day a slight attack, and then the pain seemed to disappear and the patient did not suffer from an attack until the 19th of May, and left the hospital on that day. Some months afterward the neuralgia returned, and quite as severely as before the operation. That result so discouraged Dr. Guleke that he did not propose further operation, although the reports of successes after division of all the branches of the fifth pair have been quite numerous. Dr. Shuppert, of New Orleans, reports a case where he succeeded, after operating twice on the second division and on the third division of the fifth pair, and tying the common carotid, and failed, by exsecting the facial nerve near the stylo-mastoid foramen, and five years after the last operation the neuralgia had not returned.

Dr. Guleke did not resort to stretching of the nerve before the exsection, because he had not heard sufficiently of it at that time, but at present so many reports of the success of the method had appeared that it should not be overlooked. However, the process of the treatment of these cases will remain doubtful so long as we are not enabled to make a diagnosis of neuritis and neuralgia of a central or peripheral lesion of the nerve.

Dr. T. M. Markoe opened the discussion upon the question involved in Dr. Guleke's communication, by suggesting, in view of the many cases of like character now collected, that the most important question to be settled with reference to these operations was whether or not the radical, very difficult and extremely dangerous operations, which have been performed in a considerable number of cases, offer the patient so much better chance of final cure than the less extensive operations, like that in the case cited by the President, that we were justified in resorting to them. He was not prepared to answer the question fully, but his own experience and observation, his personal experience, it was true, being limited to one case, inclined him to the opinion that perhaps the severer operations were not justifiable in most cases.

His own case was as follows: A young man had suffered very severely from inferior dental neuralgia for many years. The pain was limited strictly to the nerve and its branches, and he operated by the old method, using a small trephine and then a fine chisel, and finally exposed the nerve, raised it from its bed, and removed a piece about an inch in length. That was in April, 1861. The wound did perfectly well, the patient had only one or two partial paroxysms of pain in the first ten or twelve days. After that he was entirely relieved, and remained absolutely free from pain for a very considerable period. The nerve was examined microscopically and showed no pathological change. The patient remained free from pain until 1876, when he began to suffer from neuralgia in the infraorbital, and occasionally the pain extended to the supraorbital nerve. Another operation was performed, which consisted in opening the antrum, exposing the nerve, and following it back to the point where it enters the maxillary bone. In going along the groove in which the nerve laid, he found a pair of strong scissors to be the most convenient instrument he could use for removing the thin plate of bone.

Knowing that the posterior dental came off very close to the point at which the infraorbital nerve enters the deep bony canal, he endeavored, with the point of the scissors, to break up the nerve-trunk as far as possible beyond, hoping thereby to reach the point at which the posterior dental nerve was given off. Whether he succeeded in destroying the nerve at the point of junction or not, he was unable to determine. Some months after the operation the patient was almost entirely free from pain, suffering only occasional slight paroxysms, and most of the pain was in the supraorbital nerve. Since that date (1876) he had not heard anything concerning the case, but from the benefit which the patient received by the two operations, Dr. Markoe thought he would seek for a third one did the pain return in severity, and he certainly would be willing to undertake it.

Dr. Frank H. Hamilton referred to a plan of operating lately mentioned by Dr. Hodgen, of St. Louis, in cases of persistent infradental neuralgia. It was to bisect the nerve at its point of entrance, and then reaching the nerve from the outside by another opening, drag it out for the entire length.

Some years ago Dr. Hamilton trephined the inferior maxilla near the angle and removed a section of the inferior dental nerve, half or three-quarters of an inch in length, for the relief of a persistent neuralgia of that nerve. The man had complete exemption for about a year; but then the pain returned, was as severe as before the operation, and when he last heard from the patient he was still suffering.

Dr. Hamilton called attention to a case in which the President had performed an admirable operation, but with reference to which he had some suspicion that it had been reported incorrectly. It was a case in which the brachial plexus was removed for the relief of neuralgia that persisted after two amputations of the arm. It was reported as having been much relieved by the operation. The man subsequently came under Dr. Hamilton's care, when he said that as soon as the soreness of the wound had disappeared the pain returned with a severity equal to that before the operation, and that there was a certain aggravation, inasmuch as he had had distressing hyperæsthesia of the integument of the shoulder. The pain, however, was referred to the lower part of the upper third of the humerus. He was then taking large quantities of morphine. Dr. Hamilton amputated at the shoulder-joint and gave the patient temporary relief. The pain returned as soon as the cicatrization was complete, and was as severe as before.

During the attempt to cure the man of his opium habit he died. Three days after the morphine was removed entirely, he had two convulsions, fell into coma and died. No autopsy was obtained.

Six weeks were employed in gradual diminution of the morphine which had been used hypodermically and in enormous quantities.

The President stated in reply, that the case was reported by Dr. Seguin and himself, in a journal at that time published by Brown-Séquard, and the only portion of the paper written by himself was that in which the operation was described. He saw the patient a few times only at Dr. Seguin's request, and at his request performed the operation. He saw him while the wound was healing, and then knew that the neuralgia had returned, yet he thought Dr. Seguin's observations were carefully made. Perhaps the patient's statements were not altogether reliable, because he had been previously in confinement in an asylum, and it might be that his statements were not the same at all times. Ultimately he knew that the pain was as severe as before the operation.

Dr. J. C. Hutchison remarked that Dr. Hodgen's

operation consisted in passing a perforator through the alveolar process down into the cavity where the nerve lay, and he knew he had reached that cavity by the amount of hemorrhage that occurred, and then cut the nerve off with the perforator; then making an incision in front he dragged the nerve out as described.

He also referred to cases of resection of the nerves of the face which were interesting because of the variety of measures resorted to for the cure of the neuralgia.

The first patient was a miner, æt. forty five, who had always had excellent health, and had never had syphilis. The pain from which he suffered was confined to the lower jaw and the paroxysms were exceedingly severe. After a variety of expedients had been adopted, both local and general, he resorted to the operation described by Dr. Gross in a paper on neuralgia of the jaws, read before the American Medical Association in 1870. It consisted in turning back the soft parts and the periosteum, and removing, by means of cutting-pliers and a gouge, the alveolar process, and with it the nerve. That gave him complete relief for a year; sufficiently long to give opportunity to publish it in Hay's Journal as one of cure by that method. After a time, however, the pain returned, and a Boston surgeon removed a wisdom tooth and gave relief for a number of months. That operation was reported in the Boston Medical and Surgical Journal as one effecting a cure in a persistent case of neuralgia. A few months after, Dr. Hutchison saw the patient and he was again suffering as much as ever. The patient then went to California, and his suffering was so intense that he applied to a surgeon who trephined the bone, exposed the nerve, and removed about half an inch of it. Again he was relieved. A number of months later, however, the pain returned, was as severe as it had been at any time, and he again consulted Dr. Hutchison, who, having seen Paravacini's favorable reports of treatment of these neuralgias by ligation of the carotid artery, tied that vessel. The man was entirely relieved, and at the end of two weeks was perfectly well. That was in June, 1877, and by letter two years after the doctor had been informed that the pain had not returned.

The second patient was a man who had neuralgia of the superior maxillary nerve. It began in 1848, and in 1878 Dr. Hutchison saw him for the first time. During the thirty years he had had a variety of surgical experience. He had been operated upon by Dr. Allen, who made an incision across the forehead and with temporary relief. He was subsequently seen by Dr. Mott, who declined to do anything for him, and he was under Dr. Parker's treatment for some time without operation. He was finally seen by Dr. Liddell, of New York, who divided the nerve at the back part of the orbit, and gave him relief for a time. After two or three years he came under the treatment of Dr. Isaacs, who exposed the nerve and divided it, with temporary relief. Some years subsequently he came under Dr. Hutchison's observation, and he tied the common carotid, first upon the left and second upon the right side. The operation gave the patient no relief whatever. At the end of a month he determined to go into the patient's orbit again, and did so, opening up the tract in the bone for about an inch back from the edge of the orbit, and gouged away about an inch of the nerve. The operation gave the patient entire relief. A year after the operation he was perfectly well, and, as he was a resident of Brooklyn, it was fair to presume that he remained cured, as he had not appeared making complaint.

Dr. Lange remarked that, according to statistics, in about 3¼ per cent. of all cases in which the nerve was removed the cure was perfect.

The President regarded Paravacini's operation as preferable to cutting through the tissues externally, and trephining the bone. It was not an easy operation to perform upon the living subject, because, as he had found in the two cases in which he had operated in that manner, it was not practicable to expose any considerable portion of the nerve. In Mr. B.'s case he did not see the nerve. Should he have occasion to perform the operation again, he would provide himself with an instrument resembling a miniature lithotrite, by which the nerve could be seized previously to dividing it, and then it could be dragged out. When the nerve was raised on a hook and then divided, it escaped seizure.

The external operation had, to him, always seemed severe, and he had knowledge of one case in which it proved fatal. The operation was performed by a distinguished surgeon in 1869, upon a man 60 years of age, and portions of the inferior dental and gustatory nerves were removed. The operation was not marked by any peculiarity except that there was very free oozing. It was done at 1 P.M. Exactly twelve hours after the operation Dr. Sands, who was then partner of the surgeon who operated, was summoned in great haste, and found the patient dying of suffocation. The windpipe was *promptly* opened, but the relief came too late, and the man fell backward and ceased to breathe, only three or four respiratory movements being made after the trachea was opened. Immediately after the death of the patient he ran his finger up through the rima glottidis, where he was able to appreciate great tumefaction of the tissues at the upper part of the larynx.

Autopsy showed degeneration of the muscular tissue of the heart, and it was thought that death was, perhaps, accelerated by that condition.

DIVISION OF THE GUSTATORY NERVES.

In this connection The President referred to a case in which he divided the gustatory nerves. It had the following history: John W——, æt. 71, consulted him October 18, 1877, for a disease of the tongue which appeared about six months before, and for which he had been treated with caustics without relief. On examination, the anterior third of the tongue was found indurated by cancerous deposit, and the under surface, as well as the mucous membrane investing the floor of the mouth and the gums, the seat of superficial ulceration. The organ was almost immovable, and excessively painful, the pain occurring in paroxysms, and preventing sleep. Salivation profuse and annoying. No enlargement of glands. Radical treatment was suggested, but not urged, and on October 18th, assisted by Dr. Oakley, of Elizabeth, N. J., he divided the gustatory nerves according to Moore's method, using Whitehead's gag to open the mouth. Little bleeding attended the operation, after which, and before the patient had quite recovered from the effects of ether, he endeavored to test the sensibility of the tongue with the point of a needle. The left half was quite insensitive, but the patient's testimony was contradictory in regard to the right side, leaving Dr. Sands somewhat doubtful whether he had succeeded in dividing the nerve. The patient had no trouble after the operation beyond local soreness; no unusual quan-

tity of saliva produced; spoke better, and there was no pain in the tongue.

October 23d.—Dr. Oakley wrote that there was no sensation in the left side of the tongue, but he thought there was upon the right.

November 2d.—About one week ago patient began to complain of pain in the right side of the tongue, and on the same side of the face, and slightly in the neck. Finding the right side of the tongue sensitive he again attempted to divide the nerve, and doubtless succeeded, as the tongue showed no sensibility immediately after the operation.

November 16th.—Since last operation patient has been free from pain. Tongue not sensitive when pricked with a needle.

A note from Dr. Oakley, dated May 11, 1878, stated that the patient died March 12th of exhaustion. From the time of the second operation until his death he suffered little or no pain, the section of the nerves having removed the most distressing features of the disease, namely, pain and salivation.

Dr. Hutchison asked regarding the extent to which nerves had been reproduced after neurotomy.

Dr. Lange referred to observations made by Wagner, who reported that they had been reproduced to the extent of an inch or more.

Dr. L. A. Stimson referred to experiments of the French physiologist, Legros, who determined that nerves going to the spleens of mice might be reproduced to the extent of 1 cm.

The President completed the history of Dr. Scribner's case, reported at the stated meeting held January 27th, by reading the following report:

Examination of portions of the stomach, large and small intestines, from the body of Dr. J. W. Scribner, gave the following result:

Upon the greater curvature of the stomach, and about 5 ctm. from the pylorus, was a shallow ulcer 3.5 ctm. long by 1.5 ctm. wide, in whose thickened edges lay several hard nodules, the largest about 1.5 ctm. in diameter. At this point, and for a considerable distance on either side, the stomach was bound to the transverse colon, and to other adjacent parts, by adhesions and by a congeries of irregular white nodular masses resembling those found at the borders of the ulcer, the largest being about 2 ctm. in diameter. The omentum, which at its broadest portion measured 16 ctm., was firmly bound to the transverse colon, was greatly thickened, and its surface thickly studded with larger and smaller irregular nodules. Similar nodules were found everywhere within the thickened omentum, which at some points measured 8 ctm. from front to back. Irregularly scattered over a considerable portion of the surface of the parts of the intestines sent for examination; small irregular elevations were found; most about and in the vicinity of the cæcum. The surface of the appendices epiploicæ were also, in many cases, rough and uneven. The lower portion of the descending colon was narrow, having a diameter of about 1.5 ctm.; the gut gradually enlarged upward, having, at the seat of operation, about its normal calibre, as had also the transverse and ascending colon and the small attached portion of the ileum. No stricture was found at any point, the only narrowing being at the lower portion of the descending colon.

The tumors on the edges of the ulcer, and below and behind the stomach and the thickened omentum, as well as the small scattered elevations over the peritoneal surface, had the structure of carcinoma. The post-mortem changes and the action of the diluted carbolic acid prevented the determination of the precise conditions of the surface of the ulcer. In accordance with those facts, the anatomical diagnosis would be: Primary carcinoma of the stomach, with secondary diffuse carcinoma of omentum and peritoneum; slight narrowing of the lower portion of the descending colon.

Signed, T. Mitchell Prudden.

SPONTANEOUS GANGRENE OF THE FOOT.

Dr. George A. Peters presented a specimen, accompanied by the following history:

Chas. F. Heiss, æt. 26; single; a butcher, and a native of U. S.; was admitted to the New York Hospital Feb. 7, 1880. Family history good. Personal history: Denies venereal; has never had scarlet fever or rheumatism; gives no history of traumatism. Three weeks ago was suddenly taken with a chill. On the following day he had high fever, which lasted three days. On the evening of the fourth day he went to bed feeling perfectly well, and did not awake until usual time in the morning, when he noticed that his left leg below the knee was stiff and numb, and upon looking at limb found the whole leg, from a point about three inches below knee, was perfectly white, cold to the touch, and entirely destitute of sensation. Soon after he felt pain in knee, which became very severe and lasted, without intermission, until five days ago, when it almost entirely ceased. Since the first morning the leg has steadily changed in color, until at present time the foot, ankle, and about one-third of leg, are perfectly black. The only treatment received has been quinine sulph. in moderate doses, and hot bottles about limb. Warmth and color have returned to limb for about three inches below original point. Here a line of demarcation is plainly visible. Patient has lost flesh and strength.

On admission he was in fair general condition, his face slightly pallid and anxious, and there was slight increase in pulsation in neck. Præcordial area somewhat enlarged. The apex of the heart was beating in the fifth intercostal space. The whole foot and lower quarter of leg were black, swollen, and firm to touch. Discoloration extended on outer aspect in shape of triangular prolongation as far as middle, on interior aspect only to lower quarter. Line of demarcation clearly drawn. The skin above was of dull red color as high as tibial tubercle; above this it was normal. The radial pulsation was good; arteries slightly thickened. Good pulsation in right femoral; none in the left. No popliteal pulsation on left side. Hepatic and splenic area of percussion dulness increased.

Auscultation reveals soft systolic murmur heard over aortic orifice.

Feb. 12th. Formation of new line of demarcation one and a half inches above old.

Feb. 16th. Line of separation formed.

Treatment.—General: brandy ℥ ss. every two hours; quiniæ sulph. grs. x. every four hours. Local: yeast and charcoal poultices to leg at and above line of demarcation.

Feb. 24th. Limb amputated at the knee-joint. The operation was nearly bloodless. The cutaneous temperature of the thigh was apparently good.

The specimen was prepared by the pathologist Dr. Geo. L. Peabody, who gave the following report:

On the posterior surface of the leg, between the superficial and deep muscles, there extends a cavity lined by gray and flabby granulations, from the line

of demarcation upward to the lower border of the popliteus muscle. In this cavity the vessels are lying upon the anterior wall.

The popliteal artery and post tibial to the point of origin of the peroneal are filled by a firm, partly decolorized thrombus, which ceases abruptly at the origin of the peroneal artery, but extends about half an inch into the anterior tibial. Below these points all three arteries are empty and appear healthy to the naked eye. The veins are all distended by coagula which are rather more recent than those in the arteries.

I have not thought it desirable to remove the thrombi until you have seen them, and am therefore unable to testify as to the condition of the thrombosed vessels.

The President remarked that the special point of interest in the specimen was the uncertainty experienced in attempting to diagnosticate between thrombosis and embolism of an artery, a point which was sometimes very difficult, if not impossible to decide, even with careful examination.

He then referred to a case which occurred in the practice of Dr. Conley. The patient was a woman seventy-one years old, who was suddenly taken with severe pain in the leg. Gangrene of the foot appeared and extended upward to within four inches of the knee-joint. It was thought that she had embolism of the popliteal artery. Circular amputation was performed at the knee-joint, and no arterial blood flowed on making section of the limb. The patient died from extension of the gangrene. Subsequent examinations showed embolism, although there was no evidence of valvular disease of the heart. The arteries were atheromatous.

About a year ago a man 60 years of age came under his observation, who was known to have valvular disease of the heart. He was suddenly attacked by pain in the leg, gangrene followed, and it was supposed to depend upon embolism of the popliteal artery. The limb was amputated at the junction of the middle and lower thirds of the thigh, and all the large vessels were found obliterated except the profunda. The patient was in a bad general condition at the time the operation was performed, yet he lived several weeks and finally died, the gangrene having extended *four* inches beyond the line of section. Examination of the arteries showed no embolus, but the femoral and the popliteal down to the tibials were filled completely by a thrombus having a uniform consistency.

In that case, as in the case reported by Dr. Peters, post-mortem showed that we were liable to be deceived regarding the cause of the gangrene. Moreover, he knew of no case of recovery after amputation under these circumstances, except the single one reported by Dr. Sayre. Gangrene of the stump usually followed and killed the patient.

Dr. Peters remarked that the condition of the skin in the flaps in his case indicated extension of the gangrene.

Dr. Lange referred to a case in which he amputated the thigh on account of gangrene of the foot occurring in a man 70 years of age. From the profunda downward all the arteries were completely obstructed. There was no suppuration, and the man made the most rapid recovery he had ever seen. The patient had had syphilis, had had several attacks of abscess of the joints, and he therefore elected to amputate through the thigh, because it seemed probable that the branches of the profunda were free, and might nourish the remaining parts. There was complete obstruction of the femoral. The amputation was done far above the line of gangrene. In the opposite thigh he had what was supposed to be the same kind of obstruction of the femoral without any trouble in consequence. He regarded it as a case of chronic endarteritis syphilitica.

Dr. L. A. Stimson saw a case some time ago in which amputation was done at the middle of the thigh for advancing gangrene. There was no hemorrhage. There was complete obstruction of the common iliac artery by thrombus, also the femoral for its entire length, and the arteries of the legs as well as the veins.

Dr. J. G. Curtis asked if thrombi were found extending into the small branches of both the arteries and the veins?

Dr. Stimson replied that they extended into the smaller veins as far as he traced them, and his impression was that they extended also into the small arteries.

Dr. J. C. Hutchison, a short time ago, saw a lady who was suddenly seized with pain in the knee, followed by numbness of the leg and a blanched appearance of the skin. He supposed she had embolism. There was an aortic murmur, not marked, however, but there was evidence of a large, weak heart. The second time he saw her there was no pulsation in either the anterior or posterior tibial artery. Subsequently the numbness somewhat subsided, but he had not been able since to find pulsation in the tibials. All the numbness disappeared within a few days, the pain subsided, and the limb seemed to be quite well.

Ligation of Arteries not Followed by Formation of Clot.

Dr. L. A. Stimson presented a specimen which illustrated, as had already been shown, the possible tolerance which the tissues gave to a carbolized silk ligature applied to an artery and the total absence of clot upon the proximal side. The specimen was a popliteal artery that had been ligated three months previously, after a supracondyloid amputation.

The operation was done antiseptically, the ends of the ligature cut short, and the wound healed promptly. The patient died three months afterward, from tumor in the chest, and the specimen was obtained at post-mortem. The calibre of the vessel diminished from above downward to the ligature, but there was no sign whatever of clot within it. The walls of the vessel were thrown into folds. There were no branches anywhere near the point of occlusion.

Dr. Stimson also presented, in behalf of Dr. Keyes, a popliteal artery that was removed post-mortem; death having occurred thirty-six hours after the vessel was ligated. The ligature was in place and there was no clot within it.

The absence of clot where the vessel was healed showed that clot was not necessary to perfect closure of the vessel, a point that seemed to be thoroughly established, although still questioned in some quarters. Dr. Stimson then referred to cases already reported. Ferguson had reported a case in which the femoral was ligated in the middle of the thigh. The patient died seventeen days after the operation, and not the slightest clot was found within the vessel.

Holmes had reported a case in which he ligated the carotid and the subclavian, and at post-mortem, eight weeks after the operation, the subclavian was

found closed by a diaphragm of connective tissue a quarter of an inch in thickness, but without clot in the vessel. In the carotid a ridge marked the seat of the ligature, and the author stated that the lumen of the vessel was closed by a very thin layer of non-adherent coagulum. The ligature was carbolized by drawing it through carbolized wax, 1 to 5.

The point which Dr. Stimson made was that the presence of an internal clot was not necessary to the occlusion of a vessel. Cases, however, had been recorded, in which clot had been found extending from the ligature to a large neighboring branch.

The President remarked that that was true, as had been shown by the specimens and the cases quoted; but at the same time it was known that an internal clot often existed which it might guard against the occurrence of hemorrhage. He then referred to an experiment which he performed of tying the carotid of a horse, and the specimen showed that the only thing which prevented hemorrhage was the presence of well-formed coagula on both the proximal and distal side of the ligature. He also referred to a case occurring in the New York Hospital, in which Dr. Willard Parker ligated the carotid, the subclavian, and the vertebral, and clots formed both upon the proximal and the distal sides in each artery.

Dr. Stimson thought his specimens might possibly throw some light upon the different results obtained, under apparently the same circumstances, after ligating vessels for the cure of aneurism.

The President remarked that it was a singular circumstance that ligation of the external carotid artery, which, anatomically speaking, was the most unfavorable for the application of a ligature, was almost uniformly successful. There the occlusion must take place, either by the formation of a clot or by the end becoming buried in plastic matter which surrounded it.

DECALCIFIED BONE AS DRAINAGE-TUBES.

Dr. Lange exhibited a specimen of decalcified bone to be used as a drainage-tube. He remarked that Neuber had demonstrated that the material is not absorbed at all if surrounded by blood, and cited illustrative cases. The specimen was prepared by drilling a piece of ox bone, decalcifying it in dilute muriatic acid, 1 to 2 of water, then carbolizing it in a five per cent. solution of carbolic acid, then soaking it in alcohol, and last in carbolized oil, 1 to 10.

The Society then adjourned.

KENTUCKY STATE MEDICAL SOCIETY.

Twenty-fifth Annual Meeting, held in Lexington, May 19, 20, and 21, 1880.

(Special Report for The Medical Record.)

Wednesday, May 19—First Day.

The Society met, pursuant to adjournment, at Meloeon Hall, Lexington, at 3 o'clock P.M., and was called to order by the President, Dr. R. W. Dunlap. Prayer was offered by Rev. Dr Bartlett; and Dr. W. O. Bullock, Chairman of Com. of Arrangements delivered an appropriate address of welcome.

The remaining afternoon session was devoted to the appointment and announcement of committees, and the enrolling of new members.

Second Day.

EXCISION OF ELBOW JOINT.

Dr. James M. Holloway, of Louisville, exhibited photographs illustrating a case of excision of the elbow joint, the operation having been performed in 1876. For the last two years the man has performed full duty as a farm laborer, and during the last winter has been employed in hauling hay and depositing it into the lofts of stables. He possesses power in the arm equal to that of its fellow, and is able not only to flex the forearm upon the arm, but has perfect pronation and supination. When the operation was performed he was the subject of consecutive syphilis. This complication has in no perceptible manner interfered with his progress.

EXTENSIVE NÆVUS AND CERVICAL LYMPHOMATA.

Dr. Holloway also exhibited a photograph of a rare and unique specimen of extensive congenital venous nævus, involving the arm and forearm of a young lady. No effort had as yet been made to excise the tumor.

Dr. Holloway also reported a case of cervical lymphomata, operated upon by himself, in March last, and presented photographs of the patient before and after the operation. He also exhibited the enlarged glands which were removed. They were fifty-three in number, varying in size from that of a marble to that of a hen's egg. All of the important structures upon that side of the neck were exposed, the fascia having been dissected away as upon the cadaver. The boy, aged about 18 years, made a good recovery, and there seems to be no tendency to the disease in the glands of the neck or other parts of the body.

MANAGEMENT OF PROCIDENTIA UTERI WITH RECTOCELE.

Dr. W. H. Wathen, of Louisville, read a paper, with report of case, on the Management of Procidentia Uteri with Rectocele, Cystocele, and Lacerated Perineum. In the case reported he had performed two operations; the first by amputating the cervix with his serrated scissors and compound terraculum, after which the intra- and extra-cervical mucous membranes were united after the method of Hegor by the introduction of ten interrupted silver sutures. The uterus, which measured 5¼ inches before the operation, had diminished within four weeks to 2⅝ inches in depth. The second operation was performed four weeks subsequently, and was directed to restoration of the perineum. The surface was denuded up the posterior vaginal wall to the crest of the rectocele, and the edges were united after the method of Emmet by the interrupted silver suture. The result was altogether satisfactory.

The paper was ably discussed by Dr. Thad. A. Reamy, of Cincinnati, upon invitation of the President. Dr. Reamy did not approve the indiscriminate amputation of the corvix uteri in cases of procidentia, and advocated the use of the simplest instruments possible in performing the operation. He gave an account of several cases in which after reduction of the uterus he had operated upon the vagina so as to produce narrowing of its posterior wall, and thus had secured excellent results. He dwelt with lucid emphasis upon the important function of the perineal body in its relation to the uterus and vagina.

GASTROTOMY IN EXTRA-UTERINE PREGNANCY.

Dr. W. O. Roberts, of Louisville, read a report of a case in which he had performed gastrotomy and removed a dead fœtus near the sixth month of abdominal pregnancy, followed by recovery of the patient. A few days before the operation the sac had opened into the bowel, and the contents so markedly characteristic as to odor were discharged per rectum. The case elicited much interest in view of the extreme degree of exhaustion to which the patient had been reduced, and the high degree of temperature (103) at the time of operation.

Antiseptic precautions were observed with great care; the drainage tube was removed on the fifth day, and the placenta came away on the eighth day. Twenty days have now elapsed since the operation, and convalescence is established in a most satisfactory manner.

The report of this case was received with marked attention, and a very general discussion of the subject was elicited.

THE MANAGEMENT OF ORTHOPÆDIC CASES.

Dr. V. P. Gibney, of New York, read by invitation a paper on the Management of Orthopædic Cases. This paper treated of the general principles to be kept constantly in mind in the management of cases of Pott's disease in its different stages and localities, of lateral curvature of the spine, hip disease, a term which he deemed unfortunate since it indicated nothing as to pathology, and club foot. The true hip disease, he thought, should be called diaphyso-epiphysitis, or articular ostitis of the hip, inasmuch as it began in the great majority of cases as a central bone disease, and in one or more of the centres of ossification. He did not believe that in such cases any *absolutely perfect* results were obtained by any plan of treatment known to the profession. Our aim should be to get the best possible results, giving the family to understand that a joint to some extent crippled must inevitably follow. He preferred the crutches and high shoe for treating this disease.

In the management of club-foot, as well as all the other ailments treated in his paper, Dr. Gibney insisted that time was the all-important element, *i. e.*, the surgeon must anticipate a prolonged course of treatment. The paper was ordered to be published by the Society.

Dr. J. M. Letcher, of Richmond, read a carefully prepared paper upon the most recent views of the pathology and treatment of typhoid fever.

The following officers were elected for the ensuing year: *President*, Dr. L. B. Todd, Lexington; *Vice Presidents*, Dr. J. P. Thomas, Pembroke, Dr. J. H. Letcher, Henderson; *Rec. Secretary*, Dr. L. S. McMurtry, Danville; *Treasurer*, Dr. John D. Neet, Versailles.

Third Day.

SYPHILITIC IRITIS.

Dr. Wm. Cheatham read a paper on Syphilitic Iritis. After reviewing the most important features of the clinical history of this manifestation of syphilis, he advocated the use of atropia. He said the most important indication of treatment was the prevention of posterior synechia, and the breaking up of this result when formed. He recommended to general practitioners the use of sulphate of atropia in all inflammations of the globe of the eye, since no risks are incurred by its use, and much danger avoided.

RESECTION OF JOINTS.

Dr. J. W. Lewis, of Georgetown, read a report upon resections of the joints of the extremities, and gave in detail the statistics of conservative surgery as applied to the several joints.

A very handsome banquet was given the members of the Society and its guests, at the Phœnix Hotel, by the physicians and citizens of Lexington, at which the following toasts were offered: "Our Commonwealth—Prof. Yandell; "Politically, our Commonwealth—Our Governor, Hon. Lyndon B. Blackburn, Secretary of State; "The Kentucky State Medical Society," by Prof. D. W. Yandell, M.D., Louisville. "Our Guests," by Prof. T. A. Reamy, M.D., Cincinnati. "Memories of 'Old Transylvania,'" by Dr. A. S. Allen, Lexington. "Our Medical Schools—Like the mills of the Gods, they grind slowly but exceeding fine," by Prof. J. T. Whittaker, M.D., Cincinnati. "The Medical Journals—May they put forth their leaves only for the healing of the Nations," by Prof. R. O. Cowling, M.D., Louisville. "The Law," by Hon. Wm. Preston, Lexington. "Our Literary Institutions—the Foster Mother of the Profession," by Prof. J. K. Patterson, Lexington. "Our Medical Heroes," by Dr. L. S. McMurtry, Danville.

After the reports of special and standing committees, the Society adjourned to hold its next annual meeting in Lexington, on the first Tuesday in May, 1881.

Correspondence.

PASSAGE OF THE STATE BOARD OF HEALTH BILL.

Power of the Medical Profession in Legislation and Public Affairs.

To the Editor of The Medical Record.

Sir:—In a recent editorial in the Medical Record, you define, in well chosen words, the duty of the medical profession in its relations to the State, and assert, with proper emphasis, "that the profession must, for its own protection, take a more prominent part in public affairs and legislation." The position taken in that paper will meet the approval of every intelligent physician.

The passage of the State Board of Health Bill by the New York Legislature illustrates the influence which the medical profession can exert in legislation, and in public affairs, when that influence is properly exercised and concentrated. The details of the plan of procedure by which this hitherto objectionable and oft-defeated measure was carried quietly through both Houses is worthy of record.

By the action of the National Board of Health it became my duty to endeavor to secure a State Board of Health for New York. On conferring with the friends of the measure as to the course to be pursued, it was determined to rely upon the medical profession of this State for the necessary influence to secure the requisite vote in each House to pass the bill. In order to render that influence effective, and still not take any individual physician from his home, it was decided to adopt the following plan, which was accordingly carried into effect. Immediately

after the election last fall, the name and post-office address of every member elect was obtained. With the aid of the Transactions of the State Medical Society it was not difficult to locate an influential physician in the immediate neighborhood of each elected member. Correspondence was immediately opened with these medical men, and each was requested to take an early opportunity to explain to his representative the necessity of establishing a State Board of Health, and to urge him to support such a measure if introduced into the legislature. The response to this appeal was unanimous and most cordial, and before the meeting of the legislature a large proportion of the members-elect had expressed themselves favorable to the measure. The next step was to secure the preparation of a proper bill, and this service was most acceptably performed by W. P. Prentice, Esq., Attorney to the New York Board of Health, who has great practical familiarity with sanitary laws and legislation. The bill was subsequently submitted to many sanitary authorities, by whom it was approved and recommended. The third step was to secure for the bill the personal care of a competent member of each House. Through the good offices of Dr. Theodore Dimon, of Auburn, Hon. Wm. B. Woodin consented to take charge of the bill in the Senate, and at the suggestion of Dr. James Anderson, Hon. Isaac I. Hayes, of New York City, introduced the bill into the Assembly.

The bill was introduced into both Houses during the first days of the session. Meantime petitions were circulated throughout the State, largely through the aid of the Sanitary Committee of the State Medical Society, of which Dr. J. G. Orton, of Binghamton, was the efficient Chairman. These petitions were very extensively signed by the leading citizens of each locality. A paper was also prepared by Dr. Elisha Harris, entitled "Care of Life and Health in the State of New York," and printed by Mrs. Elizabeth Thompson, who took a lively interest in the success of the effort. This pamphlet was extensively circulated by medical men in all parts of the State, and had the effect of enlisting the co-operation of thoughtful citizens, and favorable newspaper comments and editorials.

The bill was first brought forward in the Senate, having passed the Committee on Public Health with a slight, but necessary amendment. Senator Woodin, who, at his request, had been supplied, from time to time, with papers on sanitary subjects, had become thoroughly interested in the measure and in its success. Writing March 6th, he says: "I am deeply interested in the subject and become daily more so as I read and reflect. I have read far enough to become profoundly amazed at my own and the general ignorance that prevails in regard to the laws of life and health and sanitary science. I shall devote the coming week to the consideration of the bill, and shall succeed, I think, in securing every vote in the Senate. At any rate, I shall try to persuade each senator to record himself in favor of the bill." The bill encountered no opposition when under discussion, and on the final vote received but one negative to twenty-eight affirmative votes. Although this result surprised many, the friends of the bill anticipated it, partly because of the powerful advocacy of Senator Woodin, but chiefly because it was known that most of the senators had already fully canvassed the measure with their medical friends at home and were favorable to its passage.

Our experience in the Assembly was not unlike that in the Senate. Dr. Hayes was cordially and efficiently supported by Dr. Z. G. Bullock, member from Cattaraugus, and Dr. A. P. Craftas, member from Wayne. Hon. James M. Husted, the leader of the House, also became a warm advocate of the bill, and in his usual happy manner brought it forward. When put upon its final passage it failed to receive a constitutional vote through a misunderstanding as to the identity of the bill. After a week's delay, during which the profession of the State freely communicated their wishes to their personal representative, the bill was again called up and passed by a vote of 82 to 6.

So the State Board of Health Bill became a law, much to the surprise of those who did not know the secret but all-controlling influence which governed the action of individual members of the Legislature. It was wholly the work of the medical profession of the State, each man acting in his own circle of influence *at home*. No medical man, or deputation of medical men, visited the capital to urge the bill through committees, or to button-hole individual members in its behalf. And yet the bill passed regularly, and with no unusual delay, through both houses, receiving but one negative vote in the Senate and but six negative votes in the Assembly. This result is the more remarkable when it is stated that such a bill has been regularly introduced into the Legislature for eight successive years, and has never before advanced to a final vote in either house.

This experience teaches that the medical profession, exerting its influence in its own proper, and, apparently, humble sphere, is a power in society and in the State capable of accomplishing the most radical reforms.

Yours respectfully,

STEPHEN SMITH.

NEW YORK, June 7, 1880.

CATHETERIZATION OF THE LARYNX.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—The articles relating to the resuscitation of asphyxiated newly-born children, that have lately appeared in your journal, suggest to me the propriety of narrating an experience of some six weeks ago.

A rachitic child was brought to the clinic for advice. Upon examination I found the pressing trouble to be "laryngismus stridulous." The case being typical, I seized the opportunity to lecture upon the subject. In dwelling upon the conditions that might give rise to sudden attacks of suffocative dyspnœa, I depressed the tongue with the finger to examine the pharynx; it was, of course, a risky procedure, but justifiable under the circumstances; instantly laryngeal spasm was brought on. Thinking it would pass off as other seizures had done, I proceeded to direct the attention of the class to the special traits of the kind of dyspnœa then so strikingly being illustrated. Before I could conclude, it was evident that the spasm was too complete and prolonged to permit of breathing—ceasing its struggles, the child fell over unconscious, but there was no effort at breathing; with the relaxation of unconsciousness I had expected the spasm to end and automatic respiratory efforts to continue, but not so; the spasm had ceased, but so had life, at least respiratory life. The cold douche, shaking, etc., had been used, hoping to end the spasm, but they had failed. Artificial respiration was now the only hope. The child being small, the Schultz method was first tried thoroughly, but it was of no avail. The Marshall Hall and Sylvester methods

were then successively tried, but all failed. Several minutes had now passed since there had been any attempt at voluntary breathing—the eyes were fixed and glazed, the entire surface cold and cyanosed, the child, in fact, virtually dead. Taking the stethoscope and listening attentively, I found the heart beating at the rate of about 25 or 30 to the minute. Seeing that it was utterly useless to continue the external methods of artificial respiration, I called for a catheter, seizing the tongue with an artery forceps and drawing it well out, I passed it to an assistant, then taking the catheter handed me, a soft rubber instrument, I tried to enter the larynx, but I utterly failed, for the instrument was too yielding to be guided properly. Asking for a metal instrument, a No. 8 silver catheter was handed. Without the slightest difficulty I passed it well beyond the cords into the trachea below, the right hand held the instrument, while the index finger of the left held up the epiglottis and guided the point into the larynx. The heart was still acting but more slowly and feebly even than when the efforts at catheterism were begun. I now blew gently through the catheter, easily inflating the lungs. The assistant then compressed the thorax and abdomen, causing expiration. The alternate filling and emptying of the lungs was thus kept up, at proper intervals, until it had been resorted to some three or four times; still there was no attempt at voluntary respiration on the part of the child. It was evident though that the blood was being oxygenated, for the cyanosis gave place to the pinkish hue. This change of color was the first evidence that our efforts were meeting with success. At the close of the fourth or fifth artificial respiration, the first involuntary effort was made in the usual tremulous uncertain manner. Our measures were now conducted more gently. In a few minutes voluntary respiration was fully re-established, then the catheter was withdrawn.

The child made a complete recovery, and at the end of four weeks was discharged from the hospital. The rickets remained, but there had been no spasm of the larynx of any moment since the one that came so near proving fatal.

Catheterism of the larynx as a means of resuscitating the asphyxiated has been suggested from time to time, but I know of no case establishing its superiority so entirely as that which I here report. With a stiff instrument, the procedure is so simple and so much more certain than all other methods of exciting respiration, that it seems to me it should be given more prominence than it has hitherto enjoyed. My experience with the case in question proves its applicability to children, and some experiments made a few days ago upon the adult cadaver showed that it can be employed upon the adult.

These experiments were undertaken to test the difficulties of catheterization of the adult larynx. It was found that the operation was somewhat more difficult than in the infant, dependent upon the difference in the length of neck. This could be overcome, however, by thrusting up the larynx, as will be described.

The condition of unconsciousness would seem to be the most favorable to the proper performance of the operation. The condition, in fact, that exists in actual or impending asphyxia, such as the asphyxia of the new-born, of the drowned, of convulsions, of cases of opium or carbonic oxide poisoning—any case, in fact, in which the Schultz, Marshall Hall, or Sylvester methods of artificial respiration are called for. That it is greatly more certain than any of those methods, and, I may say, than any of their modifications, this case would seem to prove, and that it is not more difficult in properly instructed hands any one can test for himself. Again, let me say just here that it is greatly superior to any effort at filling the lungs by merely blowing into the child's mouth. Any one who has tried that method, and has seen how much air goes into the child's stomach and how little into its lungs, cannot doubt the force of the assertion. Touching the after-effects of catheterism of the larynx, I can only point to the fact that in the case narrated there was not a single ill consequence.

In conclusion let me recapitulate the details of the procedure.

In the adult or child with teeth, fix the jaws open by means of a cork, seize the tongue with a tenaculum or other instrument, draw it well out, and hand to an assistant. Pass the index finger of the left hand well down into the mouth, find the epiglottis, go beneath it, and place the finger over the laryngeal opening. Take a stiff catheter, No. 8 or No. 10, with the right hand, and using the left index finger in position as a guide, pass the instrument into the larynx. Be sure that the eyes of the instrument are well beyond the vocal cords. The assistant now extends the patient's arms above the head, the operator at the same time blowing up the lungs through the catheter. The arms are next brought down, and expiration accomplished by compressing the abdomen and chest. A respiratory act is thus accomplished. The procedure is continued with regularity, so as to simulate as nearly as possible the normal respiratory interval.

The extension of the arms above the head during the filling of the lungs through the catheter is more important, I should think, in the adult than in the infant.

As has been intimated, catheterism of the adult larynx is somewhat more difficult than the same operation with the infant larynx, the chief difficulty being the greater depth at which the opening to the adult larynx is situated. This can be overcome by letting some one seize the larynx from the outside and thrust it up. In that way the opening is brought in easy reach of the index finger in the pharynx, when the catheter can be readily passed.

W. M. POLK, M.D.

N. Y., May 27, 1880.

CYSTOTOMY FOR CYSTITIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Permit me to correct an error which I made in my article on "Cystotomy," published in your last week's issue. Dr. Howe has since informed me that he only introduced a speculum into the bladder in his cases after the dilatation of the prostate had been completed by other means, and then only for the purpose of examining the diseased mucous membrane. Moreover, to add that in his last case (No. 30) the relief of the sufferings of the patient was very marked.

Yours very truly,

R. F. WEIR, M.D.

NEW YORK, June 14, 1880.

THE JERSEY CITY CHARITY HOSPITAL.—Severe criticisms are appearing upon the unhygienic condition of this hospital. It is stated that it is old, badly located, badly built, and badly sewered. No excessive mortality, however, has occurred in it.

New Instruments.

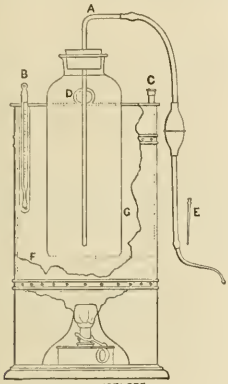
A NEW AURAL DOUCHE.

By C. R. UPSON, M.D.,

ATLANTA, GA.

Having frequent occasion, in the treatment of aural and nasal affections, to apply plain and medicated solutions to these parts, and appreciating the comfort to the patient—to say nothing of its benefits—of maintaining the solution used at a uniform temperature during the whole period of its application, I have devised an apparatus which fulfils this indication.

It consists essentially, as will be seen by the cut, of a glass reservoir of three pints capacity, which is placed in a copper water-bath, provided with a thermometer in its top—and this in turn is enclosed



CODMAN & SHURTLEFF, BOSTON.

in a sheet-iron jacket, containing a spirit-lamp—the tube of which is provided with an outer cylinder by which to regulate the size of the flame. The solution is forced from the reservoir by means of an atomizing bulb and tubing attached to a glass tube, passing through a rubber stopper, to the bottom of the vessel. The apparatus is provided with nozzles for applying the solution to the ear and posterior nares.

I would briefly call the attention of the profession to the advantages claimed for this apparatus: 1st. The solution, being contained in a *glass* reservoir, may be medicated with any remedial agent which the physician may elect. 2d. The solution may be maintained at any desired temperature—indicated by the thermometer in the top of the bath—by means of the spirit lamp. 3d. The capacity of the reservoir—three pints—being sufficient for any application which may be required at one sitting. 4th. It may be used—by attaching a longer piece of tubing and placing the apparatus in an elevated position—as a syphon. 5th. Its simplicity in construction, there being no complicated parts to become disarranged.

In addition to the uses already named—as an aural and nasal douche—it will be found a valuable means of applying solutions to the mucous membrane of the bladder, vagina, and even to the cavity of the uterus itself. I have for a considerable time been using this apparatus—though in a rude form—and have found it so useful that I have had a more perfect one made for me by Messrs Codman & Shurtleff, Instrument makers, Boston, Mass., who will supply such other members of the profession as may desire one.

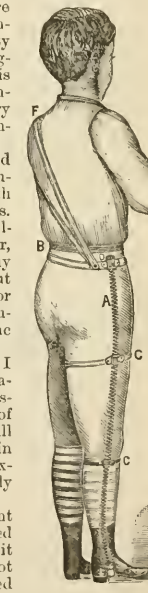
Since penning the above, a troublesome patient has impressed upon my mind the advisability of having the free use of both hands while syringing the ear, in order to secure which I have bored a second hole in the rubber stopper of the reservoir, through which I have inserted a tube (of the same size and shape as that which accompanies the douche) but a short distance, not allowing it to touch the solution. To the upper end of this tube I have attached an ordinary atomizing bulb with a sufficient length of tubing to allow of its resting upon the floor—thus enabling me to compress it with my foot.

APPARATUS FOR INVERSION OF THE FOOT.

By GREGORY DOYLE, M.D.,

SYRACUSE, N. Y.

In operating on talipes equino varus, I find it comparatively easy, after dividing the contracted tendons, to enable the patient to place his foot on the ground right side up, *i. e.*, with the entire sole facing downward. In the great majority of cases, however, there still remains that persistent inversion of the foot, a deformity nearly as unsightly as the original trouble. To remedy this inward rotation, I have constructed an instrument very clearly illustrated in the accompanying cut:



I have a patient two years old who has been using this instrument nearly three months with the most satisfactory results. While wearing it the little fellow can walk, run, sit down, or, in fact, get himself into any conceivable position without disarranging the instrument, or in any way hindering its complete constant eversion of the feet.

On the 27th of April last, I brought him before the Onondaga Medical Society and illustrated the practical working of the spiral rotating power. All the members who took part in the discussion concerning it expressed themselves as entirely satisfied with its workings.

In applying the instrument the belt is first to be fastened around the pelvis, and when it is necessary to rotate the foot *outward* the shoe may be turned

A. Spiral steel spring. B. Belt around the hips. C. C. Loops and straps to hold spring in position. D. Set-screw by which tension is regulated. E. Plate by which spring is fastened to shoe. F. Shoulder-strap to prevent belt rotating. Where springs are used on both limbs the shoulder-strap is unnecessary.

turned two or three times, as the case may require, and fastened on the foot. This has a decided and constant tendency to bring the foot into a normal position and retain it there. If a freer adjustment be desired it can be accomplished by the set-screw, D.

In cases of abnormal lateral mobility of the ankle, an ordinary ankle brace may be used in connection with the spring. The appliance works equally well where it is desired to *divert* the foot as in cases of talipes valgus or splay foot.

As will be seen by the above cut the subject is represented with the instrument applied over the wrapper and drawers, so that when he is fully dressed it is almost entirely hidden from view.

Children who have the congenital or acquired habit of walking with the toes turned in (popularly known as pigeon toed), can in a short time be educated with the spiral spring to walk properly.

I have applied this same rotating power to a case of long neck or torticollis with equally satisfactory results. The principle is the same, with a slight modification in construction.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from June 6 to June 12, 1880.

Bartholf, J. H., Capt. and Asst. Surgeon. Now on leave of absence; relieved from duty in Dept. of California, and to report to Comd'g Gen'l, Dept. of the Columbia, for assignment to duty. S. O. 123, A. G. O., June 4, 1880.

Reed, W., 1st Lieut. and Asst. Surgeon. Granted leave of absence for one month, with permission to apply for an extension of two months. S. O. 124, A. G. O., June 5, 1880.

Gray, Wm. W., 1st Lieut. and Asst. Surgeon. Relieved from duty at Fort Point, Cal., and to return by steamer on May 31st to his proper station, Vancouver B'ks, W. T. S. O. 75, Div. Pacif. and Dept. Cal., May 26, 1880.

* Emigrants at Castle Garden.

The Diseases of Underwork.—We have heard a great deal about the diseases of overwork, and it would be interesting to see if something cannot be said now regarding the "diseases of underwork." That man is naturally a lazy animal is a proposition often made and never refuted. We have a great many lazy people even in this country. It is to be hoped that some enterprising pathologist may take a special study of these. He may find a new disease. There are certainly cases of adipose tissue and gastrosthenia. Who will be the first man to write a book on the subject?

Fuller Fund Prize.—At the annual meeting of the Rhode Island Medical Society, the Fuller Fund prize of two hundred dollars was awarded to Dr. C. V. Chapin, house physician at Bellevue Hospital, in this city, for the best essay on "The Sympathetic Nerve and its Relation to Disease."

Mr. W. U. McGuffey writes: In the Medical Record, No. 24, second column of the 678th page, seventeenth line from top of page, for "cardiac" read "cardiac." On the same page and column, twenty-third line from bottom of page, for "spasms and conditions" read "spasms and convulsions." Two lines below, for "emanations" read "emotions." In the twelfth line from the bottom, for "cadera" read "chorea."

Dr. Barstow, Medical Superintendent of Sanford Hall, Flushing, gave a reception at the asylum to the members of the Medical and Surgical Society on the afternoon and evening of June 12th. Besides the members of the Society, a number of distinguished invited guests was present. An elegant supper was served, and the evening was, as usual, a thoroughly enjoyable one to all present.

Errata.—For "veratrum," occurring twice on page 559 of the Record (May 22, 1880), read *veratrine*. The ointment was then made by prescription, five to twenty grains of veratrine to an ounce of lard, or simple ointment.

The Eleventh Annual Commencement of the New York Medical College for Women was a very successful affair. There were nine graduates, all but one being from Massachusetts or New York. The valedictory, by Dr. Christiana I. Fuence, was devoted to a comparison of women with men in the practice of the arts and professions. Professor Bolton, of Trinity College, read a "Historical Sketch of the Early Practice of Medicine by Women."

An Examination of Candidates for the U. S. Marine Hospital Service will take place at the Custom House, in this city, June 21st. The examining board consists of Dr. C. S. D. Fessenden, Surgeon-in-Charge at the Port of New York, and of Surgeons Doering, of Portland, and Miller, of Chicago. The examinations will last about a week. From twenty-five to thirty candidates have applied. The position competed for is that of Assistant-Surgeon, with a salary of $1,600 a year and quarters. There is said to be three or four vacancies.

An Orthopædic Hospital has been founded at Bologna, Italy, through the munificence of Professor Rizzoli. He has given $250,000 toward its establishment.

Books Received.

Pathogenetic Outlines of Drugs. By Heinicke. Translated by E. Tietze, M.D., Philadelphia. New York: Boericke & Tafel. 1880.

System of Medicine. Edited by J. Russell Reynolds, M.D., F.R.S., etc., with additions, etc., by Henry Hartshorne, A.M., M.D. Vol. III. Philadelphia: H. C. Lea's Son & Co. 1880.

Original Lectures.

ON VARIOUS FORMS OF FUNCTIONAL CARDIAC DISTURBANCES.

By BEVERLEY ROBINSON, M.D.,

LECTURER UPON CLINICAL MEDICINE AT THE BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

GENTLEMEN:—Functional or neurosal conditions of the heart differ essentially from those which are organic or inflammatory in their nature. In the one case we have no evident lesions when the heart is examined post-mortem, and in the others we have usually, if not always, some obvious change in valves, or orifices, or heart-walls. During life they differ, also, with structural diseases. Their symptoms are more variable, more painful and distressing frequently, and they are continually forcing themselves upon the patient's attention. About their importance no one can doubt, since they are frequently confounded with permanent lesions, and yet are themselves amenable to wise, careful, judicious treatment. Functional trouble of the heart may be temporary and passing, or it may be permanent in character. It may be part of a general nervous temperament, or it may be dominated by some purely accidental circumstance. It may be primary and essential, and then, so far as our knowledge to-day extends, seated in the cardiac ganglia. It may be of reflex origin, or dependent upon some remote disease of the genito-urinary system, especially in women. Such are those cases which are found with a prolapsed or displaced womb, or with an ovary the seat of chronic inflammatory change. Further, functional trouble of the heart may be closely allied, or connected with, all those different pathological changes as they affect the blood, the central nervous system, and the stomach. Finally, we have "irritable hearts"—hearts which are weary and worn, owing to the cares and anxieties of life, to long night-vigils, to overwork, both mental and physical. In this latter category we shall have to consider the hearts which have become irritable in men of the best type—in those who strive and struggle for their own and others' rights or happiness, and who are the prey, as it were, of their personal self-abnegation and sacrifice: such an one, at times, is the overworked and too conscientious family practitioner. Functional disturbance of the heart is marked by cardiac palpitations. These palpitations may be violent and accompanied with strong, rapid pulsations, or they may be moderate and conjoined with weak and slow beats of the radials. Almost always with an attack of cardiac palpitations, we have a lack of regularity or proper rhythmic succession in the cardiac sounds. Palpitations may be brought on by more or less physical exertion, as the fact of going upstairs, or lifting a weight of some magnitude. Again, they may be brought on by an incident of an emotional character, which has disturbed greatly the nerves which govern the heart's normal movements. Too often they come on without assignable cause and at times when one might least expect them. In the middle of the night a patient is frequently awakened from a peaceful sleep and is suddenly tormented with most distressing palpitations, and at the same time very gloomy forebodings. This condition is encountered particularly, however, with persons passed middle life, who have somewhat enlarged hearts and atheromatous arteries. They have, when they awake, an attack of true cardiac asthma. In searching for the proximate cause, we shall be able at times to affirm that it lies in a dyspeptic condition. The stomach is at fault, and when its deranged digestion is quiet and better ordered, the attacks of cardiac asthma are cured. You all know of the disease described by Graves and Basedow—of the three principal classes of symptoms: first, those which pertain to the prominent eyes; second, those belonging to the enlarged thyroid gland; third, those which are annexed to the overacting heart. In such patients there is no counting the pulse accurately with the fingers at times, so fast does it go. Well, this disease is by some located in the sympathetic system, and it is this location, doubtless, which explains the rapid cardiac contractions. Of course, all heart trouble in this disease is not purely functional, for we find in its advanced stages that the heart becomes enlarged—how much owing to continued overaction, I am not wholly prepared to say. In an analogous category with Graves's disease come those murmurs at the apex, and rapid, irregular beats of the heart which are met with in chorea. We can but attribute these symptoms to the want of synchronism about contraction of the intrinsic cardiac fibres, and particularly of the musculi papillares. And now I wish to draw special attention to the condition known as "irritable heart." This name was first given to it in our late civil war, by Prof. Da Costa, of Philadelphia, and to those who wish an interesting and highly scientific consideration of an important subject, I refer them with strong emphasis to his writings in the United States Sanitary Commission Reports, 1867, in the *Am. Jour. Med. Sciences*, 1871, and in the Toner Lectures for 1874.

Such reading will be very profitable, for it will be noted and acquired that what was a frequent form of disease in the army, owing to overmarching, to diarrhœa, to fevers, is also becoming frequent in civil life, owing to tobacco, tea-drinking, sexual excesses, and inordinate physical exercise in the way of dancing, rowing, and baseball. Under this name is included what Fothergill has described as "hyperæsthesia" and "sub-paralysis" of the heart. This affection is marked by irregularity of the cardiac rhythm, overaction of its movement, pain in the precordial region, and a feeling of faintness. In the milder forms rest will, in a brief period, greatly ameliorate this condition. In aggravated cases it renders the patient unfit for the routine duties of business or professional life, and remedies affect it favorably only by very slow degrees. Upon more than one occasion hypertrophy of the cardiac walls was evident both before and after death. Never thus far, however, have either the muscular or nervous fibres been found degenerated. During life the heart beats very rapidly, the impulse is more diffuse, though not perhaps increased always in force, and there is a moderate blowing murmur covering the first normal sound, and heard with greatest intensity at the apex. This is not invariably true, however, as the first sound is at times only more abrupt than usual, but is wholly free from the presence of a murmur.

The second sound is clear, but, according to Fothergill, not as markedly so as in a dilated heart. There is almost invariably a feeling of oppression around the precordia, and the brain is apt to be attacked with vertiginous sensations. The patients are taken occasionally with sudden and painful palpitations, and it is no unusual thing for this to occur in the middle of the night. Sleep is at times much

disturbed and these patients are unusually restless. They cannot lie on the left side on account of the increased pain caused by this decubitus. There is evidence of cardiac disturbance in the very frequent and depressible pulse. Upon the slightest exertion, the from relatively quiet and tranquil, will become agitated and extremely rapid and it is not remarkable to see it mount to 120 or 140 beats per minute.

The extremities perspire easily and have a cold, clammy feeling, which is an additional proof of general nervous prostration. These patients are at times affected with severe dyspnœa, and yet, when we count the number of respirations, we do not find them increased so as to be above the normal. It is a remarkable circumstance that this affection has been many times confounded with pulmonary phthisis. I can understand many reasons why, even after careful research, one might properly hesitate between it and hypertrophous dilatation—the more so, as irritable heart is often accompanied with or followed by this form of organic change. But it appears to me somewhat far-fetched, with the signs above given, that any one should be in aspect of consumptive carelessness. All physical signs, moreover, of lung disease are absent; and the irritative cough present, with the slight and interrupted spitting of small pellets of blood-stained mucus, are not sufficient properly to withdraw one's attention from the heart.

The prognosis of irritable heart is favorable if the whole disease consist of temporary exhaustion of the sympathetic; but if, in consequence of repeated overexertion, the heart becomes organically affected, then we have to do with an affection which is almost always prolonged and sometimes serious. Such cases are reported as having followed an affection of the uterus, and also the inveterate use of tobacco. Usually the signs of the resultant lesion are similar, viz.: there is extended impulse and increase of precordial dulness on percussion—both of which point to the existence of an enlarged heart. An analogous form of heart affection may be caused in individuals who have undergone very intense exertion without having previously been in training for it. Such an example is that of Clifford Allbutt, who has given a full account of his own experience in an article upon "The Effects of Overwork and Strain on the Heart, etc.," in *St. Geo. Hosp. Reports*, vol. v., p. 23. Dr. A. had made a very lofty ascent, and was about to go still farther and higher when he was taken suddenly with a stifling sensation and painful cardiac pulsations in the epigastric region. Unable to proceed, owing to the distressing sensations from which he suffered, he lay flat on his back for awhile and then, feeling better, attempted once more to continue his ascent on foot. The same painful feelings returned almost immediately, so that he was compelled to delay his onward march some time and send his companion in advance to secure lodgings for them during the night. Finally he was able to go on. When he again reached level ground his normal feelings returned, and that same evening he was able to eat his supper with appetite and go, without discomfort, to bed.

During the night, after several hours of sound sleep, he awakened with similar painful sensations to those he had experienced during his afternoon walk. In this instance there had evidently been over-distention and temporary debility of the muscular walls of the right ventricle, which had been brought on by an acute strain upon the heart strength. Overexertion, without preliminary training, here occasioned but passing dread, with intense oppression, while there can scarcely be a doubt that, under like circumstances, rapid death has been the frequent and sad result. We should bear in mind an example like this whilst remembering that heart disease can ordinarily be traced to the pre-existence of rheumatic fever, of scarlatina, typhoid, typhus, etc. Still, mechanical causes are at times equally injurious, and affections of the valves or cardiac walls may thus be occasioned. It is a singular fact that but little emphasis is laid upon these causes by the majority of English and French authorities. Even so accurate and complete an analyzer as Hope barely alludes to them, and such men as Jenner write, as late as 1870, only to deny their influence. Doubtless, as remarked by Allbutt, the practice of this distinguished clinician did not lead him in the way of encountering many such cases. In the view of Clifford Allbutt it is regrettable that, although so much has been published in regard to cardiac pathology, the character and mechanism of brute, the therapeutical bearings of numerous cases, this equally important subject has been almost completely overlooked. And yet certain occupations do undoubtedly give rise to organic cardiac disturbances. Heart disease among soldiers has been fully described by Myers in 1870. Peacock mentions it in a special manner as existing among those who work in tin and copper mines, and Da Costa among those who make excessive expiratory efforts, as glass-blowers and cornet-players. Most of you saw the lad I presented at this clinic only a few weeks since, who had already acquired considerable hypertrophy of heart, with obstinate recurrent attacks of hæmoptysis, due to nothing else than the continuous fatigue and strain in his trade. The gist of this matter has evidently been ascertained by Da Costa with that clearness and correctness of insight which stamp his observations. He shows conclusively, in his monograph on this subject, that it is not so much *interrupted* exercise which does damage to the heart, even if it be of violent nature, as it is the professions in which the circulation is constantly impeded or hurried. Of course it is not affirmed that violent games will not produce both functional disturbance and occasional organic difficulty—notably hypertrophous dilatation, for examples of the contrary are shown. Thus, among what are ordinary amusements with young people, such as dancing, rowing, base-ball, we find instances of functional trouble which finally pass into organic heart disease.

Still, when these latter could be vouched for, they have occurred first in those persons who were predisposed to have irritable heart, and second, among persons who had no let-up in their active amusements. With base-ball players Da Costa cites two cases of hypertrophous dilatation. But here again the injurious results followed almost continuous play, and not play that was interrupted during several days or weeks at a time.

In volume xviii. of "Ziemssen's Cyclopædia," Dr. A. Brayton Ball, of this city, has contributed an excellent article on "Physical Exercise," and under the division of "Results of Overexertion" shows that, so long as muscular exertion conforms to the law of rhythmic action, it develops the muscles and augments their strength; but, if the exertion become continuous, then it decreases their power, and finally leads to atrophy, or, worse still, to degeneration. Applying this to the heart, it is not difficult to appreciate that through overexertion we shall inevitably diminish the duration of cardiac repose by encroaching upon diastole through increased rapidity of action. Thus we approximate to a condition of almost

continuous work for this organ, which must occasion the same detriment to it as it does ultimately to any one of the purely voluntary muscles which is being constantly called upon after an analogous manner. Doubtless the heart is sooner and more injuriously affected among those who are poorly fed, breathe an impure atmosphere, and are victims of alcohol, than among those who suffer from no such pernicious circumstances. Dr. Ball makes a few forcible remarks against the senseless habit of long-distance walking which is so intensely the fashion of the moment. In it he finds a useless expenditure of reserve force, which can only be made with the certainty of causing future permanent injury to the contestants. According to this author, the best way probably to prevent bad consequences to health resulting from active physical exercise is to appoint a competent medical man in each one of our large institutions of learning, where there are many students, and, therefore, many who engage in outdoor sports, whose duty it shall be to examine each young man with respect to his physical condition. After this examination has been thoroughly made, only those of vigorous build, and who at the same time enjoy good health, shall be permitted to engage in games or contests for which just these attributes are essential, so that harm may not result from indulgence.

In regard to the treatment of all such cases of irritable heart, or of those in which debility has already shown itself by some dilatation, special importance must be attached to rest on the back; and with "heart-weary" people it is a great point gained to have them avoid just those professions which are calculated to increase their disease. Above all, let the thorough-going, typical, too rapid American be perfectly assured, as Da Costa remarks, that constant running to catch a boat or a train, or "bolting" all meals, is bound to injure his heart as much and more than the coats of his stomach. Sexual excesses are also a frequent cause of irritable heart, and functional disturbance thus caused is not the price paid only by men or women of profligate habits. Moral men—men whose duty to the state is properly shown by a vigorous and increasing family—are sufferers, and have become so by an apparent ignorance of the fact that because indulgence is not socially censurable, it is individually of possible injury to health. Such individuals (clergymen, farmers, lawyers, etc.) often owe their general lack of energy and bodily activity to irritable hearts thus occasioned. We all know many of the disastrous consequences which are the immediate outcome of drinking to excess. Among these none are more frequent than the weakened heart and soft, weak, rapid pulse of the steady drinker, or of one who frequently "makes a night of it." To some persons tobacco is relatively innocuous; to others it is a poison, even in mild and minute doses. To many, mild cigars are not injurious, but strong tobacco completely unnerves them. How many young men suffer cardiac palpitation which are attributable to no other cause? The close student is often just the one who is thus affected. After the excitement of examination is passed, then it commences to tell, and he can scarcely walk a block at a rapid pace without feeling his heart leap into his mouth. At night he hears his arteries throb, his heart beats in a very irregular manner, and sleep is prevented for several hours. To remedy this, whatever else be done, tobacco must be put aside for several months.

The green-tea drinkers of our mothers' and grandmothers' days were certainly more numerous than they are in our own day, and, I judge, must have had very irritable hearts. For even now, and when English breakfast tea is pre-eminently a lady's drink, still attacks of painful palpitations are common among them, and to remedy them we must adopt Fothergill's plan of prescribing *cocoa* as a beverage, with a doubting faith, however, lest they soon again relapse into their former pernicious habit of excessive tea-drinking. To show the influence of the mind over the action of the heart, Fothergill cites the case of a medical student who, when asked a question the answer to which required thought, had immediately a changed cardiac rhythm and intermissions of the pulse-beat. Whenever the answer was given without thought, the action of the heart remained undisturbed. We are all of us aware how much our heart-action is influenced by emotions or temporary excitement, but we are not all aware how much control of the cardiac centre may be acquired by an effort of will. The accomplished statesman is, however, able to control every utterance which indicates emotion, and this is, perhaps, as great a proof of regularizing heart-action as the others familiarly cited of the finished coquette or the winner at Creedmoor.

In his usual brilliant way, Fothergill touches the keynote of this matter in saying there are "stout-hearted" and "faint-hearted" people—those who can be relied upon in an emergency and those who cannot—those, in other words, who can control their hearts under circumstances of great excitement or impending danger, and those who then become powerless and useless.

There are many other causes of cardiac palpitations that we have not as yet alluded to. Among the frequently encountered are plethora, anæmia, dyspepsia, and gout. We have already seen that an overtaxed heart becomes irritable. So in a certain way do we find the heart of an individual whose blood is in excess. The muscular fibre of the heart is unduly excited, the origins of the pneumogastric trunks receive too much blood, and there are frequent and violent palpitations as a result of the preceding conditions. These symptoms are apt to occur among individuals who, for one reason or another, have abandoned active and abstemious habits of life for those of ease and self-indulgence. There is no more prolific source of functional heart trouble than an anæmic state. We are constantly encountering it in city practice. Numerous causes may be assigned for the presence of anæmia, but once present it will often become the source, not only of cardiac palpitations, but also of many secondary phenomena, which indeed appear to be very similar to those we find in connection with organic heart disease. The prognosis and treatment being so very different in these two conditions, it should make us very cautious in affirming our diagnosis. Usually, functional heart disorder, due to anæmia, is accompanied by numerous other symptoms which fully establish its etiology. Such are headache, intercostal neuralgia, cold extremities, leucorrhœa, etc. Palpitations are often aggravated, if not directly occasioned, by the presence of atonic dyspepsia. Wind accumulates in the over-distended stomach after a meal, and soon the heart is pushed aside and its circulation is directly interfered with and becomes markedly laborious. This same mechanism will account for cardialgia which is so apt to show itself in hysterical women during a paroxysm. In both cases the immediate exhibition of a carminative, such as the compound tincture of lavender, aromatic spirits of ammonia, or melissa water, will, by bringing up the wind from the stomach

or excessive to be localized, give almost instantaneous relief. In speaking to you at a previous lecture of the effects of spasm of the capillary system, I pointed out to you how sudden palpitations might be produced in a wholly unexpected manner, owing to spasm of the arterioles. I recently thus effect upon the rhythmic beats of the heart was presumably due to an accumulation of lithic acid in the blood, and even in the last edition of the work of your eminent Professor of Practice it is thus described. But within a few years, thanks to the distinguished researches of Sutton and Sir William Gull, but more especially of Greenfield Sikes, of King's College, London, it is now accurately determined that there is hypertrophy of the muscular tubes in some cases, of the fibrous tissue of the walls of the arterioles in more numerous instances, and of a combination of both changes in a very limited number of examples, which accounts for gouty palpitations. Doubtless uric acid is still to be found in excess in the blood, but it does not seem to be the proximate factor in causing spasm throughout the capillary system. This, once again, is due to an evident, determined pathological lesion. Why it is that gouty palpitations come on during the night particularly, I am not prepared to say. After all, in the consideration of cardiac palpitations, we must not lose sight of the fact that cardiac excitability varies very much with different individuals: some there are whose heart palpitates from even the slightest emotions; others bear with the greatest stoicism, or rather most perfectly calm, quiet circulation, all sorts of sudden shocks or dreadful occurrences. All the causes which affect merely the rapidity and force of the cardiac action, influence it through the sympathetic system; those which act through the pneumogastric alter the rhythm of cardiac movements. This is distinctly shown by the results of the experiments of sectioning those nerves.

While we can separate in our experiments the control which belongs to each system of nerves, this is not always possible with certain morbific agencies. The symptoms present often show conclusively that they have acted through both systems. While the nervous trunks no doubt usually carry the impressions and modifying stimulus to the heart, it is often true that the nerve-centres themselves are primarily disturbed.

Apart from the symptoms which can be localized, and, therefore, attributed to the heart directly without much reason for uncertainty, there are many general symptoms which manifestly must differ according to the different cause or pathological relations of the cardiac disturbance.

Physical investigation discovers clearly two facts: 1st, that there is no evidence of structural lesion. 2d, the presence of signs which enable us to affirm that the heart's walls and orifices are sound. If we bring percussion to our help, we find the heart has its usual size. Whenever functional trouble is conjoined with organic trouble, ordinarily the heart is, without question, more or less enlarged. Palpation of a heart functionally disturbed finds the apex at its normal seat; does not recognize such increased power as one would expect to find if the organ were hypertrophied, and seldom has a sensation approximating that of a "thrill." If auscultation be employed, there are usually no murmurs, and the heart-sounds, barring what is due to excitability, are healthy. If murmurs exist they indicate the accompanying blood condition, and this is indicated more by their seat and time of greatest intensity than by anything in the actual tone of the murmurs themselves. We have had great reason to believe, during the last few years, that many cardiac murmurs, once assumed to be evidence of organic trouble at the orifices, are only due after all to what should be considered functional trouble. And in the same line of reasoning I would now hold that, even with very pronounced disorder of cardiac action, it is not correct to infer the existence of either dilatation or fatty degeneration of cardiac fibre. The causes mentioned above are usually the origin of all the symptoms, and once they are effectually removed, the heart will come right of itself. The first sound of the heart affected with functional disturbance is sometimes accompanied with a clearly distinct metallic timbre, which is due, oftentimes, not as Hope affirms, to the noise of the cardiac impulse against the sixth rib, but simply to a stomach inflated with the gases of imperfect and prolonged digestion. I have seen this symptom persist for many weeks, and then quietly subside under the influence of a well-systematized treatment directed against the dyspepsia. In the diagnosis of functional trouble of the heart, the first and most important matter is to determine that no organic heart affection exists. Afterward we must endeavor to determine to what extent the signs present are occasioned by complicating symptoms of functional nature. This we are unable accurately to affirm in a certain number of cases, after a single examination, no matter how carefully and accurately made. Upon weighing fairly all symptoms present, the age and circumstances of the patient, his preceding history, his hereditary tendencies, the nature of his employment, etc., we are still obliged to apply the touchstone of treatment in order to reach the exact truth. Even physical examination, so sure at times in the results afforded, will occasionally leave the mind uncertain as to the correct interpretation of the signs it makes known. The normal sounds of the heart are so much obscured by rapidity and irregularity of action, and so many general phenomena are present which may, at first, be attributable to organic disease, that we are forced to suspend judgment for a time. True it is that the varying degree of painful symptoms, their lack of permanency particularly, and the absence of grave disturbance, such as dropsy, hemorrhage, paralysis, etc., all point more directly to functional disorder than to structural disease.

But how many examples of the latter kind remain for a long period ignored, owing to the simple, though not always recognized fact, that they are covered up, or concealed from view, as it were, by the presence of a complicating neurosal affection, only those who practice frequent auscultation can be aware. Now it is just this very troublesome element of disease, the nervous one, which it is important to eliminate by judicious treatment, and to do this quickly and effectually we must rely, to a certain extent, upon the proper use of well-selected therapeutical means, but we should also rely greatly upon moral power. If the physician consulted be thoroughly conversant with the complex nature of the affection he is called upon to treat, and yet feels confidence in his own resources, he will take positive ground by affirming in the beginning that many, if not all of the distressing symptoms experienced by the patient, are the sequelæ of a deranged nervous system. He is abundantly justified in so doing, first, because in the majority of instances the future will prove the truth of his statements, and in the few instances in which he may, perhaps, be partly in error, the immense moral weight obtained from the start is of incalculable advantage to the patient. And even

supposing, what is only rarely true, that there is in reality present an advanced stage of organic cardiac disease, we know well, by daily contact with hospital patients, that freedom from emotional excitement, perfect rest and tranquillity, good food, haematinics, and the moderate use of digitalis, strychnine, and carbonate of ammonia, will work wonderful results. Make such a patient despair by telling him he has incurable or real cardiac disease, and soon the onward and downward tendency of his disease will be so marked, in spite of all our efforts, that we shall have to deplore rapidly fatal cases in which, by a justifiable deceit, there was the possibility of several years of life. Of course such a line of conduct as I have traced would not be permissible where sudden death might be anticipated or major interests of great moment are at stake. And look for a moment at a sad, though usual example, of daily occurrence: Take a young fellow, like one among yourselves, who is simply run down temporarily in bodily vigor by too great sedentary occupation, combined with mental strain, and, perhaps, abuse of tobacco and coffee. He commences to be troubled with disagreeable, or even painful cardiac sensations. He cannot sleep comfortably at night, and after a half-dozen whiffs of a cigar, or a rapid walk of short duration, his heart seems suddenly to stop, or to beat forcibly and rapidly for a few moments, and then give intermittent and irregular shocks, which make him believe that all his internal machinery is out of gear. Under these circumstances he consults some experienced physician, who informs him solemnly that he has heart disease. What is—what can be the result—but gloomy forebodings, and a restless, irritable feeling which forbids all steady, honest work, and makes him for months and years the victim of groundless fears? Better far that the examination had never been made, or the medical man consulted, for after a time, with improved hygienic surroundings, and more sleep and leisure, such cases might often come out all right. If not, abandonment for a time of tea, coffee, and tobacco, and the use of moderate doses of henbane, chloral, or aconite, with the local application of a belladonna plaster in the precordial region, will get the heart soon in good working order. During a painful attack of cardiac palpitations it may be advisable to give an opiate or an antispasmodic remedy. Tincture of lavender, aromatic spirits of ammonia, chloric ether, elixir of valerianate of ammonia, etc., are all good, and may be severally employed with advantage to the patient in relieving his distress. For several years past it has been my habit to combine the three first in equal quantities with an amount of syrup equal to the three in bulk. Of this mixture I give a teaspoonful in a little water every hour, until the painful feelings are notably relieved. Alcoholic stimulants are not debarred by this method of treatment, especially if the patient be weak and complain of fainting sensations.

There are numerous examples, however, in which the functional trouble accompanies a moderate degree of organic cardiac trouble, and so soon as the former is relieved, the latter remains innocuous with a little judicious care for a long series of years. The functional trouble may be dependent upon the condition of the blood, the stomach, or the gouty diathesis, or what is still tolerably frequent—a combination of different pathological conditions. Manifestly, in all such cases, while carminatives, small doses of digitalis, or the remedies already indicated, may be usefully employed to relieve occasional disturbance, paroxysmal in character, permanent relief can only be obtained by remedies directed against the causal agencies at work. If a plethoric state be present, use mild depletory measures, such as small, repeated doses of the neutral salts; if anæmia be the underlying difficulty, iron, generous diet, and life in the open air, are mainly to be relied upon; for relief of dyspeptic trouble, regular meals, riding on horseback, and rationally formulated stomachics, varied according to prominent indications, should be persistently insisted upon; as for gout, potash and lithia salts are our sheet anchors, and soon an improvement of the cardiac condition will follow their exhibition. If the indications be complex, our formulæ should be made, so far as possible, to meet the requirements of the individual case.

Original Communications.

ON GONORRHOIC IRIDO-CHOROIDITIS.

By CHARLES J. KIPP, M.D.,

SURGEON TO THE NEWARK CHARITABLE EYE AND EAR INFIRMARY, AND OPHTHALMIC SURGEON TO ST. BARNABAS AND GERMAN HOSPITALS, NEWARK, N. J.

The following cases are published as illustrations of a disease, the existence of which is still doubted by some authors. With regard to the frequency of this affection I concur in the opinion of Förster ("Graefe und Saemisch, Handbuch der Augenheilkunde," Band 7, p. 86) and Leber ("Bericht über die zwölfte Versammlung der ophthal. Gesellschaft," Heidelberg, 1879, p. 129), who believe that if, in every case of iritis, an examination be made of the urethra, or the history of the case be carefully inquired into, it will be found that this disease is not an uncommon one. How the gonorrhœa causes the disease of the iris and choroid is not known. Mackenzie and other English writers believe that it is caused by metastasis. Leber (*op. cit.*) thinks that the gonorrhœal rheumatism and iritis are the result of a diffusion of the gonorrhœal poison through the system by means of the circulation—a kind of metastasis of the virus, which, according to recent investigations of Neisser, is said to consist of peculiar micrococci.

Case I.—A gentleman, about twenty years of age, contracted gonorrhœa some years before I saw him, which was followed by inflammation of right knee-joint, and iritis of right eye. Since then he has had repeatedly attacks of rheumatism. He has never had syphilis. Some months ago he again contracted gonorrhœa, and this attack was also followed by inflammation of knee-joint. He still has a slight urethral discharge. Two days ago his left eye began to pain him. On examination I found in the left eye an injection of the subconjunctival vessels on the temporal half of the sclerotic. There was no visible change in cornea or iris. Vision was perfect. The right eye showed no signs of inflammation, but the pupil was bound down by numerous broad posterior synechiæ, and obstructed by a dense pigment deposit. Vision = $\frac{5}{20}$. The vision of this eye has been impaired since the attack of inflammation several years ago. Two days later the whole ocular conjunctiva of left eye was intensely injected; the aqueous was clear; the pupil widely dilated from the instillation of the sulphate of atropia, and the iris neither swollen nor discolored. An examination with the ophthalmoscope showed the interior of the eye healthy. On the following day there was great œdema of

the ocular conjunctiva. The aqueous was cloudy, the iris swollen and discolored, the pupil much smaller than the day before, and in the pupil was a grayish exudation. The eye was very painful, there was photophobia and lachrymation, but no purulent discharge whatever. During the next three days the aqueous became more turbid, and on the fourth day the lower two thirds of the anterior chamber were filled by a grayish gelatinous fibrinous exudation. Vision was now greatly impaired and the pain was exceedingly severe. On the following day there was less chemosis and less pain; the exudation in the anterior chamber had undergone no change. The pain had again increased. There was now, also, considerable circumcorneal injection in the right eye, which, up to this time, had been free from pain. The anterior chamber contained an exudation similar to that in the other eye, and the iris was swollen and discolored. The patient was now nearly blind in both eyes. During the next two days the eyes underwent but little change, except that the exudation seemed to contract. On the following day there was increased pain in the left eye, the chemosis was more marked, and the aqueous was again quite muddy. The right eye was decidedly better. During the following week there was a steady improvement in both eyes. In the left the chemosis gradually diminished. The aqueous became clear, the gelatinous exudation assumed first the shape of a lens, and then that of a disk, in which form it remained suspended in front of the dilated pupil for several days, and then gradually disappeared. About this time a filmy exudation was noticed to cover the lower portion of Descemet's membrane, and a mass of pigment made its appearance on the outer pupillary margin. The vitreous was so hazy that the details of the fundus could not be made out with the ophthalmoscope. Two weeks later there was still injection of the subconjunctival vessels for some distance around the cornea of the left eye. The cornea and the aqueous were perfectly clear. On the anterior capsule of the lens were several concentric grayish rings (the remains of the exudation), and the vitreous was still hazy. The tension of the eye was somewhat below the normal. Vision = $\frac{2}{3}$. About six weeks later, all injection of the ocular conjunctiva of left eye had disappeared. The iris was still somewhat discolored, but not swollen. The vitreous was clear and the fundus oculi apparently normal. Tension and vision were normal. The eye remained in this condition for about two and a half months; then there was again some pain, and injection of the vessels near the outer margin of the cornea, caused by the development of a phlyctenula in the limbus conjunctivalis, which speedily disappeared again. Since then the eye has given him no trouble. Vision is perfect. The urethral discharge disappeared shortly after the appearance of the iritis.

The treatment consisted in the application of leeches to the temples, frequent instillation of a one per cent. solution of the sulphate of atropin; cold applications to the lids, and the administration of one-half grain doses of calomel three times daily during the first week, and of large doses of iodide of potassium after that time. Morphine was given freely whenever there was much pain in the eye.

Remarks.—The fact that the two different attacks of gonorrhœa were each followed by iritis, shows, I think, that there was some connection between the urethral disease and the eye affection. Similar observations have been made by Mackenzie, Förster, and others. Mackenzie, in his classic "Treatise on the Diseases of the Eye," Am. Ed., 1855, page 581, states "Each time the patient eat has gonorrhœa he is liable to an attack of synovitis or iritis, or suffers first from the one and afterward from the other. In some cases, however, there has been no new gonorrhœa, although a second or third attack of inflammation has affected the joint or the eye." Förster (*op. cit.*) says: "That this connection is not an accidental one is shown by the regularity with which different attacks of gonorrhœa in the same person are followed by iritis."

Case II.—A young man, about twenty years of age, presented himself at St. Michael's Hospital for the treatment of his inflamed right eye. Some five years before he had had a severe attack of acute rheumatism. About six months ago he contracted gonorrhœa which was soon followed by inflammation of his right knee-joint and right hip-joint. During this attack his right eye became very much inflamed and painful. His physician looked upon the eye disease as a gonorrhœal conjunctivitis, and treated it successfully. Four months ago he had presented himself at this institution with a small ulcer of the cornea, which healed speedily under the usual treatment. After that he was entirely free from eye trouble till ten days ago, when his right eye became painful. He still had some gleet. On examining his eye I found great congestion and œdema of the whole ocular conjunctiva. The cornea was clear. The aqueous was cloudy, and in front of the lower half of the iris and the pupil was a thin membranous exudation with sharply-defined upper margin. The entire iris was discolored but not much swollen. The vitreous was hazy. Details of fundus could not be made out. Three days later the aqueous was clear, and the membranous exudation had nearly disappeared. All evidences of the eye affection had disappeared four weeks later.

The treatment consisted of leeches to the temple, instillations of a one per cent. solution of the sulphate of atropin, and the administration of salicylic acid, and the sodic carbonate in fifteen-grain doses three times daily.

Remarks.—Since an interval of about four months intervened between the disappearance of the ulcer of the cornea and the development of the iritis, it is highly improbable that there was any connection between the two eye diseases. It cannot, however, be denied that the rheumatism may have had a share in causing the irido-choroiditis.

Case III. A rather thin but healthy man, forty-three years of age, who had never had syphilis or rheumatism, and had always enjoyed excellent vision, contracted gonorrhœa about three weeks before his eye disease began. I saw the patient for the first time in consultation with Dr. Lehlbach, on the 16th of November. The right eye had then been inflamed five days, and the left eye three days. There was still some discharge from the urethra. He had no rheumatism. The condition of the eyes was as follows: Right: both lids are puffy. The palpebral conjunctiva is congested but not swollen. The ocular conjunctiva is intensely injected and œdematous. There is no disease of the cornea. The aqueous is turbid. The iris is discolored but not much swollen in its upper half; in its lower half it is covered by a whitish granular deposit. The pupil is dilated, and its centre is occupied by a grayish disk-like exudation. (Atropin had been used for several days.) In the vitreous were numerous floating opacities which prevented examination of background of eye. Vision so much reduced that he could count fingers only at two feet. Tension normal; visual field intact; very

great pain in eye; no purulent discharge. Left: lids, conjunctiva, and cornea same as right. Lower two-thirds of anterior chamber filled with a grayish gelatinous exudation, the upper margin of which is convex. Pupil contracted; fundus cannot be illuminated. Has only perception of light in this eye. Tension and field normal. Excessive pain; no purulent discharge.

Although leeches had already been applied to both temples, six more were applied to each side. The hourly instillations of a one per cent. solution of sulphate of atropia were continued, and iodide of potassium in fifteen-grain doses was administered three times daily.

November 18th. Right: no change. Left: Exudation somewhat diminished; upper margin irregular; pupil irregularly dilated; several broad posterior synechiæ. Has still pain in eyes, and there is now some mucous discharge from eyes. Has been perspiring freely since yesterday. Ordered inunctions of mercurial ointment, twice daily, in addition to the other prescriptions.

November 20th. Right: conjunctiva as before; pupil widely dilated; whitish exudation on iris has disappeared; vitreous opaque; vision as before. Left: exudation in anterior chamber has been absorbed; lower half of pupillary margin irregular; vitreous opaque. Can recognize light from darkness only. Has still pain in both eyes. Continued treatment.

November 26th. Right: less œdema, otherwise no change. No pain. Less secretion. Left: aqueous again somewhat turbid; pupil more contracted than before, otherwise no change. Same treatment.

November 28th. Right: less œdema and less injection of conjunctiva. No other change. Left: there is again some fibrinous exudation in anterior chamber, otherwise as before. No change in treatment.

November 30th. Right: less injection and œdema of ocular conjunctiva, otherwise no change. Counts fingers in lower half of visual field. Left: less swelling of ocular conjunctiva; exudation in anterior chamber has again disappeared; pupil irregular, but wider than before; vision as before. Discontinued inunctions and substituted salicylic acid and sodic carbonate in fifteen-grain doses for potassium iodide.

December 12th. Right: ocular conjunctiva is pale and not swollen; aqueous clear; pupil widely dilated; vitreous still opaque. Left: same as right. Vision as before. In addition to the other remedies gave pilocarpinum, one-quarter grain hypodermically, daily, which produced neither profuse perspiration nor salivation, but caused great depression, and was therefore discontinued a few days later. Potassium iodide in thirty-grain doses, three times daily, was then given, also sulphate of quinia, three grains, three times daily.

January 19th. In the right eye the vitreous is now much clearer. Optic papilla and retinal vessels are seen indistinctly. The vitreous in the left eye is about as opaque as before. His vision has sufficiently improved to enable him to walk about with safety. Continued same treatment.

March 20th. Till yesterday the sclerotic of both eyes was white. There is now some circumcorneal injection and a few phlyctenulæ are seen on margin of cornea in both eyes. Vision is now V. = $\frac{6}{9}$, in both. Patient has had an attack of diphtheria since I last saw him.

June 5th. The phlyctenulæ disappeared in a few days under the use of calomel dusted into the eyes. Since then the eyes have been free from irritation. There is now an abrasion of the epithelium almost in the centre of the cornea of the right eye. The vitreous still contains grayish opacities. Vision as before.

Since then I have not had an opportunity to test the man's vision, but it must have greatly improved, as he is now able to keep his account-books and read large print.

Remarks.—This case was one of the gravest cases of irido-choroiditis from any cause that I have ever seen. The disease attacked both eyes at the same time and with the same severity, and continued for more than six months, after which useful vision was restored by a gradual clearing up of the vitreous. As an uncommon feature of the case, may be mentioned the absence of all symptoms of rheumatism, although similar cases have been observed by Mackenzie, Ricord, and others.

An analysis of the above cases shows that in all of them a urethral discharge was still present at the time the irido-choroiditis made its appearance. Inflammation of one or more joints preceded the development of the eye affection in two cases, and in one it did not. Both eyes were affected in two cases, and one eye only in one case. All of the cases recovered. In all of the cases there was much pain in and around the eyes, there was slight seromucous discharge, and greatly impaired vision. The tension was normal in two, and somewhat reduced in one case. The visual field was intact in all. There was more or less œdema of the lids, intense injection and œdema of the entire ocular conjunctiva, a gelatinous or fibrinous exudation in the anterior chamber, discoloration and swelling of the iris, contraction of the pupil, and more or less opacity of the vitreous in all of the cases.

The treatment consisted of leeches to the temples, in cold applications to the lids, instillations of a solution of atropia sulphate, cathartics, inunctions of mercurial ointment, and the administration of potassium iodide, sodic salicylicate, pilocarpinum, and morphium sulphate.

SANITARY ADMINISTRATION AND ENDEMIC DISEASE.

By HENRY M. LYMAN, M.D.,

PROFESSOR OF PHYSIOLOGY AND NERVOUS DISEASES, RUSH MEDICAL COLLEGE, CHICAGO.

PROMINENT among the causes which produce, in the ranks of the medical profession, that degree of apathy regarding sanitary effort about which our professional sanitarians complain, is the unscientific attitude assumed by the average health official toward the endemo-epidemic diseases which are naturalized in certain localities. This attitude grows, in great measure, out of the habit of looking upon disease as an evil to be extinguished, without much regard to the character of the measures employed. Now disease, like its congener, pain, is not an evil. It is a most valuable symptom of evil—a symptom without which the discovery of evil and its elimination would be absolutely impossible. Thoughtless people often remark that if they had the power they would annihilate disease and death. We can, indeed, conceive of a state of things in which such uncomfortable events could find no place; but such a state is incompatible with existence in a material universe. Much as we may desire to have things differ from the condition in which we find them, we must accept our position in this universe, and seek to make the best of our situation. In order to attain

this end, it is absolutely essential to fall into line with the forces of nature, and to work with instead of against those forces. We may thus hope by degrees to adjust our existence to the conditions that are imposed upon it, and then we shall be free from the evil consequences of a lack of harmony with our surroundings. Disease in such a state would be an unknown, for disease is the result of an inharmonious relation between the internal forces which sustain the life of the individual, and the external forces which form his environment.

Disease, therefore, being merely a symptom, is not the object against which the efforts of the sanitarian should be directed. Disease may be compared with the movement of the mercurial column which indicates the varying intensity of the vibrations of heated matter. When we desire to cool the room, we do not remove the thermometer—we close a damper, we open a door. Precisely analogous should be the behavior of the sanitarian. Instead of cursing the fever that prevails in a community, he should regard it as a most valuable indicator of the active presence of some noxious force which disturbs the harmony that should exist between the individual resident and his environment. This disturbing force will be found either within or without the individual, and intelligent investigation will always succeed in thus referring the cause. Obviously, therefore, the measures necessary for the removal of the causes of disease must be varied to suit each malady. Limiting our inquiry to the class of infective diseases, we shall find it necessary to adopt different methods in order to harmonize ourselves with the efficient cause of each member of the class. If, as in the case of cholera, or yellow fever, the causes are purely exotic to a given locality, careful quarantine is the proper measure to adopt. But, if quarantine shall fail to keep out the infective agent, we must rely upon local sanitation and personal hygiene, upon actual deportation of the movable population, and the most rapid possible diffusion of the disease among those who elect to remain upon the infected spot, so that the epidemic period may be shortened, and the number of "acclimatized" persons may be increased. If, as in typhus fever, the cause resides in human effluvia, then ventilation, cleanliness, and abundant supplies of food are the appropriate antagonists of the cause of the disease. If, as in the case of typhoid fever, the disease is originated by decomposing fecal matters, we need not regard the secondary and comparatively unimportant fact that the disease may be communicated by one person to another; but we should bend all our energies to the removal of the filth which vitiates the air and the water of the infected region. If, as in the case of small-pox, measles, and scarlet fever, we know not either the original localities nor the external conditions that engender the disease, but only know that by exposure to the action of a particular virus the body may be defended against future assault by a similar virus, we should seek for such protection. This we have learned to do in the case of small-pox; and, when we shall have enlarged our knowledge to the full measure of science, we shall also do the same thing in the case of measles, mumps, and scarlet fever. Centuries of experience have proved the impossibility of protection by quarantine against small-pox. The ancient nations of the East long since gave up the attempt, and still protect themselves by free exposure to the disease. But, as the protection thus obtained is purchased at a considerable cost of life, it was a decided improvement when the method of inoculation was originated; and now we find our greatest advantage in the widest possible diffusion of the disease in a form still more considerably modified by the passage of the virus through the body of the cow. In all these methods, however, the principle is the same, to wit, the most perfect and general adjustment of the community to the action of small-pox virus by a continued diffusion of the disease in one of its various forms. One of the lessons taught by this experience is the fact that *in proportion to the pandemicity and endemicity of virulent diseases will be the diminution of their danger.*

From the same experience we may learn the true course which should be adopted in our efforts to ameliorate the sanitary condition of mankind. Where we cannot reach the primitive cause of an endemic, virulent disease, we should not seek to "stamp it out" by a quarantine that never succeeds, but we should strive to attenuate the virus by its widest possible diffusion. The opposite process simply creates an increased susceptibility, and favors the occurrence of uncontrollable epidemics—like the epidemics of small-pox and of measles that swept away the North American Indians and the Pacific Islanders. By constant familiarity with the causes of a virulent disease, hereditary tolerance becomes, at length, a most valuable defence against its dangerous prevalence. The history of syphilis affords an instructive illustration of this fact, and our experience of the diminishing protection afforded by vaccination is another suggestive example. Let us suppose that, as a result of hereditary tolerance, the susceptibility to small-pox exhibited by the European population at the close of the last century, could have been represented by 100 upon a graduated scale. Let the additional tolerance affected by vaccination at that epoch be represented by a depression of susceptibility to 1 on the scale. This will represent a difference of 99 in favor of vaccination, which will then be almost perfectly protective against small-pox. But, after a time, as a consequence of infrequent exposure to the unmitigated virus of small-pox, the degree of hereditary tolerance will diminish, and the susceptibility of the population will correspondingly increase. Let us now suppose that in the course of eighty years the degree of susceptibility has risen till it can be represented by 125 on our scale. The protective power of vaccination being still represented by 99, the present susceptibility of the vaccinated population will now be $125 - 99 = 26$, and small-pox will prevail to a corresponding extent in spite of previous vaccination. This provision of science is what we actually observe in practice—a fact which proves the complete absence of a scientific foundation for the hope that small-pox can be exterminated by assiduous vaccination. We can only tame the monster—we cannot destroy him. The same line of reasoning is equally applicable to measles, scarlet fever, and other virulent diseases. In communities like our own, and like the British Islands, where these maladies are endemic, and where their constant prevalence is due to local conditions outside of the human body, rather than to the element of a contagious virus—witness the comparative rarity of scarlet fever in France, though it rages continually on the opposite side of the English channel—the proper course is that which will favor their widest possible prevalence. But, out of consideration for the ignorance of men, it is inexpedient to undertake active measures for the propagation of unmodified measles or scarlet fever. It is better to leave their diffusion to the unassisted operation of natural methods, until

we have learned how to modify their *materies morbi*, as we have learned how to attenuate the virus of small-pox. In this connection, a recent observation by Pasteur (*Nature*, Feb. 19, 1880, p. 388, and *Le Progrès Médical*, May 1, 1880) is very suggestive. He found that the disease called *fowl cholera* could be communicated to healthy fowls by inoculation with virus derived from diseased fowls. Repeated culture "by transference of minute drops from liquid to liquid does not weaken the virulence, but by a certain mode of culture M. Pasteur *can* weaken it. If twenty out of forty fowls be inoculated with the very virulent virus, they nearly all die; but if the other twenty be inoculated with the attenuated virus, they all become ill, but very few die; inoculation of those that recover with the very infectious virus does not kill them. The novelty here is the preservative effect of inoculation in a disease caused by a living organism (in the virus of small-pox, etc., no life has been proved). The cholera of fowls may be prevented from becoming fatal, and the author describes the return to health of a fowl inoculated in the large pectoral muscles. He expresses the hope of obtaining artificial cultures of all kinds of virus, and notes the encouragement obtained for the search of vaccine virus of virulent maladies."

This "attenuation of virus" is one of the natural processes which serve to extinguish virulent diseases that have become epidemic outside of their native territory. Witness the benignity of syphilis at the present time as compared with its ravages three hundred years ago. Witness the mortality of plague, cholera, yellow fever, etc.—greater at the commencement of each epidemic than at its close. Other causes co-operate; but the attenuation of the *materies morbi* is one of the principal factors by which a diminishing mortality and final extinction of the epidemic is affected. This natural method, however, has the disadvantage of preparing the way for a renewal of the epidemic when the protective effects of its first incidence have in like manner disappeared. The true way, therefore, to prevent these revivals of infective disease is to cultivate its virus, and to maintain its presence in the community as carefully as we do in the case of small-pox. If the suggestions of Pasteur ever bear fruit, we shall manage scarlatina just as we manage small-pox, and we shall propagate among our children the modified scarlet fever with as great assiduity as we now disseminate the modified variola. Until that time, however, the truly scientific method with scarlet fever, as with all kindred diseases whose origin is concealed, will consist in permitting its unrestricted prevalence, in order that the community may secure the advantages accruing from continuous personal and hereditary adjustment to the causes of the disease. The individual suffering and mortality consequent upon such a method constitutes no reasonable objection, for that mortality is a real advantage to mankind. By weeding out the feeble offspring of the community, the prevalence of epidemic disease is a constant source of vigor to the race. It is in newly forming and fluctuating communities, where the heterogeneous elements find varied conditions unfavorable to health, that epidemic diseases are most prevalent. In such communities they are to be reckoned among the most potent means of adjustment between the population and its unwonted environment. The survivors of an epidemic enjoy a better chance for life, and their ability to transmit a larger amount of physical vigor is correspondingly increased. Nor are the injurious consequences, occasionally noticed among the convalescents of an epidemic, to be considered objections to this doctrine, for they are completely balanced by the more numerous examples of radical and permanent improvement of health and vigor which result from an attack of epidemic disease, but pass unnoticed because less conspicuous than the unfortunate cases. It is true that our individual instincts prompt us to avoid evil in every possible way, and the advocates of sanitary interference with the laws of nature argue that the community should come to the aid of the individual in his effort to protect himself against disease. But, with reference to endemic diseases, this is one of the many instances in which the interests of the individual and the interests of the community are entirely divergent. A truly scientific administration will give heed to that law of nature which subordinates the parts to the whole—the individual to the community. If, however, the contrary principle is to be adopted, and the highest good of society is to be subordinated to the selfish instincts of its individual members, very well. Only let us clearly understand the kind of stuff for which we are called upon to pay.

Such, then, are the conclusions of science, and such they have always been, though entertained with continually increasing confidence by every genuine student of nature since the morning when Darwin and Spencer, and their co-workers, let in daylight upon the problems of the universe. But this is far from being the creed of the average politico-sanitarian, who desires a high salary for acting the part of a benevolent despot in the attempt to "stamp out" disease. The cause of this phenomenon is not far to seek, and its investigation is instructive. The cause of this wide severance between the doctrines of science and the practice of officials lies in the fact that sanitary science has hitherto been cultivated almost exclusively by officers of the army and of the navy. To these very estimable gentlemen the world is indebted for the greater part of the progress that has been made in sanitary knowledge, and it is to their writings that the sanitary neophyte is almost compelled to turn for the information that he needs. But the problems which these military sanitarians have studied, are the simplest that can be presented for solution. The homogeneous society over which they preside exists for but one end—warlike efficiency. The army must be kept in the highest possible condition of vigor, no matter what it may cost, or who else may suffer in consequence. The military sanitarian, therefore, has only to consider a problem that has been reduced to its lowest terms—a problem in which the elements are almost purely physical. If certain measures prove adequate to the maintenance of the health of the army, it is entirely superfluous to discuss their concurrent effects upon mankind at large. This is the application of science made easy. But when we turn to the vast and many-sided organizations of civil society, the problem of sanitary administration becomes correspondingly complex and difficult. Mankind cannot be rightly treated like a passive machine in the hands of its rulers.

Every question which touches society as a whole, possesses attributes that have no necessary relation with a military engine like the army or the navy. Society is made up of free, intelligent, moral beings, and it is absolutely essential, in dealing with society, that this fact should be kept prominent in the foreground. How will a given measure affect a soldier's physical constitution, is the question to which the military sanitarian addresses himself. How will a

given [illegible] affect more or less physical, social, intellectual and moral conditions in the form which the same question would take in the midst of civil sanitarians. Unfortunately, too many of our newly-fledged officials have not yet learned the difference between these two forms of inquiry; and they for the most part continue themselves until sharply rebuked in some court of law with the attempt to extend over civil society the narrow methods of military life. As Dr J. S. Billings has recently remarked, in his introduction to Buck's work on Public Health and Hygiene, they do not trouble themselves about anything but the supposed physical utility of their measures, leaving for a period of leisure the work of reconciling their results with the moral code. This is a rather clumsy way of stating the fact that the ordinary sanitarian is in the habit of working from the standpoint of a narrow specialist, and, like all narrow specialists, he is for this reason continually doing harm where he would do good. The great want of the present time is a capacity for breadth of view regarding sanitary administration, but such breadth can never be attained by the study of the writings of military and naval authors alone. Nor can the needful degree of wisdom be acquired through mere imitation of the methods that are considered legitimate among the civil authorities of the old world where the spirit of military despotism is the dominant power. If our sanitarians desire to secure the respect of thoughtful people, and if they are really solicitous about the highest welfare of the human race, they must, in this free and enlightened country, consent to review their studies in the fullest light that can be derived from the principles of science, philosophy, and morality. Too many of these people appear to be actuated chiefly by an itching desire to get some dirty little place of prostitution under their fatherly care, or by a wilful determination to compel the adoption of some equally narrow and unscientific measure, simply because they have heard that it was useful to men placed under the abnormal conditions of soldiers in barracks, of soldiers on shipboard, or of criminals in jail. Such exhibitions are characteristic of ignorance and immaturity; consequently, the sooner our sanitary students can be educated up to the broad level of science and philosophy, the sooner they will become—what they are yet far enough from being—entitled to rank among the great benefactors of the human race.

THE HOT WATER VAGINAL DOUCHE. A SIMPLE APPARATUS FOR ITS ADMINISTRATION.

By C. HART MERRIAM, M.D.,

LENOX GROVE, N. Y.

More than twenty years ago (in 1859), Dr. Thomas Addis Emmet first employed hot-water vaginal injections in a member of his own family, and the result was so satisfactory, that, from that date till this, scarcely a patient has fallen under his care in whom they have not constituted an important factor in treatment. To Dr. Emmet belongs the credit of demonstrating to the profession that the action of hot water upon the pelvic viscera is to disgorge the tissues, to produce tonic contraction of the vessels, thus allaying both active inflammation and passive congestion; and that it tends to restore to the normal a weak and flabby uterus, by exciting to contraction its relaxed muscular fibres.* It acts like magic on an engorged and tender uterus, and its local application effects in a few minutes what I knew of no better means for removing in twenty-four and sleepless days of a hysterical woman, than a prolonged hot water vaginal injection, when administered by an experienced hand. These injections will frequently enable a patient to sleep in less time than could be done by any remedy in the pharmacopœia.†

These facts were slow to be appreciated by the profession, but the time has now come when it is almost universally conceded that we possess no other remedial measure so efficacious, so universally applicable, and so potent in the treatment of uterine diseases, as the hot water vaginal bath. It constitutes, so to speak, the chief corner in gynecological therapeutics. This much being admitted, the all important question arises concerning the best method and simplest apparatus for administering the douche. Here opinions differ. Dr Emmet lays great stress upon the importance of the *intermittent* current, as derived from the Davidson or other bulb syringe. But the advantage gained from it has, I believe, been over estimated, and for the following reasons:

1. The resistance afforded by the amount of water in the vagina (patient on her back) is sufficient to materially lessen the force of the jet.

2. The only nozzles fit to be used for vaginal injections, are conceded to be those without the terminal hole, i.e., with three lateral openings; hence, unless the nozzle is actually pushed behind the cervix and into the posterior cul-de-sac, all three streams fail to strike the cervix at all, and even in this case but one jet could possibly do so.

3. Clinical experience has not yet satisfactorily proven that the interrupted stream has decided advantages over the constant, and both are known to yield excellent results.

4. Dr. Emmet's own patients, like all others at the Woman's Hospital of the State of New York, are there treated by the constant stream, and with results that are most enviable—as shown both by the published records of cases, and by the testimony of hundreds of grateful patients.

Moreover, granting that the intermittent stream is superior to the constant, it is not far from the truth to state that in nine cases out of ten, as met with in ordinary practice, the assistance necessary to the proper administration of the bulb-syringe jet is practically unattainable. And the effort of working the bulb one's self is such a tax upon the patient's strength, that even Emmet admits that "when, from the force of circumstances, the injections cannot be thus administered (by the hand of an experienced nurse), it is better to use a fountain, or siphon syringe, than that the patient should attempt to give them to herself."‡

This, then, being the case, it is evident that the vast majority of patients require some simple form of apparatus that will enable them to take the hot baths thoroughly, without fatigue, and without the aid of an assistant. Such an apparatus is shown in the figure on opposite page. It consists of a bath-pan (B) of tin, zinc, copper, or galvanized iron, and a reservoir pail (A) of two gallons capacity, together with about eight feet of rubber tubing, a tube clamp and a hard rubber nozzle.

The reservoir (A) is connected with the nozzle (E) by means of half (4 ft.) of the rubber tubing (C), on the middle of which is the clamp (D). The hard-rubber nozzle (E) is made large, so as not to injure

---

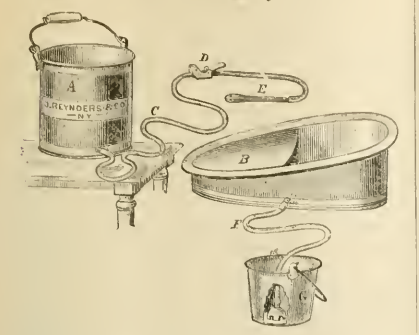
† Principles and Practice of Gynecology, 1879.

the soft parts, and has three lateral perforations about its bulbous extremity, but has no hole in the tip. Metallic nozzles should never be used in hot baths, because they retain so much heat as to be uncomfortable to the parts with which they are in contact, become discolored readily, and are not so



easily kept clean as those of hard rubber. One end of the other piece of tubing is attached to the side of the bath-pan, near the bottom, while the other end remains free.

The method of using this apparatus is as simple as the affair itself. The patient lies upon her back, on a hard bed or couch, with the bath-pan well up under her hips, and a small pillow under the hollow of her back. If a hard bed is not available, a board (and an ordinary "cutting board" does very well) must be placed under the bath-pan, to prevent its sinking so far below the edge of the bed that the water cannot escape through the outflow tube, the free end of which hangs over the side of the bed into any convenient waste vessel (G). The reservoir pail, filled with hot water at the proper temperature, is placed upon a stand beside the bed, or hung on a hook in the wall, if more convenient, and the nozzle introduced deeply within the vagina. Everything is now ready, and all the patient has to do to start the stream is to open the clamp (D). If the clamp be left open the flow will continue for three-quarters of an hour, or more, unless the pail is elevated much higher than necessary. But since it is not generally advisable to give the bath for more than twenty minutes or half an hour, there is ordinarily considerable water left in the reservoir, and this serves to keep the balance from cooling so rapidly as it otherwise would. When the prescribed time has expired, the patient should be instructed to depress the perineum with the nozzle, before withdrawing it, in order that the water remaining in the vagina may drain out, and a towel now placed against the vulva will prevent wetting the clothing. In the evening the bath is best taken after the patient is undressed for the night, and in the morning it is advisable for her to remain in the recumbent posture for some little time afterward.

My friend, Dr. E. C. Dudley, of Chicago, in describing a vaginal douche devised by Dr. F. H. Lord, of Plano, Ill., makes the following just criticism of the fountain-syringe and bed-pan ordinarily employed in gynæcological practice: "The fountain-syringe, quite generally used for the vaginal douche, requires no assistant, and is easily managed by the patient, but it is nearly useless, since, on account of its small size, it requires re-filling several times during each application. The common bedpan is open to a similar objection, since it requires to be emptied several times during each application."* Further on in the same article, Dr. Dudley speaks of the proper method of administering the douche, and says: "It should invariably be given with the patient lying upon the back, with the shoulders low, the knees drawn up, and the hips elevated on a bed-pan, so that the outlet of the vagina may be above every other part of it; then the vagina will be kept continually overflowing while the douche is being given." "It should be given at least twice every day, morning and evening, and generally the length of each application should not be less than twenty minutes."

The apparatus herein described I first had constructed early last August, and at present I have nearly forty sets in use. They give universal satisfaction, and yield results which, in the average patient, were previously unattainable. In the preparatory treatment of cases of laceration of the cervix, and the like, are they especially serviceable.

In presenting this simple vaginal douche to the profession, in this country, I lay no claim to originality of idea, for numerous more or less similar contrivances have, from time to time, been constructed, and its essential features are the same as those of a similar apparatus employed by Dr. Atthill, of Dublin.

The reservoir and bath-pan, as made by John Reynders & Co., New York, are painted in such a way as not easily to be affected by the hot water.

Progress of Medical Science.

Renal and Hepatic Colic.—At a meeting of the Medical Society of London, Dr. DeHavilland Hill reported a case of the above disease. The patient, an apparently healthy woman of fifty-eight, was suddenly seized with severe vomiting of a bilious character, followed by collapse. Four days after the onset of the disease she complained of spasmodic pain in the cardiac region, preceded by rigors, of which she had three. This was followed, on January 17th, by severe pain in the left lumbar and inguinal region, and also accompanied by rigors. There were two similar attacks after this, one on February 2d, the other on April 16th, in the latter of which she died, having suffered from great pain over the abdomen, accompanied by vomiting of a stercoraceous variety. At no time was there jaundice. On post-mortem examination, the pelvis of the left kidney was found to contain a calculus, and both of the organs contained a number of small cysts. A large concretion was to be seen in the ileum, about two feet from its termination, and there was fistulous opening leading from the gall-bladder into the duodenum. —*Lancet*, April 3, 1880.

Tuberculosis and Infection.—Referring to Prof. Cohnheim's latest views on the contagiousness of tuberculosis (*Facultät's Programm*, Leipzig, 1879), Dr. Friedländer remarks: The power of communicating contagion is an indisputable property of all tubercular affections. The experiments of Salomonsen and the author on the rabbit's eye, clearly proved this

* Chicago Med. Gazette, Jan. 5, 1880.

fact. It was also ascertained that characteristic infection occurred without exception in every instance where tuberculous substance was employed for inoculation. The pathological characteristics as revealed by the microscope, are not always sufficient to differentiate tubercular from syphilitic lesions, or from non-specific products of chronic irritation. Thus, neither miliary eruptions, nor the appearance of giant cells, nor cheesy degeneration, even when occurring conjointly, sufficiently characterize this affection. Hence the importance of the conclusion that contagion must form an absolutely and, moreover, the only reliable criterion of suspected tuberculosis. Adopting this new criterion, we must class with tuberculosis cheesy pneumonia, scrofulous degenerations of lymphatic glands, and generally, also, fungous arthritis; whereas simple tissues, being not inoculable—*e.g.*, lupus—are to be excluded.

The carriers of infection are presumably specific parasitic organisms. Tubercular virus commonly enters the system by inhalation through the respiratory passages. Thus the primary lesion is frequently found in the lungs, whence the disease may be carried to the pleura and the bronchial glands, or, through agency of the sputa, to the alimentary canal. This produces the common form of pneumo-intestinal phthisis. The intestinal tract is also liable to direct infection through the agency of diseased cow's milk. This leads to phthisis mesenica, so frequent in children. According to Weigert, tubercular meningitis may arise from infection through the upper portion of the nasal cavity. Excretion of the virus through the kidneys may cause uro-genital tuberculosis. The primary affections of bones and joints are explained by previous infection of the blood and local traumatism, causing increased deposition of vitiated material. Acute general tuberculosis arises from overabundance of the virus. The lesions of the thoracic duct and pulmonary veins render this a very plausible explanation of the rapidity and wideness of dissemination in such cases. Local tuberculosis is not essentially a distinct process. Their interrelation is analogous to that subsisting between chancre and constitutional syphilis. The so-called phthisical *habitus* is a result of already existing disease, not a predisposition to acquire it. Heredity is its common cause. The virus may communicate itself to the ovum and spermatic fluid, and thus be found in the newly-born. A child in this way affected may pass through long periods of latency of the virus, but its presence in the body is shown by the development of the phthisical *habitus*. Syphilis and tuberculosis are thus strikingly analogous diseases (according to the author), as indicated by the direct personal communicability of their contagion.—*Allg. Med. Cent. Zt.*, March 27, 1880.

The Pathology of Mammary Epithelial Tumors.—In the *British Medical Journal* of March 20, 1880, we find a timely editorial on this subject. It was suggested by papers recently read before the Royal Medical and Chirurgical Society, on cancer of the breast, and a peculiar diseased condition of the nipple. Some interesting questions regarding cancers in general, and more especially regarding mammary epithelial growths, were thus raised. Dr. Thin examined four tumors and pronounced them cases of duct-cancer, which he believed to be identical with the so-called adenoma of the mamma. Besides duct-cancer, Dr. Thin recognized a second variety of epithelial growths, the ordinary scirrhus of pathologists. These two varieties are said to derive their distinctive qualities from the two kinds of epithelium found in the normal mamma, these being the columnar epithelium of the ducts and the secreting epithelium of the acini. The peculiarity of duct-cancer is the formation of rounded columns of cells, which sometimes form perfect epithelial tubes. A point of clinical interest is that tumors which, under the name of adenoma or chronic mammary tumor, have been regarded as non-malignant, do, in some cases, run a comparatively rapid course and produce death. Waldeyer called such tumors cancer, and recognized their connection with the galactophorous ducts. Many cases of rapidly-growing tumors have been probably confounded with scirrhus cancer. On the other hand, Labbé and Coyne relate the case of a woman aged sixty-seven, in whose breast a painless tumor remained stationary for thirty-four years. It then began to grow, and, after two years' continued active growth, it was removed. It had all the essential characters of a duct-cancer, and not those of a scirrhus. The inference is justified, that at present it is impossible to always determine the nature of a tumor without microscopical examination. We remember an illustrative case which occurred at the surgical clinic of Strasburg. Prof. Lücke removed a mamma, which was the seat of a rapidly growing tumor, having all the clinical appearances of scirrhus. A microscopical examination by Prof. v. Recklinghausen, showed it to be a characteristic adenoma. This term is, however, apt to mislead, inasmuch as the new growth forms no secreting structure, and does not even originate in the pre-existing secreting elements of the gland. On the other hand, many surgeons will hesitate to apply the term duct-cancer to a growth that usually remains localized for many years without constitutional infection. But the progress of pathology has taught us the necessity of taking into account the anatomical structure of tumors in all questions of nomenclature. Hence the chronic mammary tumor, or adenoma, is frequently a true cancer. The growing epithelial tubes and columns not only displace, but destroy, the surrounding bundles of connective-tissue. The effect on the latter varies very much in different instances. In many cases it is comparatively slight and leads to a capsular formation; sometimes the newly-formed tissue is incompletely developed as regards quality, but largely developed as regards quantity, and we have then the adeno-sarcoma of Billroth. In other and rarer tumors, the destructive effects on the connective tissue are, in some parts of the growth, greatly in excess of any new formation of that element; and there is then a tumor that clinically is apt to be mistaken by the surgeon for scirrhus. Whether a growth that springs from a morbid action connected with the more highly differentiated columnar epithelium of the large ducts is more malignant than one that springs from the epithelium of the smaller ducts; or whether mere proximity to the surface and consequent irritation of the diseased epithelium, in its earlier stages, endows the unknown cancerous agent with greater virulence, are questions that can as yet only be answered by hypothesis.

Tracheotomy in Croup and Diphtheria.—The much-vexed question of tracheotomy in certain cases of croup has received renewed attention in a series of papers, three in number, read at the meeting of the British Medical Association, in August, 1879.

Dr. A. H. Corley, of Dublin, after giving a brief resumé of the subject, to show that the operation is now looked on with more favor in Ireland than for-

merly, says that there are three questions involved, viz., the object of its performance, and the time and selection of its performance. While holding to the view that croup, or false membranous laryngo-tracheitis and diphtheria, or false membranous pharyngitis, are simply varieties of the same disease, the writer says that even if they are considered distinct affections, it is of no practical consequence, as the object is the same in either form, viz., the removal of all mechanical obstructions. If the diagnosis between true and false croup is made early enough in the disease, the operation is not attended with much risk.

Mr. R. W. Parker, of London, holds essentially the same views, and says that there have been well-marked examples of croup, in which, after tracheotomy had been performed, there were symptoms of diphtheria. He attributes the high rate of mortality to the following causes: a long-continued use of depressing drugs, such as antimony; deferring the operation until secondary symptoms have developed; neglect of proper after-treatment. He advocates the use of sulphate of copper, in doses of two to five grains to the half-ounce of water every five or ten minutes, and if the obstruction is not speedily removed by free vomiting, tracheotomy should be resorted to without delay. Particular attention must be paid to preventing the formation of false membrane afterward.

Mr. William Thomson, of Dublin, also recommends the operation, and advises the supra-thyroid region, rather than the infra-thyroid, as, by the former method, the risks of wounding vessels are obviated, while no advantage is gained by operating low down, he having performed tracheotomy twice successfully when false membrane existed below the opening. He lays great stress on the necessity of keeping the aperture clear by means of a spray of lactic acid (ten grains to the ounce), or lime-water.

Dr. Buchanan, of Glasgow, has given statistics of fifty cases in which tracheotomy was performed by him. Of this number seventeen were classed as croup, and thirty-three as diphtheria, the latter including all those forms in which there was a deposit of false white membrane on the tonsils, palate, or fauces. Of the seventeen patients operated on for croup ten died, one immediately after the operation, the other deaths taking place after an interval ranging between three hours and four days. In diphtheria the mortality was twenty-one out of thirty-three. Here also one patient died immediately after the operation, the others in from six hours to thirteen days. Dr. B. claims that, according to these statistics, the operation is justifiable, as it was not resorted to until all other means had failed, and it gave the patient the only remaining chance of life.—*Brit. Med. Journal*, April 10, 1880.

Internal Urethrotomy, Followed in one Case by Fatal Suppression of Urine, and in another by Impotence and Atrophy of the Penis.—The following cases are reported by Dr. A. L. Ranney, of this city. In the first, the patient, married and twenty-four years of age, had had gleet for several years, and complained of a gradual diminution in the size of his stream of urine. He also had suffered from retention of urine at various times, which was generally relieved by hot baths, together with the use of a catheter, but as the urinary passage gradually became smaller he was unable to make use of the latter. An examination revealed an extensive induration of the spongy portion of the urethra, and no instruments could be passed to a greater distance than one inch from the meatus, except a whalebone guide which readily entered the bladder; the condition remained the same when he was anæsthetized. The bladder being emptied by means of an aspirator, on the following day, when under the influence of an anæsthetic, whalebone guide was introduced, and internal urethrotomy performed by passing Gouley's urethrotome over it. After this a No. 18 English sound was introduced every other day for ten days, with instructions to continue its use afterward once a week. Fifteen months afterward he again came under observation, suffering from retention of urine. It was found that the anterior stricture had closed. No signs of renal disease were discovered on examining the urine. The anterior stricture was then divided by means of an Otis's urethrotome, the posterior strictures being dilatable and admitting a No. 18 (English) sound; but slight hemorrhage followed the operation. Ten grains of quinine, with one of opium, was given at once, and a hot sitz-bath ordered. Eight hours after he was seized with a chill, in the meantime he had passed no urine, nor was there any found in passing a catheter. All means of relief failed, and he died sixty-seven hours after operation. No false passage was found on post-mortem examination, nor were there any signs of renal disease, except great hyperæmia of the kidney.

The second case was that of a married man, forty-nine years old, who had had gonorrhœa twenty years previously, but never had syphilis. Previous to September, 1879, he complained of partial incontinence of urine, together with frequent desire to void urine, and a slight diminution of the stream. At that date circumcision was performed to relieve the diseased condition, but with no benefit. Internal urethrotomy was then resorted to, being followed by profuse hemorrhage. The latter operation resulted in impotence and a diminution in the size of the penis, there being about this time symptoms of renal disease developing. On examination, March 29, 1880, a circular cicatrix could be seen over the place where circumcision had been performed, a normal amount of integument remaining. The glans penis could neither be seen nor felt, the prepuce hanging over the place where it should have been. Each of the testicles were of normal size, but retracted. The skin of the former penis was indurated, and the flow of urine over it had caused an excoriation. The remnant of the penis measured about one inch, and its circumference was normal. The scrotum was large and flabby, appearing empty, as the testicles were retracted. The corpus spongiosum occupied its normal position in the perineum.—*N. Y. Med. Journ.*, May, 1880.

The Microscopical Investigations of the Havana Yellow Fever Commission.—In speaking of the results of his investigations in reference to the nature of the yellow fever poison, Dr. Sternberg, of the U. S. Army, states that in the examination of the blood of patients affected with the disease, and also of the air of the infected districts, no germ or organism could be found that might give rise to the affection. He is at present engaged in the examination of the atmosphere of New Orleans, in order to determine whether any germs exist in the air when the city is in a comparatively healthy state.—*Reprint from N. O. Med. and Surg. Journ.*, May, 1880.

Mr. Christopher Heath has recently been elected president of the Board of Examiners of the Royal College of Surgeons of England.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, June 26, 1880.

THE HISTORY OF THE PHILADELPHIA FRAUDULENT MEDICAL COLLEGES.

THE history of the fraudulent medical colleges of Philadelphia is one that is humiliating to every American. It is not alone that such institutions existed, but that they existed and flourished with increasing prosperity for more than a quarter of a century. But though, on this account, some reproach falls upon all, the keenness of disgrace touches especially the city of Philadelphia. Her civil authorities had long known that this business was going on, and that ignorant men were every year being clothed with the responsibilities of the physician. Yet they did nothing in the matter. Her medical men were no less aware of the iniquity. But from her famous colleges, her historic societies, her immortal leaders in medical science, there came no efforts to clear the reputation of the city or the profession. The editor of a penny newspaper has done more than all the organized strength of the profession to destroy the diploma-mills and remove the stain upon the medical pre-eminence of Philadelphia. This is not a very proud moment for the physicians of that city. She has lost her prestige as a legitimate medical centre, and has won the reputation which comes from issuing three thousand spurious diplomas.

There is every prospect now, however, that the career of these colleges is at an end. Legal processes have been instituted against the trustees of one institution; the dean of another is languishing in jail; the proprietors of a third will soon have all their powers destroyed and their charter annulled.

The manufacture of diplomas in Philadelphia began in 1853, at which time the legislature chartered the American College of Medicine. In 1858 the name was changed to the American College of Medicine in Pennsylvania and the Eclectic Medical College of Philadelphia. In the diplomas subsequently issued, sometimes one part of the above title was given and sometimes the other. Various kinds of degrees were conferred, but most of them were medical. Finally a division of the charter and school was made. Dr. Wm. Paine took the American College and Dr. Buchanan the Eclectic Medical College. In 1865 the name of the American College was changed by the legislature to the Philadelphia University of Medicine and Surgery. Under this name the institution has flourished for fifteen years and gained a world-wide reputation. Dr. Buchanan, meanwhile, continued his own college, adding other fictitious names to it. In 1872 the State Legislature investigated these institutions. It was discovered that medical degrees were given after a few days' study, and that degrees of all kinds were sold at moderate rates. An instance was cited in which a degree of LL.D. was conferred on a child two years old. In consequence of the revelations thus made, the charters were repealed. Dr. John Buchanan, however, carried his case to the Supreme Court, and showed that the charter of his Eclectic Medical College was given before the legislature had reserved a right to repeal such instruments. The Court sustained the plea, and the college was kept on its feet. The Philadelphia University of Medicine and Surgery did not stand on the same footing with the other college. The question whether the legislature had a right to repeal its charter is a delicate one, but it seems probable, on the whole, that it had. Dr. Wm. Paine, however, did not choose to go to law about the matter. Instead of this, he took the risk, and continued operations in spite of the repeal.

At about this time the Institution was sold out to a ministerial syndicate of four. These persons ran the "University" with great success, it being under the immediate and able control of the Rev. Mr. Miller, Dean, and the Rev. Mr. Ingraham, President. Degrees of all kinds were issued, some of them very novel and ingenious. One of these confers all the privileges and immunities of a physician upon members of "The University Hospital;" another confers the privileges that belong to a student of medicine in the "University and Hospital of Philadelphia." Since 1859 over six hundred medical degrees have been issued from this "University" alone. Most of these were conferred on persons in the United States. A full list of the names is published in the *Philadelphia Record*, of June 14th. Two hundred and twenty of the persons holding these diplomas live in Pennsylvania and contribute to the elevation of the medical status of that State. New York comes next in number, and has sixty-six. Then follow various Western States, Ohio leading. Ten names are given of persons living in Germany.

While this University was thus in active work, Dr. John Buchanan, with his Eclectic Medical College and other institutions, had been no less busy.

The activity of his traffic and the elasticity of his collegiate nomenclature may be best learned from the following: A reporter of the *Philadelphia Record* bought of him, in open purchase,

One diploma of M.D. from the Eclectic Medical College; two diplomas of M.D. from the American University of Philadelphia; one diploma of M.D. from the Livingstone University of America; one diploma of M.D. from the National Eclectic Medical Association; one degree of D.D. from the Livingstone University; one degree of LL.D. from the American University, and one degree of D.C.L. from the Livingstone University.

Only one of the above institutions, the first, so far as we can learn, has even a chartered existence. The Livingstone University is located in Camden, N. J. An attempt was made to get a charter for it from the New Jersey Legislature. This attempt failed, but Dr. Buchanan ran the University just the same, using the alias of James Murray, D.D., Dean.

In addition to the Paine-Miller and the Buchanan diploma-shops, a quasi-medical college, known as the Electropathic Institute, has been unearthed. By a twenty-five hours' attendance on lectures, and the payment of $50, a degree of Master of Electricity can be obtained, and was so obtained by a *Record* reporter. This degree enables the possessor to treat all diseases, upon the theory taught at the School, a theory which is so unique as to deserve explanation. It is briefly this: No medicine ever cured disease. All diseases are simply disturbances of the electrical currents of the body. Those attended with inflammation, sharp pains, or extraneous growths, are simply evidences of too much positive electricity; those attended with dull pains, degenerations, and tendency to decomposition, are evidences of too much negative electricity. To effect a cure it is only necessary to change the abnormally negative to positive, or *vice versa*. Upon these theories the Electropathic Institute did its work, and graduated its students. Strange to say, it had received the endorsement of a number of prominent and presumably intelligent Philadelphians.

The decline and fall of all these institutions began about six months ago. The Philadelphia University of Medicine and Surgery then received a thorough exposure, and its ministerial supporters were disgraced. Still the civil authorities had no evidence by which they could convict them, and had no money with which to procure evidence and institute proceedings. Meanwhile, Dr. Buchanan, with his colleges, was still selling his diplomas, and evading all attempts to capture him. A plan was, however, at last arranged by the editor of the *Record*, for entrapping the wily President. Applications under assumed names, for diplomas, were sent to him from two distant country towns. After some negotiations the diplomas were forwarded, the money for them paid, and receipts given. Further evidence of sale of diplomas was obtained from other persons, and also by personal investigation of the collegiate building. On the 9th inst. Buchanan was arrested for using the mails to defraud, thus violating the laws of the United States; he was held in $10,000 bonds. On the next day a new indictment was brought against him for violating the State law in selling diplomas. This law, enacted in 1870, makes it a misdemeanor for any institution authorized to confer degrees, to sell such degrees, the penalty being $500 fine, and an imprisonment not exceeding six months. Under this charge Buchanan was held in further bonds of $2,000. Finally, upon the evidence of some of his associate professors, who testified that he had forged their names, he was held in bonds of $1,000 for the crime of forgery.

On June 14th, legal proceedings were begun in the Court of Common Pleas, for judgment of ouster against the trustees and officers of the Philadelphia University of Medicine and Surgery. The attempt will be made to show that, for five years past, this University has exercised powers which it had no right to assume; and that this exercise of power has been of injury to the commonwealth. There are, we believe, some nice legal points in this case, but that the decision will eventually be against the University there can scarcely be a doubt. A similar process will be, or has already been, instituted against the Eclectic Medical College.

The cords of the law are now being tightly drawn around the bogus medical colleges. If there is anything left of them after the law is done, the force of an aroused public sentiment may be relied on to complete the work. Diploma-selling is stopped for the present, and Philadelphia's reputation as a medical centre may cease to have its shady side. But we cannot feel sure that the cure is yet a permanent one. The fact that diplomas can be bought, and that diploma-selling is a paying business, has been widely advertised and will become known to the not overscrupulous, as well as to those who are honest. Permanent protection, though so urgently needed, is not yet insured. It cannot be obtained more surely than by the enactment of a wise law regulating the practice of medicine. With such a law, with civil authorities alert and medical organizations not wholly devoted to secret discussions and punctilious care in their reporting, Philadelphia may be able to purify its reputation and attain a scientific eminence which, if not supreme, will at least not be questionable.

THE INDIANA STATE MEDICAL SOCIETY.

The recent annual meeting of the Indiana State Medical Society, of which a full report appears else-

where in this issue, was a notable one in several respects. The Society held its session for only two days, but during that time accomplished an amount of work, in the way of reading and discussing papers and of practical business, which was extremely creditable to its members and to its activity as an organization. Some thirty or forty papers were read in full, or by title, and referred. It was voted in the beginning that no time should be devoted to social amusements, and that in future the length of the annual sessions should be extended to three days.

A feature of the meeting was the prominence of papers on sanitary matters, and the various branches of State medicine. In the discussions, also, these topics held a large place. The necessity of forming a State Board of Health was forcibly presented, and, while waiting for this, the voluntary organization, known as the Indiana Health Commission, received help and endorsement from the Society. This organization, which is the work of the State Medical Society alone, has now existed for several years and is a great credit to the enterprise and humanity of the medical profession of Indiana. The question of regulating the practice of medicine also received much attention. There was no disagreement as to the need of such regulation, but the proper kind of a law could not be agreed upon, and the Society adjourned, leaving the matter in the hands of a committee.

The contributions to practical medicine, if not of exceptional value, were, for the most part, very creditable and useful papers. On the whole, the Society did very good work, and justified its reputation as an active and wide-awake organization.

Death from Bromide of Ethyl.—The fatal case from inhalation of bromide of ethyl, before referred to in these columns, occurred under the care of Dr. Levis, May 26th. The patient was a young man suffering from stone in the bladder. He had been for several months in Jefferson College Hospital waiting for an operation. He had phthisis, and was much emaciated, but his kidneys and heart were sound. Dr. Levis, at the request of the patient and his friends, operated in order to give him his only chance of recovery. Everything being ready, about a drachm of bromide of ethyl was poured on a cloth and held over his mouth and nose. The patient took a few inspirations, and then quietly stopped breathing before the operation had commenced. Artificial respiration failed to restore him. At the autopsy the lungs showed pulmonary phthisis in an advanced stage, and the bronchi were full of mucopus forced into them by the attempts at artificial respiration. Nothing special was noticed in the gross appearance of the other organs.

London, of late, has been one of the healthiest cities in the world; its death-rate has been from eighteen to twenty per one thousand. Four months before, the same city was one of the most unhealthy of cities, its death-rate running up nearly to forty per thousand.

Reports of Societies.

THE NEW YORK SOCIETY OF GERMAN PHYSICIANS

Stated Meeting, April 23, 1880

Dr. L. Boff, President, in the Chair.

Neurectomy of the optic nerve for irido-cyclitis.

Dr. Greening reported a case of this kind, in which he had performed the operation for sympathetic affection of the eye. He had adopted Knapp's method in that instance. Section of the nerve was practised without previous cutting of any of the muscles of the eyeball. He added, that the nerve should always be cut as far back as possible; section near the bulbus oculi was to be avoided. The advantage of this method was the possibility it afforded of removing a large portion of the optic after eversion of the eyeball. In the same manner all the ciliary nerve-branches could be readily excised.

Dr. Knapp said that he had performed this operation three times during the present week. The last case was one of glioma, and he thought the operation had unquestionably saved the patient's life, since the malady was apparently progressive, and all the diseased portion of the nerve had been successfully excised. He also recommended the employment of a double hook, for grasping the optic nerve, and pulling it forward for inspection, previous to section. This would enable the operator to cut beyond the site of disease. Schweigger's method undoubtedly possessed the advantage of affording much space, but it involved too extensive cutting. This operator, it would be remembered, performed section of the internal rectus muscle, followed by cutting of the optic nerve. Then the eyeball was everted and both oblique muscles severed.

It must be admitted, however, that bulbar eversion was frequently very difficult, often quite impossible of accomplishment, unless the muscles were previously cut. In one of his patients a decided amelioration of the sympathetic ophthalmia had followed the operation. A previous agglutination of the iris had been partially relieved. Still, the permanent benefit remained somewhat doubtful.

Dr. Greening mentioned that neurectomy for endothelioma had been performed by Knapp, as early as 1874.

Gangrene of appendix vermiformis, perforation, diffuse peritonitis.

Dr. Wendt presented a specimen of acute gangrene of the vermiform appendix, apparently following a violent muscular effort. The history was furnished by Dr. Neumer, of the St. Francis Hospital. H. M., æt. 29, U. S., laborer, admitted to hospital, service of Dr. Lellmann, April 19, 1880. Has been in good health all his life, excepting only slight malarial trouble and mild rheumatic attacks. Four days previous to admission, while attempting to lift a heavy stove, he felt a sudden jarring in right iliac fossa. On the following day, without a previous chill, he was seized with severe abdominal pains. On admission patient was quite weak, showed marked abdominal tenderness, especially about the right iliac region, considerable tympanites, persistent vomiting of greenish matter, and some retention of urine. The respiration was chiefly costal, temp. varied from

99 to 102¼°. He sank rapidly, and died on the following day,

An autopsy was made twelve hours after death, and the following appearances noted: Diffuse purulent peritonitis; abdominal cavity contained faecal matter; numerous recent adhesions. Appendix enlarged, black, and gangrenous throughout. At about its middle there was an ulcerative perforation, of the size of a cherry-pit. The inflammatory process had stopped short at the peritoneum, there being no affection of the pelvic areolar tissue. Other organs without noteworthy lesions.

The etiology of the perforation was of some interest. The question arose whether the muscular effort started the whole morbid process, or whether there existed previous disease of the appendix without symptoms. In this instance the peritoneum, although itself extensively and severely involved, assumed the rôle of a protecting membrane, preventing the spread of the inflammation to the adjoining cellular tissue.

Dr. Klotz favored the view of pre-existing ulcer; he did not believe that muscular exertion could cause gangrene and perforation.

TUBERCULAR ULCERS CONFINED TO THE COLON IN A CASE OF PHTHISIS.

Dr. Wendt presented specimens consisting of portions of the lungs and large intestine, taken from a man who died at the St. Francis Hospital. C. M., æt. 42, German, cigarmaker, admitted March 29, 1880. Service of Dr. Lellmann. No hereditary taint. When fourteen years old received an injury resulting in bony anchylosis of right knee-joint. Otherwise enjoyed good health until about two years ago. At that time he began to cough and expectorate sputa streaked with blood. Emaciation also began to show itself. Hæmoptysis denied. Nine months ago profuse diarrhœa supervened and remained uncontrolled to date. Examination revealed bilateral pneumophthisis, slightly enlarged liver, no other abnormities. Progressive exhaustion, death April 9, 1880.

An autopsy was made twelve hours after death. The lungs showed the characteristic lesions of tubercular phthisis. Numerous apex cavities were found. Gastro-intestinal mucous membrane thickened throughout its entire extent, many ecchymoses, enlarged mesenteric glands and tubercular deposits in mesentery and omentum. The colon showed numerous tubercular ulcers, whereas the small intestine contained not a single one.

This patient died with the ordinary symptoms of the common affection pneumo-intestinal tuberculosis. The case was brought forward on account of the somewhat remarkable condition presented by the intestines. It would be remembered that Cohnheim had lately asserted tuberculosis to be a specific contagious disease. Tubercles, cheesy degenerations, and even giant cells were according to that author by no means criteria of the malady. The only trustworthy proof of its existence was the power of infection. According to Cohnheim intestinal ulcers were caused by local infection through the agency of swallowed sputa. Hence we would expect to find the first ulcers in the small intestine, and did in fact commonly meet with them there. In this case the mode of origin must have been a different one, perhaps local irritation superadded to a general infection of the system with tubercular virus. At any rate, Cohnheim's views did not cover every case.

Dr. Jacobi thought that the small intestine caused so rapid a propulsion of its contents, that time for infection there was not given.

Dr. Knapp referred to Cohnheim's experiments and said that foreign bodies generally caused tuberculosis in rabbits. Therefore reliable information could not be obtained from experiments on those animals. He had injected gliomatous matter into rabbit's eyes and invariably obtained inflammatory products, which resembled tubercular deposits.

CROUPOUS PNEUMONIA AND ICTERIC HEPATITIS—SUDDEN DEATH.

Dr. Wendt presented the organs of a man who had died at the German Hospital. F. B., æt. 38, for some time past addicted to drink, never sick before admission, which took place on April 21, 1880. He stated that he had felt ill for ten days, but continued to work until yesterday. Early on the 20th of April or during the night of the 19th, he was suddenly siezed with a severe rigor. This was followed by pains in the right side, dyspnœa, nervous disturbances, and general depression.

A lobar pneumonia of the right side was diagnosticated. The rectal temperature rose to 104°, where it remained unaffected by the treatment, consisting of large doses of quinine (40 grains) and other measures. Cyanotic collapse supervened, stimulants proved unavailing, and he died on the 22d of April, just two days after the commencement of his disease.

The autopsy elicited the following conditions: Abdominal cavity contained about a pint of turbid, icteric fluid. *Situs viscerum* normal, with the exception of a marked hypertrophy of the left lobe of the liver.

The heart. The pericardium contained about three ounces of bloody serum. Subpericardial fat in great abundance. The right auricle was found extremely attenuated and contained yellowish clots, which were rather firmly adherent to its walls. Similar clots were found in the vena cava superior and could be traced into the jugular veins. The other cardiac cavities also contained such coagula, but in less abundance.

The lungs. Croupous pneumonia of middle lobe of right lung, but on pressure there appeared a dirty, faintly fetid, thickish fluid. Remaining lobes and other lung nearly normal; *the kidneys* appeared healthy; *the spleen* was small, the pulpa friable, congested; it was bound down by firm adhesions to neighboring structures; *the liver* of firm consistency, much enlarged, intensely yellow, the acinous markings obscure; *the bladder* contained about six ounces of icteric urine, slight thickening of its walls; *the gastrointestinal canal* appeared normal; *the brain* could not be examined.

The cardiac appearances were remarkable, the walls of the right auricle were so extremely attenuated at one point, as to justify the notion of an imminent rupture. The liver presented the first stage of an icteric hepatitis. The disease ran a course which corresponded more nearly with a severe infectious malady than with an ordinary croupous pneumonia.

Dr. Jaconi questioned with regard to the condition of the blood. He thought that the heart appearances pointed to a possible leucocythæmia, and begged for a microscopic examination to determine more precisely the nature of the malady.

ATAXIA WITHOUT PARALYSIS.

Dr. Jaconi exhibited a young man who was afflicted with that rare form of ataxia which was unaccompa-

and by parasitic manifestations. The patient had probably had diphtheria. His sensibility had returned unimpaired, but the tendon reflexes had entirely disappeared. The patellar phenomenon was altogether absent. Appropriate treatment had been followed by slight improvement, but the tendon reflexes had not returned.

PROGRESSIVE CONTRACTION OF STOMACH WITH GASTRIC HYPERTROPHY.

Dr. Jacobi showed the above specimen, and gave the following history: A man, aged two years old, who was in former years rather addicted to gluttony, had suffered for six months from frequent attacks of vomiting. The patient gradually grew worse, and rapid emaciation set in. The spasmodic vomiting did not completely empty the stomach of its contents, for until quite recently, termed faces were evacuated. The stomach, however, did not largely participate in digestion, since unaltered ingesta were rejected some fifteen minutes after a meal. The diagnosis was not definitely established. Cancer, disseminated in small patches through the gastric walls, was thought of. Also, dilatation of the stomach, following gastritis. In the latter case, it was thought possible that peritonitic adhesions had bound down the organ to neighboring structures, thus causing abnormal tension and producing the observed symptoms.

An autopsy revealed a condition of things, of which very inadequate accounts are given by the various text-books. The stomach was found to be shrunken to the size of a loop of large intestine. It was concentrically hypertrophied, a condition which might be regarded as the final stage of a subacute gastritis, with superficial ulceration. The walls of the stomach, although in general considerably thickened, showed also areas of marked attenuation. The cardiac extremity was the seat of several cicatricial spots, and at the œsophageal junction, a hard lymphatic gland was found. This enlarged gland was presumably in a condition of sarcomatous degeneration.

Similar gastric contractions occurred in conjunction with certain œsophageal disorders, and derangements at the cardiac orifice caused by cancer, or cicatrical retraction. The symptoms were always more or less vague, and devoid of pathognomonic import.

Dr. Langmann thought the case was one of contraction incident to phlegmonous gastritis.

Dr. Wendt observed that the pathologico-anatomical appearances were opposed to the probability of recent phlegmonous gastritis. In such cases purulent matter could be obtained on pressure of the gastric walls.

Dr. Jacobi agreed with Dr. Wendt, stating that the patient had never been sufficiently ill to warrant the assumption of a phlegmonous gastritis. The patient had not even been confined to his bed until shortly before his death.

EXTIRPATION OF ONE LATERAL HALF OF LARYNX, PHARYNX, AND BASE OF TONGUE.

Dr. Gerster showed specimens removed as above from a patient at the German Hospital, and remarked as follows: During the month of November, 1879, Dr. Gruening found in a man, aged 50, a flat ulcer situated near the laryngeal entrance. Specific treatment was resorted to in order to give the patient the benefit of the doubt as to the specific or non-specific character of the ulcer. The ulcer spreading, an operation was decided upon. Preliminary tracheotomy was done on Jan. 19, 1880, and on the 5th of March the operation was performed in the following manner: after ligature of the lingual artery on the right side, the larynx was exposed by incision in the median line. Then the right half of the thyroid cartilage together with the true and false vocal chords, the right portion of the pharynx, the right half of the hyoid bone and a part of the base of the tongue, had to be removed. In spite of the digital tamponnage, some difficulty was experienced, on account of the final putrescence of Trendelenburg's tampon-cannula. This cannula was constructed for introduction into the lower part of the larynx of small species, in order to prevent the aspiration of blood. After the insertion of an œsophageal tube, the wound was washed with a 10 per cent. solution of chloride of zinc, and filled with small pledgets of Lister's gauze. The operation was well borne, nutrition was readily sustained by feeding through the tube, and the patient was up and about on the 20th day after the operation. He had gained six and a half pounds. The patient was now able to articulate by closing the opening in his neck. His voice was a harsh, rather deep whisper, but was distinctly audible. Deglutition was still accompanied by the entrance of ingesta into the respiratory passages. This fact was explained by the extensive deficiency of the pharynx and base of the tongue, as well as by the circumstance that the remaining half of the larynx obviated the possibility of approach between the tongue and the entrance to the trachea. The progress of cicatrical retraction would doubtless remove this unpleasantness. The microscopical examination of the tumor revealed an adeno-fibro-sarcoma, which was probably identical with the tumor described by Maas (*Arch. für klin. Chir.*, vol. xix., p. 507) as an adeno-fibrous carcinomatoma.

Dr. Curtman showed his magnetic apparatus (*vide* Med. Record, May 1, 1880, p. 484), and illustrated its practicability by demonstration.

INDIANA STATE MEDICAL SOCIETY.

Thirtieth Annual Session, held at Indianapolis,
May 19 and 20, 1880.

(Special Report for The Medical Record.)

Dr. G. R. Weist, President, in the Chair.—First Day.

The Convention was opened with prayer by R. Ansgus, D.D., LL.D. A committee of five on credentials was immediately appointed. Dr. E. S. Elder, Chairman of the Committee on Arrangements, made his report, detailing the arrangements for the session with hotels, railroads, etc., and referring to the large number of papers on State Medicine that had been handed in.

The President, Dr. J. R. Weist, then stated that the character of his formal annual address would prevent his referring in it to any practical recommendations for the action of the Society. He would, therefore, make such recommendation at that time. This he did, presenting his points under four heads:

PRACTICAL SUGGESTIONS.

1. As to the length of the session, every year the number and value of the papers presented to the Society increased. The discussions upon these were often extremely valuable, but at present there was scarcely any time for such discussion. For this reason it seemed imperatively necessary to increase the length of the annual session to three or four days, if

the Society was ever to fairly represent the status of its membership or the character of the work of which the medical profession of Indiana was capable. Another reason for lengthening the session was, that at present there was no time whatever for social features that might be, in his opinion, introduced into the annual meetings with great advantage.

2. In regard to printing papers in the transactions, he said that the printing in the volume of transactions of the Society the papers read at its meetings entailed a useless expenditure of money, failing as it certainly did of bringing either notoriety or honor to their authors. It was well known that the transactions of State societies and of the National Association are not generally read, even by the members.

A good paper, then, thus printed, was practically lost to the profession. Medical journals of wide circulation are willing, he said, to publish all papers of real value offered to them. Give the authors of papers presented to the Society permission to publish them where they please, placing after the title, "read before the Indiana State Medical Society," and all valuable papers will, at an early day, be properly placed before the profession and attract the attention they deserve. Papers that respectable medical journals will not publish are not deserving of a place in the transactions.

The money thus saved might be well expended in rewarding such of the members as, by original research, add new facts to the store of professional knowledge.

3. As to the importance of county societies, it is desirable that the State Society use all proper means to impress upon the minds of its members the importance of giving great attention to their county societies, in order to make them the best possible, and to make it apparent that all the energy spent upon district, inter-state, and other similar societies, is a loss to the county organization, and therefore to the State Society.

4. As to representation in the American Medical Association. It having been the custom for the county societies, as well as the State Society, to appoint delegates to the American Medical Association, the profession of the State has, he said, sent to this national organization twice as many delegates as it is entitled to send. This is clearly wrong, and if continued, will lead to misunderstanding and harm. The proper plan would be for the county societies to nominate from among their own members the number of delegates to which they are entitled by law, while the State Society appoints them. All parts of the State may then be represented in the National Association, and the delegates at the same time have the honor of being State delegates.

Drs. Commons, Boyd, and Charleton were appointed a committee to consider the suggestions submitted by the President.

REPORTS.

Dr. G. V. Woolen, Secretary, reported that he had collected from the various County Societies, during the past year, $1,023. He also reported favorably as to the credentials of Brown, Franklin, Johnson, and Owen counties.

Dr. F. J. Van Vorhis, Librarian, made a brief report.

Dr. Alison Maxwell, Chairman of the Committee on Publication, reported that 1,100 copies of the Transactions of the Society for 1879 had been printed, at a cost of $599.60. Copies had been sent to prominent medical journals, fourteen in number. Two of these journals had reviewed the volume, one had simply acknowledged its receipt, the rest had paid no attention to it.

The following were appointed a committee on ethics: Drs. James F. Hibberd, Richmond; J. W. F. Gerrish, M. Sexton, P. H. Jameson, G. L. Andrews. The following were appointed a committee on medical assurance: Drs. J. R. Beck, Fort Wayne; F. S. Newcomer, N. B. Howard, Sr. Drs. L. D. Waterman, Indianapolis; Benj. Newland, F. W. Beard, P. McNabb, and J. T. Bells, were appointed a committee on finance.

A paper was then read by Dr. I. C. Walker, of Indianapolis, on

A REMARKABLE CASE OF CEREBRAL TUMOR.

The patient, a man, aged 59, was attacked with vomiting, headache, insomnia, and slight mental aberration. Temperature slightly raised, pupils normal, articulation distinct; no constipation, no disturbance of motion or sensation anywhere. The case continuing, there were gradually developed symptoms of compression: dilated pupils, slow pulse, stertorous breathing, but no paralysis. The patient died, but more, it seemed, from gradual exhaustion than from direct effect of compression of the brain. Post-mortem showed a large amount of serum (℥ ii.) in the cavity of the arachnoid. A cystic tumor was discovered on the left hemisphere, situated immediately to the left of the longitudinal fissure, covering the most of the upper and lateral surfaces of the middle and anterior lobes, weighing three and one-eighth ounces; sack one and one-eighth ounce, and measuring five and three-fourths inches in length, two and one-half inches in width, and one and one-half inch in depth. This was situated under the dura mater and above the visceral arachnoid, with a marginal attachment to the falx cerebri at the upper edge of the longitudinal fissure. The outer margin, ends, upper and under surfaces were free everywhere from adhesions of any kind except at the point named. This patient suffered through life at irregular intervals with affections of the head and attacks of vomiting. He was well developed physically, and mentally had much more than average intelligence, business capacity, energy and force of character, which remained unimpaired until his last illness. Dr. Walker believed that the tumor began when the patient was twelve years old. At that time he had received a blow on the head, and had suffered from cerebral symptoms at intervals ever since.

The paper was discussed by Drs. J. H. Woodburn, Hanghton, and others.

Dr. William Lomax, Marion, read an interesting report of a case of Injury to the Head, with Fracture of the Skull. The paper was referred to the Committee on Publication, to be printed in the transactions of the Society.

In the afternoon of the first day the session opened with a report of the Select Committee by its Chairman, Dr. J. F. Hibberd, on ex-President Newland's address last year on

STATE MEDICINE.

Three points presented by Dr. Newland were specially examined. These were in regard to the duty of the State:

1. To foster and protect the health of her citizens.

2. In some way to so label proprietary medicines that all who choose may know their composition.

3. Within certain limits to inquire into the preten-

sions of practitioners of medicine, and point out the qualified to public recognition.

1. In regard to the first point, the committee presented concisely but forcibly arguments for the establishment of a State Board of Health. The responsibility which lays upon the medical profession of strongly urging the creation of such a board was also shown.

2. Declaring the evil of proprietary medicines, it was concluded that any legal measures restricting or forbidding such traffic would be impracticable. It was affirmed that the evil was not so great as it might be, because most patent medicines were not positively dangerous. In conclusion, it was said:

"The best method of dealing with this difficult problem at this time that suggests itself to us is to call the attention of a competent State Board of Health to it, requiring that they gather the facts concerning it, and thoughtfully work out a conclusion that shall indicate active interference, or, what seems more likely, determine that for the present, at least, the condition of *laissez faire* is best."

3. As regards regulating the practice of medicine, the committee expressed their belief that it was the duty of the State to see it done.

The views of the committee were summarized in the following resolutions:

Resolved, as the sense of the Indiana State Medical Society: 1. That the time has fully arrived when the people of Indiana are entitled to have the benefit of sanitary science applied to public affairs for the maintenance of the general health, and that it is the reasonable duty of the Legislature to establish a State Board of Health, with ample power and means to apply existing sanitary science, and to aid in its further development; and that this board should be composed of men noted for their acquirements in medical hygienic engineering, legal and executive knowledge.

2. That the matter of proprietary medicines and patent nostrums should be turned over to the State Board of Health for their thoughtful consideration.

3. That it is the duty of the State of Indiana, through her Legislature, to establish boards to inquire into the qualifications of all persons claiming the right to practice medicine in the State; and that while all should be required to have a competent knowledge of biological laws and elementary medicine, each class or school of doctors should be examined by a board composed of members of its own guild.

Dr. J. D. Gatch, of Lawrenceburg, then read a report on "Harmony and Associated Action in Connection with State Medicine." The paper was lengthy, able, and comprehensive, and was listened to with the closest attention.

The Committee on Credentials presented resolutions, which were adopted, refusing admission to the delegates from Fulton County Medical Society, on the ground that the said Society was composed, in part, of irregular practitioners.

Papers were read by Dr. J. W. Hervey, of Indianapolis, on "Some of the Unsolved Problems in Public Hygiene and Synteretic Jurisprudence," and by Dr. J. Van Voorhis, B.L., of Indianapolis, on "Expert Evidence." Both papers were well received.

Dr. Thad. M. Stevens, of Indianapolis, submitted the report of the

INDIANA HEALTH COMMISSION.

The history of the organization, which originated in the State Medical Society, and is solely the work of medical men, was given. It had recently extended its scope by the formation of District Health Commissions, thirteen in all, throughout the State. It hoped to supply, in part, the lack of a State Board of Health, and to stimulate a general interest in sanitary matters.

The following resolution was offered for adoption:

Resolved, That the Indiana State Medical Society require each county society in the State, to require of each of its members to keep a record of births, and sex of those born, of deaths, and causes of death, as occurring in their practice, and a note of every epidemic or endemic disease in their precinct, also such other facts as they may deem proper in connection with vital and sanitary statistics, and report the same to the local commission as instituted by the State Health Commission, so that the said local commission can report the same to the State Health Commission for the purpose of a condensed report by it to the State Medical Society, and that each county society shall cause to have printed blanks to each of its members according to a form to be furnished by the State Health Commission, and that the Secretary of this Society notify each county society of this action.

Dr. Stevens then read a carefully prepared paper on "The Sanitary Survey of Indianapolis." He showed that the city presented many hygienic defects, but was capable of being made a very healthy place.

Dr. Mary F. Thomas read a paper advocating "Women Physicians in Lunatic Asylums." This, with the three preceding papers, was referred to the Health Commission.

Dr. Stevens also read a paper on "What are the Essentials to Regulate the Practice of Medicine?" and Dr. S. S. Boyd, of Dublin, a paper on "Medical Legislation."

Dr. John M. Kitchen, of Indianapolis, presented to the Society a memorial of the Marion County Society, asking the Legislature to regulate the practice of medicine, and submitting a bill providing measures for this purpose.

Dr. J. F. Hibberd, of Richmond, argued against the Marion County plan, and offered another as a substitute. The chief points of this were embodied in the following resolution which was adopted:

Resolved, by the Indiana State Medical Society, That a law to regulate the practice of medicine in Indiana should require one board of examiners for each system or school of medicine in the State that has a State society or organization; that the law should authorize each State society or organization to select the members of the board of examiners for practitioners of its own professional faith; that a law to regulate the practice of medicine in Indiana should require every person who enters the profession, after the law takes effect, to be examined by a board of examiners, but such person must be a graduate of a medical college in good repute to entitle him to an examination; that a select committee of five be appointed to embody the principles adopted in the foregoing resolution in a bill for a law with all necessary details, to be submitted, if possible, to this session of the Society for its approval, with a view to having it presented to the next Legislature as a bill for a law to regulate the practice of medicine in Indiana which has the approval and support of the Indiana State Medical Society.

The following were then named as the special committee on the resolutions, and the afternoon session closed: Drs. Hibberd, P. H. Jameson, Gerrish, Edmunds, and Beard.

At the evening session President J. R. Weist delivered the annual address on

PROBLEMS IN RELATION TO THE PREVENTION OF DISEASE.

The address was an eloquent and impressive presentation of the importance to the State of attention to the health of its people. Speaking of his own State, he said:

"The annual loss to our own State from preventable sickness and mortality, could it be correctly calculated, would create astonishment. A calculation based on the same data used in estimating the preventable loss of life and money in the United States by disease, gives this result: an annual unnecessary loss of more than 5,000 lives and more than 6,000 persons constantly sick from causes which are preventable; this sickness and mortality entailing an annual loss of more than $4,000,000."

Dr. Weist also referred to Dr. Benj. Lee's figures, by which it was estimated that the cost of a large epidemic is $2,000,000; that of preventing it, $800,000.

On the

SECOND DAY

the special committee appointed to consider the suggestions of President Weist in regard to business of special importance reported in favor of extending the sessions from two days to three days. The committee also favor restricting the Society to the consideration of medical matters and topics allied thereto, and oppose anything tending to give the annual gathering the nature of a social meeting. The sessions were to be strictly for work.

A paper was then read by Dr. William Commons on "Ergot, Its Use and Abuse."

Dr. W. R. McMahan read an article on "The Active Form of Pernicious Fever." This paper also attracted considerable interest, and was referred to the Committee on Publication.

The Committee on Ethics having reported on various charges against county societies and individuals, further papers were read by Dr. C. B. Stemen, of Ft. Wayne, on "Gall Stones, with a Death;" by Dr. Joseph R. Beck, of Ft. Wayne, on "Two Cases of Tumors of the Anterior Vaginal Wall;" by Dr. J. S. McMurrey, of Frankfort, on "Death from Heart Clot."

THE ELECTION OF OFFICERS

for the ensuing year then took place, resulting as follows: President, Dr. Thomas B. Harvey; Vice-President, Dr. John D. Mitchell; Secretary, Dr. E. S. Elder; Corresponding Secretary, Dr. G. W. Burton; Treasurer, Dr. H. W. H. Kemper; Librarian, Dr. F. J. Van Vorhis.

After this the Society had a slight diversion, Dr. J. R. Beck being publicly reprimanded by the President for wantonly assaulting Dr. W. D. Wood.

A number of papers were referred to the Committee on Publication without reading.

Dr. Stevens, Secretary of the State Health Commission, reported back the papers referred to that commission, with recommendation to publish. It was further recommended, and the recommendation was endorsed, that the President appoint a committee of five to present the subject of women physicians in hospitals for insane women to the State Legislature.

At the close of the report, delegates were elected to the National Convention.

In the afternoon session it was ordered that 3,000 copies of the budget of the State Health Commission be printed for circulation.

Dr. W. S. Haymond, of Indianapolis, read a paper on "Human Longevity."

Dr. J. R. Beck, from the Committee on Necrology, reported the death of eight members during the past year.

A number of papers were presented and referred to the Committee on Publication without reading.

The subject of medical legislation engaged a large share of the closing hours. In the discussion,

Dr. R. N. Todd rose on a question of privilege. The report of Dr. J. F. Hibberd, of the day before, on legislation necessary to regulate the practice of medicine in Indiana, he said, contained most offensive matter regarding the motives of the medical colleges of Indiana. He defended the colleges from the attack of Dr. Hibberd, and disclaimed the motives that gentleman had attributed to them in his remarks.

Dr. I. C. Walker also rose to a question of privilege concerning the same subject, and after a few remarks moved that the objectionable sentences be stricken from Dr. Hibberd's report. Carried.

Considerable debate followed as to what kind of a bill for the regulation of the practice of medicine should be presented to the Legislature. It was finally voted that the Committee on Medical Legislation be authorized to draft the needed bill, and report at the next meeting of the Society.

The Society then adjourned, to meet the third Thursday in May, 1881.

MICHIGAN STATE MEDICAL SOCIETY.

TRANSACTIONS OF THE FIFTEENTH ANNUAL MEETING,

Held in Grand Rapids, May 12 and 13, 1880.

(Special report for THE MEDICAL RECORD.)

The members of the Society assembled in the Superior Court room at ten A.M., and was called to order by Dr. Geo. K. Johnson, President. Prayer was offered by Rev. J. Morgan Smith, of Grand Rapids, after which Dr. J. O. Edie, member of the Executive Committee, welcomed the Society, in a few appropriate remarks, to the hospitalities of the physicians and citizens of the Valley City.

The roll was then called by the Secretary, when a large number of members responded to their names.

The Executive Committee reported a programme for the entire meeting, and gave notice that cards of invitations to receptions to be given the Society by Dr. and Mrs. G. K. Johnson and Mr. and Mrs. F. B. Gilbert, on Wednesday evening, would be distributed to the members of the Society in attendance and their ladies.

Several physicians, not members of the Society, were proposed for membership, and their applications were duly referred.

Dr. Bingham, of Brighton, moved that a committee of five be appointed to consider the matter of reorganization into a delegate body, and give their views upon the subject in a full report at the next meeting. Adopted.

THE USE OF ALCOHOL IN MEDICINE.

The Secretary read the following communication from the Woman's State Christian Temperance Union:

"1. Is the use of alcoholic liquors an absolute necessity in the practice of medicine?

"2. Is not their prescription in great danger not only of resulting in their self-prescribed use as a medicine, but also of fostering a habit of their use as a beverage?

"3. Is not the danger of their use as a medicine, resulting in their abuse as a beverage, so great as to demand from the medical profession the utmost care in their use?

"4. Is the use of beer as a tonic, either in sickness or in health, a necessity?

"As mothers and wives who entrust to your healing care not only our own health and lives, but the health and lives of those whose well-being is of inestimable value to us, we appeal to you to use your utmost influence to protect us and them from the danger which threatens us from the free and sometimes reckless prescription of alcoholic liquors.

"We ask of your honorable and learned association such an expression on this subject as shall influence the medical faculty to exercise such care in the use of this terrible agent of evil as may avert such deplorable consequences."

After considerable discussion, the communication was referred to a committee of five, with a request to report at the next meeting.

Dr. Sharra, of Detroit, read a paper

ON INHALATION IN THE TREATMENT OF DISEASES OF THE RESPIRATORY TRACT.

The writer believes that success in the treatment by this method depends upon the careful selection of both the patient and the agent to be employed. The effect of a given inhalation depends upon the temperature, moisture, and amount of exercise required, as much as upon the medicament used. The respiratory tract is intended to receive only ordinary air, and it is not astonishing that ill effects are often produced by the inhalation of medicated air. In many acute affections of the bronchial tubes and lungs, the heat and moisture of the vapor inhalation will cause such swelling and irritation of the mucous membrane as to greatly aggravate the diseased condition. In other cases the muscular effort is productive of mischievous exhaustion.

The paper speaks of four different methods of inhalation. Atomization is the most useful in diseases of the upper air passages; the steam apparatus being preferable for the larynx, trachea, and nose.

Vapor inhalations consisting of air inspired through medicated hot water, the writer finds very beneficial in those varieties of nasal, pharyngeal, and bronchial catarrh characterized by dryness of the mucous membrane; in cases of thickening of the mucous membrane after acute laryngitis and bronchitis; in chronic bronchitis and fibroid phthisis with extensive structural change in the adenoid tissue; and in chronic catarrhal pneumonia and bronchitis attended with incessant cough. He thinks that great harm is sometimes done by the use of these inhalations in some cases where there is great irritability of the mucous membrane.

Under the head of the inhalation of gases, he speaks of the treatment of pulmonary phthisis by nitrogen diluted with atmospheric air. The gas is generated in a large inhaling apparatus by the action of a solution of ferrous sulphate on iron-filings. He has found it beneficial in some cases; its action is sedative and it is therefore most useful in acute and chronic inflammatory conditions with irritability of the terminal nerve filaments. He thinks the inhalation of the fumes of burning drugs, and slowly evaporating tinctures, balsams, etc., will come into more general use. The method is easy of application and can be used without fatigue. These dry inhalations are best borne in chronic affections attended by excessive expectoration.

In regard to the philosophy of the action of this method, the writer believes that the systemic effect of a drug introduced by inhalation is not produced through the medium of the blood, but by its local effect upon the terminal nerve filaments of the pulmonary and bronchial mucous membrane.

Hence the [illegible] of this mode of medication rests more upon the [illegible] than the general effect produced, and it cannot be relied upon for curative results without attendant dietetic and hygienic treatment.

Dr. Bigelow then read a paper written by Dr. J. J. Mulheron, entitled

RHEUMATISM *vs.* LEAD-POISONING.

He said that rheumatism is often the result of lead-poisoning. Lead colic, when it does occur, is certainly pathognomonic, but is by no means a necessary symptom of the poisoning. The symptoms are often heavily marked. We have a history of flesh, malaise, dullness of spirits, constipation. How often this condition is treated with a blue pill at night, followed with a dose of salts in the morning. The sulphate of magnesia is the best possible remedy for the lead-poisoning, relieving the bowels and forming an innocuous sulphate with what remains. The physician who gives this, does often better than he knows. If, however, the trouble is not nipped in the bud, rheumatism is diagnosed and treated with the "sure cases." Still the symptoms know no abatement until the patient goes to some sulphur spring and is cured. Mrs. P—— had such symptoms during the winter of 1877, and was advised to go to Mt. Clemens and take some sulphur baths. After a short stay she was thoroughly cured. An examination of the cooking utensils in this lady's house revealed the presence of lead.

Dr. H. O. Walker, of Detroit, read a paper upon

LITHOLAPAXY AND LITHOTOMY,

with a report of eight cases of removal of stone from the bladder, four by each method, with a death in each series. In the procedure by lithotapaxy, three of the cases resulted happily, with no untoward symptoms.

Case I.—Aged 67 years; date of symptoms, twenty-five years. Had had operation for lithotomy and repeated crushings, without permanent relief, when rapid lithotrity was performed. Time of operation, one hour and ten minutes. Sixty grains of phosphatic stone removed.

Case II.—Aged 17; date of symptoms, two years. No. 29 F. evacuating tube used. Time, one hour and thirty minutes. Amount of stone removed, 347 grains.

Case III.—Aged 27; date of symptoms, seven years. Time of operation, one hour and twenty minutes. Amount removed, 287 grains.

Case IV.—Died. Result of injury to prostate. The doctor exhibited Bigelow's lithotrite and evacuating apparatus, with which he had made his operations. He also exhibited a new urethrotome, which he had devised for the purpose of cutting "large-sized strictures."

The meeting then adjourned to 2 P. M.

AFTERNOON SESSION.

The meeting was called to order by the president. After roll-call a large number of proposals for mem-

bership was made and referred to the Committee on Admissions.

Dr. G. K. Johnson, President of the Society, next read his annual address, the subject of which was heat, or thermic force.

A vote of thanks was duly tendered for the same.

Dr. Eugene Smith, of Detroit, then read a very interesting paper on "Inflammation of the Eyes in New Born Babies," claiming, with proper treatment and care, that inflammation could always be cured.

Considerable discussion followed, in which Prof. Jones, of Chicago, Drs. Pratt, of Kalamazoo, Fuller, of Grand Rapids, Brodie, of Detroit, Bennett, of Coldwater, and Hitchcock, of Kalamazoo, took part. On motion, the paper was referred to the usual committee.

Dr. A. F. Kinne, of Ypsilanti, read an interesting paper on "Eclampsia from Uræmic Toxæmia, Promptly Relieved by the Emetic Operation of the Veratrum Viride." On motion, referred to the Committee on Publication.

DUBOISIA MYOPOROIDES.

Professor C. J. Lundy, M.D., of Detroit, read a paper on "Duboisia Myoporoides," a "New Therapeutic Agent in Diseases of the Eye." Preparations of the extract and of the sulphate of duboisia were exhibited to the association. His experiments show that it dilates the pupil rapidly and completely, and thoroughly paralyses the muscle of accommodation. Its action is more prompt than that of atropia. When a solution of the sulphate containing two grains to the ounce was employed, the pupil began to dilate in four minutes in some cases, and dilatation was ad maximum in fifteen to eighteen minutes. With weaker solutions dilatation of the pupil did not begin for fifteen or twenty minutes, or longer. Paralysis of the ciliary muscle was easily produced by a two-grain solution of the sulphate of duboisia. Weak solutions produced slight paresis of the ciliary muscle.

The pupil remained dilated from forty-eight hours to six or seven days, according to the strength of the solution employed.

Paretic conditions of the ciliary muscle disappeared in twenty-four hours, but when paralysis was complete, the muscle did not regain its contractile power for four or six days.

Weak solutions which dilated the pupil very widely scarcely affected the accommodation. When four to six drops of a two-grain solution of the sulphate of duboisia were instilled into each eye, in the course of an hour the following conditions were observed: Rapid and complete dilatation of the pupil, paralysis of accommodation, more or less retinal hyperæmia, dizziness, a staggering gait on attempting to walk, a certain degree of intoxication, confusion of ideas, drowsiness, flushing of the head and face, dryness of the skin, diminished salivary secretion, and in a few instances marked dryness of the mouth and throat, slight elevation of temperature, and increase of the pulse rate. Had used duboisia in central perforating ulcer of the cornea, in phlyctenular keratitis, in acute iritis, in spasm of accommodation, to paralyze the ciliary muscle, and in cases where atropia produced irritation. It was contraindicated in peripheral perforating ulcer of the cornea, and, from its action on the intra-ocular circulation, it was also contraindicated in glaucoma, in choroidal inflammations, of whatever nature, and in inflammation of the retina.

Referred to publishing committee.

A paper was then read by Wm. H. DeCamp, M.D., of Grand Rapids, entitled

THE ACTUAL CAUTERY.

The author said that it is well known by all members present that the *actual cautery* has been recorded among the early remedial agents in surgery.

In looking up its early history, he found it first mentioned at a period about 500 years B.C. It was then used for arresting hemorrhage, and for little else. For a remedy or agent in surgery to keep its place in the list of standard remedies for a period of 2,400 years was enough to prove its usefulness and superiority over many others, less obnoxious to the minds of those suffering from maladies demanding its use.

It is not his purpose to discuss its many good, or other qualities, or show a differential value between it and other agents; but simply to give to the society his experience and knowledge of the different forms of the same, and the improvements of the present day in instruments capable of producing and maintaining the requisite degree of heat required for the surgeon's use.

Modern writers spoke most highly of the electric cautery for procuring this result. This means of heating by electricity was one that could be used to better advantage than any other.

From an examination of the standard surgical authorities of the present day, he was satisfied they gave the preference to this means of procuring the heat to any other mode. This he thought was true for uses upon the uterus or fauces where any radiated heat is inadmissible. The kind most highly spoken of was that of Middeldorpff's, of Breslau. The portable instruments were not sufficiently active to give good results. The instrument that was as near to a perfect one as we well can imagine is that known as the Cantère Paquelin, as it is made by G. Tiemann & Co., with its improvements and attachments. The working of this instrument in his hands lead him to place it as the first in importance to all others.

The paper was discussed by Drs. Maclean and Fuller, and on motion was referred to the publication committee.

Dr. I. S. Hamilton, of Tecumseh, Dr. D. S. Hall, of East Saginaw, and Dr. Eleazer Hall, of Saline, were, by a vote of the Society, made honorary members.

The meeting then adjourned till 10 A.M. next day.

Second Day—Morning Session.

The meeting was called to order by the President and the roll called by the Secretary, when Dr. Foster Pratt, of Kalamazoo, chairman of a committee appointed at the last annual meeting to report upon President Cox's address on "Criminal Abortion" proceeded to read his report.

The committee claimed that the moral sense of the community was greatly debased on this subject, and should be quickened to make a higher and truer estimate of the enormity of this crime against all moral and physical laws. The medical profession condemn it, nature herself pleads against it, human laws forbid it, but fashion, laziness, and sordid selfishness unite to plead for it and with far too much success. The report was an able one, and reflected credit upon the committee. It was on motion referred to the Committee on Publication, with instructions to publish.

THE PROGRESS OF SURGERY.

Dr. Theodore A. McGraw, of Detroit, Chairman of the Committee on Surgery, read quite a lengthy and exceedingly interesting and able paper. The

paper discussed the general results due to advances in surgical knowledge, without considering the minute details, but especially the influence which the recent developments of science have had upon the profession itself.

He urged the necessity of popularizing operative surgery, to be done by the mass of the profession as opposed to allowing nearly all of it to drift to large centres of population to be done by specialists. He said that the late war in America had helped to educate a vast number of surgeons, and that as a consequence there has never been an age or a nation in which operative surgery was so practised by the whole profession as in the nation since the war. He spoke, however, of the unfavorable tendencies which threaten to transfer the control of many branches of surgery from the general profession to specialists. Ophthalmology, he said, was fast becoming as thoroughly special as dentistry. Laryngology and gynæcology has already fallen largely into the hands of a select few. It is both to the duty and the profession an exceedingly important question, how far the profession should yield to this tendency. He urged that the general practitioner should not neglect and abandon altogether any field of practice, but qualify himself to practice any part of the medical art, as there are thousands of emergencies constantly happening in everyday practice which require immediate and skilled attention. The wounded artery, the compound fracture or dislocation, must be treated skilfully and without delay. The strangulated hernia demands prompt attention, and the extravasated urine must be speedily evacuated. The prompt recognition and proper treatment of a cancerous lump in the breast, the early stage of hip disease and periostitis, may be relieved and the patients rescued from death or saved long years of suffering, by availing themselves of the services of a skilled surgeon at home, while it would be impracticable for them to receive the protracted course of treatment necessary at a long distance from home. He also urged in favor of home treatment, the genial influences of friends, pure country air, and his accustomed habits. While acknowledging that the one who has performed a certain operation many times may have learned things which never would have otherwise come to him, the limits of special practice, on the other hand, tend inevitably, to a certain extent at least, to dwarf the man. What he gains in technical knowledge he loses in grasp of principles. He urged that the general practitioner should be skilled in the use of the ophthalmoscope and laryngoscope, whose uses have rendered it possible to make ophthalmology and laryngology specialties. Of the hindrances in the way of the general practitioner of surgery, he spoke of the numerous costly instruments he might have to purchase, never to use but once, and the new methods of operating, requiring much more of the surgeon's time than was formerly required. He said, whatever else may be said of Lister's antiseptic treatment, it was not true that it can be applied properly without great expenditure of time. In a hospital where trained assistants have everything ready, all passes off quick, but in private practice, the time consumed in getting the spray apparatus to work would be sufficient, under the old system, to have dressed the wound, etc. The antiseptic method, too, demanded greater watchfulness, as the dressings must be changed the moment there were indications of threatened exposure to the ingress of septic germs, and especially as they must always be attended to by the surgeon himself or a trained assistant. According to German surgeons the preparation of a patient for a capital surgical operation is a formidable affair. The surgeon, before operating, takes a complete bath and changes his clothing, requiring the same of his assistant and the bystanders; the operating room being thoroughly disinfected, also all sponges, instruments, etc. The success of these practitioners has been wonderful, hence it was a severe objurgation upon every surgeon to do likewise. Imagine the revolution this adoption would cause in American practice. Should the antiseptic system prevail it will force the surgeon out of general practice, as he cannot comply with the above who is called to cases of puerperal fever, measles, etc. It will not do to bathe in the morning, and afterwards visit patients, perhaps becoming contaminated, to operate at noon. He must commence the operation as free from contagion as if life hung on the very dust in the air. Looked at in this light, the fate of Listerism would seem to be one of great import to the profession. Some simple methods of killing bacteria may be invented, however, which would save time and labor. With a certain few operations the difficulties as to render necessary a long course of special study, as the time and study learned for successful treatment can with most medical men be more profitably devoted to other matters.

They will fall into the hands of those who have given them especial attention. For this reason specialists will always be useful. Still, your committee cannot but conclude that this is accessible to any man in the profession. The principles can be grasped by any person of average intelligence and industry. What is to be thought of our present system of medical education? No more is required than was thought necessary thirty years ago: metropolitan schools, claiming to be the best in the land, conferring a degree on a candidate who has never made a chemical analysis, never looked through a microscope, has had no real experience in any part of the profession. The very foundation of scientific surgery of to-day lies in chemistry and physiology; and is it not notorious that chemistry is learned by the student as he sleeps through lectures; his knowledge of physiology is gleaned from some lectures, and of morbid anatomy is limited to a few specimens on a dirty tray passed around the class.

The student who wishes to learn must pay large extra fees, but to the most of them the large clinical advantages of Philadelphia and New York are not of much benefit, their means not allowing them to deviate from the regular catalogue. Packed in amphitheatres, they are taught surgical diagnosis on patients whom they are not permitted to touch, and can barely see from far off. The clinical patient is brought before them once or twice—cured, if he dies. The daily care of wounds is never witnessed except by the chosen few who are able to pay extra fees for extra advantages. We hazard nothing in saying that the mass of graduates from our largest schools get their diplomas without even having had a clinical drill of any value in any department of surgery. It is assumed, of course, that the moment the degree is conferred, the candidate by some mysterious process becomes at once proficient, though a few hours previous his knowledge may have been of the vaguest kind.

THE STATE BOARD OF HEALTH.

The Secretary, Dr. Ranney, read a paper by Dr. Hitchcock, of Kalamazoo, being a report of the State Board of Health to the State Medical Society. The

Board urged upon the various health officers of State the necessity of complying more closely with the law in regard to furnishing statistics of diseases dangerous to public health. The following resolutions were presented from the Board for the consideration of the Association:

Resolved, That in the opinion of the members of this society, the laws of the State requiring physicians to report to the local board of health, or to the health officers of their locality, all cases of sickness and death, of diseases contagious or dangerous to the public health, are wise and proper and ought to be complied with.

Resolved, That the law requiring health officers and clerks of local boards of health to make yearly reports to the State Board of Health, on blanks furnished them by the Board, is just and reasonable, and necessary to the most efficient work of the State board; and that no physician should accept the office of health officer who does not intend to comply with the law.

A motion to adopt the first resolution brought on quite a spirited debate, the opposition being led by Dr. Brodie, of Detroit, who claimed that the State had no right to either ask or compel the physicians of the State to perform any such services without remuneration. Drs Jerome, of East Saginaw, and Hitchcock, of Kalamazoo, urged the adoption of the resolution on the ground that all physicians should be willing to perform the work for the benefit of humanity. The resolution was finally adopted, and the report ordered published.

A paper by Dr. C. C. Yemans, on Herpes, followed.

Herpes, he said, is supposed to be due to reflex nervous irritation. It is, strictly speaking, limited to face, including eyes.

Local treatment.—Keep parts clean and dry. Ointment usually irritates. Covering with cosmeline so as to exclude all air, sometimes relieves, as also calomel, corn-starch, or roasted flour. He had success in herpes of mucous surfaces, with equal parts of iodoform and tannin.

The following resolutions were referred to the judicial council, by request of Dr. Chase, of Otsego, who presented them:

Resolved, That the Committee on Judiciary try to frame for the consideration of this Society, some rule of procedure or by-law that will guard this Society against the admission to our membership of men who have never graduated at a medical school or attended a medical school, until they shall have undergone an examination as to professional acquirements by the Board of Censors of this Society, and received a favorable recommendation by the board that they may be admitted to membership.

The following preamble and resolution was adopted:

Whereas, The State Medical Society of Michigan views with gratification the evidences that its labors for a more elevated standard of medical education have not been without reward, in the fact that all the medical schools of this State have made a preliminary examination and a three-term graded course a requisite for graduation, therefore

Resolved, That we, the members of the State Medical Society, pledge ourselves individually and collectively to support only such schools as require for admission a thorough preliminary examination, and for graduation at least a three-term graded course of lectures in three years of study; and that we will use our influence to prevent students from attending any college with an inferior standard of preparation and graduation.

The President, Dr. Johnson, appointed Dr. Brodie, of Detroit; Dr. Drake, of Hastings; Dr. McGraw, of Detroit; Dr. Topping, of De Witt, and Dr. McLean, of Ann Arbor, as a committee to nominate suitable persons for officers of the Association for the ensuing year.

The session then adjourned until afternoon.

Afternoon Session.

After roll-call, Dr. Fuller, of Grand Rapids, on invitation, presented a paper describing two very severe cases of crushing of the feet, and the treatment used to save the members from amputation. He advocated the free use of stimulants in such cases; this and free drainage of all such wounds, he thought was the best manner of treating such injuries. Whisky in small doses was a mere stimulant, but in large doses it reduced the pulse.

The day had gone by for reducing the pulse by bleeding by the quart as the old school of doctors used to do.

The report of Drs. Brodie and Hitchcock, the committee appointed by the Regents of the University to assist in the examination of the graduates of the Medical Department of the University, was read by the former. The report spoke in commendation of the ability of the candidates for medical degrees, and expressed the wish that all students could have a more thorough common education, and that all applicants for entrance to the medical department ought to be required to take at least a course in Latin and Greek, as was required to enter the freshman class in the literary department.

On motion, the report was ordered to be printed in the Transactions of the Society.

The Committee on Nominations presented the following as persons suitable to fill the various offices of the association for the ensuing year:

First Vice-President, Dr. E. P. Christian, of Wyandotte; Second Vice-President, J. W. Hagdorn, of Lansing; Third Vice-President, C. J. Landry, of Detroit; Fourth Vice-President, J. H. Bennett, of Coldwater; Recording Secretary, G. E. Ranney, of Lansing; Treasurer, G. M. Topping, of Detroit.

The report of the committee was accepted, and being adopted, the various candidates were declared duly elected.

The next business was the balloting for President, which resulted as follows: Whole number of votes cast, 76; Dr. Thomas, 45; Dr. Whalen, 28; scattering, 3.

Dr. Thomas, of Bay City, having a majority of the votes cast, was declared President of the Association for the ensuing year.

Drs. Foster Pratt, H. B. Shank, and E. S. Snow, members of the Judical Council whose terms of office expired this session, were re-elected.

A vote of thanks was tendered Dr. and Mrs. Johnson and Mr. and Mrs. Gilbert for their elegant entertainments, and to the physicians and citizens of Grand Rapids, who had spared no pains to make the assembling there useful and in every way pleasant.

A paper by E. B. Ward, M.D., of Lansingbury, on "Medical Superstitions," was read by title and referred to the publication committee.

On motion of Dr. Parmenter, the Society then adjourned, to meet in Bay City on the second Wednesday of June, 1881.

New Instruments.

A NEW ATTACHMENT TO THE HIP SPLINT.

By A. B. JUDSON, M.D.,

NEW YORK.

I have found the device shown in the accompanying cut useful as an attachment to the long hip splint. It consists of a curved band of steel which

projects stiffly from the upright in such a manner that one arm presses against the anterior surface and the other against the posterior surface of the lower part of the thigh. It takes the place of the adjustable piece which carries the retentive band at the level of the knee. Its object is to secure additional fixation of the hip-joint by holding the femur more steadily in a line parallel with the axis of the upright piece of the splint. It is applied, after the rest of the apparatus is adjusted, by placing it on the lower part of the thigh, and then pushing the tenon into the mortise (both shown in the cut). Its position may be modified by changing the length and direction of the short, straight piece which terminates in the tenon. It is kept in place by a cord or piece of webbing, fastened above to the upper part of the upright, or to the pelvic band, which, by the way, should be joined to the upright, in such a manner as to be adjustable, but, when properly adjusted, unmovable, except by the surgeon. A piece of webbing may be buckled around the thigh and the splint to assist in fixing the joint laterally.

I have used this attachment in two severe cases of advanced hip-joint disease, long enough to be satisfied that it secures better fixation, and that it is worn with comfort and a measure of relief. As fixation is undoubtedly one of the principal functions of the long hip splint, this little apparatus promises to be of value.

129 E. SEVENTEENTH STREET.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from June 13, 1880, to June 19, 1880.

SMITH, A. K., Major and Surgeon. Having reported in compliance with S. O. 74, C. S., A. G. O., is assigned to duty as Medical Director of the Department, relieving Surgeon J. C. McKee. G. O., No. 9, Dept. of Arizona, June 1, 1880.

GODDARD, C. E., Major and Surgeon. Granted leave of absence for four months. S. O. 128, A. G. O., June 11, 1880.

PAULDING, H. O., Capt. and Asst. Surgeon. Ordered before the Army Med. Board, in session in New York City, for examination for promotion, and on its completion to return to proper station. S. O. 132, A. G. O., June 16, 1880.

ADAIR, G. W., Capt. and Asst. Surgeon. Ordered before the Army Med. Board, in session in New York City, for examination for promotion, and on its completion to return to proper station. S. O. 132, A. G. O.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending June 14, 1880.

Week Ending	Typhus Fever	Typhoid Fever	Scarlet Fever	Cerebro-spinal Meningitis	Measles	Diphtheria	Small-pox	Yellow Fever
June 12, 1880.	2	5	34	4	40	25	0	0
June 19, 1880	0	6	58	2	33	27	0	0

THE HOSPITALS OF PARIS AND NEW YORK. — The city of Paris has nineteen hospitals, public and private, including its municipal Maison de Santé. Fifteen of these are general in their character; that is, they have beds for medical, surgical, and lying-in cases. The remaining four are devoted to children's diseases, scrofulous diseases, accouchements, etc. The hospitals are nearly all very large, the total capacity of the whole nineteen being 9,673 beds. Of these, St. Louis is the largest, and has 843 beds. The famous Hôtel-Dieu has 563 beds. The average number is 509.

A comparison of these statistics with those of New York hospitals brings out some interesting contrasts. There are, altogether, in this city, about thirty-three hospitals, containing accommodations for between 6,000 and 7,000 persons. Of these hospitals, sixteen are special and seventeen general in their character. The special hospitals are, naturally, quite small, their average capacity being only a little over 100 beds. The general hospitals have an average capacity of about 300 beds. There are two hospitals, Charity and the Emigrant, with 1,000 beds. Bellevue has nearly 700.

It will be seen that our hospital accommodations are nearly as great, in proportion to our population, as those of Paris. That city has two millions of inhabitants, while we have only eleven hundred thousand. Our hospitals are more numerous, smaller in size, and more divided up for the accommodation of special diseases. We are not inclined to find fault with this arrangement. It is possible to have large hospitals managed in the best manner, and such hospitals furnish better opportunities for clinical instruction. Nevertheless, it is a fact that our model hospitals are those of medium size, and it is, of course, easier to secure good management for this kind. There is an impression, on the other hand, that many of the Parisian hospitals are quite deficient in respect to diet, nursing, and practical medical skill. This is a charge that cannot be brought against New York. Her hospitals are sufficiently numerous, and are, almost without exception, well-officered and well-managed. We can only regret that the vast mass of

clinical material which they offer is utilized so slightly in comparison with that abroad.

The Concours held at Rush Medical College, May 27th, for the position of Clinical Adjunct to the Chair of Diseases of Children, resulted in the choice of Dr. J. Suydam Knox, of Chicago. Dr. Knox is a gentleman well known in Chicago for his scientific attainments.

Chicago Medical College.—Dr. H. Gradle has been elected Professor of Physiology in this College, vice Dr. D. T. Nelson, resigned.

Drs. C. F. Fulsom, of Boston, and Mrs. Clara T. Leonard, of Springfield, have been appointed members of the Massachusetts Compound Board of Health, Lunacy, and Charity, in place of Drs. Wood and Allen, whose terms had expired.

The Death of Dr. Alfred S. Taylor, the well-known toxicologist, is announced.

A New Carbolized Dressing.—Dr. Rudolf Tauszky, of New York, writes to us concerning a new carbolized dressing which he has used with excellent results in the out-patient department of the Mt. Sinai Hospital. It was devised by a German physician, and the formula is as follows:

℞. Acid carbolic-cryst	25.00
Rosin	60.00
Stearin	00.15

Mix with 700 parts of pulverized chalk, or plaster-of-Paris; keep in a closed vessel, as otherwise part of the carbolic acid evaporates. The mixture contains about three per cent. of carbolic acid. If warmed it becomes liquid, and may be used in that state. It forms a most excellent dressing for torpid ulcers, carcinomatous ulcerations, moist gangrene, burns, etc.

The International Surgical Record is the name of a new weekly journal just started in this city, edited by Achillis Rose, M.D. It contemplates devoting its columns exclusively to surgery, and will publish complete translations from foreign medical literature.

Preventing Measles among Children.—In a recent elaborate report on measles, made by the Committee on Hygiene to the King's County Society, the opinion was expressed that it was not advisable to quarantine cases of measles, nor to keep children from school when there was measles in the family. It was believed very difficult to prevent the spread of the disease by mere measures, and the result was not worth the expense and inconvenience.

Four New Branches of the British Medical Association have been formed already this year, and attest the prosperity of the Association. In order to form a Branch it is necessary for at least twenty members to organize and apply to the Council for recognition. The new branches are, three of them in Australia and one in England.

The First Case of Yellow Fever in this port this season came in from Aspinwall June 16th, on a Pacific Mail steamship. On June 7th, the day after leaving Aspinwall, a steerage passenger was taken sick of yellow fever, and died June 12th, on board. The next day a cabin passenger was taken sick, and was still suffering when the vessel arrived on the 16th. He was removed to the quarantine hospital, where he died that night.

A Curious Epidemic of Cholera Morbus has recently occurred in Adams, a country town of 6,000 inhabitants in Massachusetts. In the course of a few days four or five hundred people were attacked. Women and children were most affected. The attacks resembled very much those of cholera morbus, but were often not as severe. There have been no fatal cases reported at date of writing. The cause of the epidemic has not yet been found; all speculations as to diet, water, air, etc., have furnished no satisfactory theory.

The Streets of New York.—The pathologist who wanders along Twenty-third Street on a pleasant day will not feel the need of a hospital in which to prosecute his studies. He will meet, within three blocks, a case of paralysis agitans, a double fracture of the femur, several amputations, a paraplegic, a blind man (amaurosis mendicantis), and a case of genu varum.

The Guy's Hospital Controversy is continued in the June number of *The Nineteenth Century*. Drs. Octavius Sturgis and Seymour Sharkey write in a peace-making spirit. Miss Lonsdale replies to the various articles that appeared the previous month. She apologizes for the warmth of her first article, explains a little, reasserts her position, and convicts Dr. Moxam of some misstatements.

Miss Alice Bennett, M.D., has been elected resident female physician to the Morristown Insane Asylum, at a salary of $1,000 a year.

Dr. Robert H. Chase, of Washington, D.C., has been elected resident physician to the same asylum, at a salary of $2,000 a year.

A New Hospital is to be built at Philadelphia, to be called St. Agnes' Hospital, and to be conducted on a plan similar to that of the St. Mary's Hospital. It will cost about $100,000, and will accommodate 300 patients.

Failure of the Law to Regulate the Practice of Medicine in Kansas.—According to the *Kansas Medical Index*, the law which has now been in operation for several years, to regulate the practice of medicine, has not been a success. The failure is due to the fact that the law is so obscure in its meaning that no one can be convicted under it. Furthermore, the medical profession of the State has not taken enough interest in the matter to carry any case up to a superior court, and thus have mooted points decided.

As it at present exists, medical students can get a license to practice from the examining board, and that without having to undergo a severe examination.

Meat-bread is the name of a preparation recently presented before the Paris Academy of Medicine by M. Scheurer-Kestner.

It was discovered by this gentleman that if meat be chopped up finely and mixed with dough in a proportion not exceeding one to two, the meat is digested during baking. Bread thus prepared does not taste very well, but it keeps a long time, is very digestible, and is excellent for soups. The bread is better if the meat (beef) is first cooked. There should be no fat and but little salt added. The preparation is to be tried in the army.

Of the Candidates for Admission to the College of Surgeons, England, over one-third were rejected at the examinations held during the week ending May 15th.

PROGRESSIVE SCLEROTICOTOMY has been treated with good results by partial division of the external rectus. This treatment is based on the theory attested by Emmert and Graefe, that posterior staphyloma is caused by pressure exercised on the optic nerve by the external rectus during converging movement.

JABORANDI IN THE TREATMENT OF SEROUS EFFUSIONS.—The London correspondent of *The Lancet and Practitioner* writes: "The use of jaborandi is on the increase, and the latest application of it is in the treatment of pleuritic effusions. Dr Hunt, of the Wolverhampton Infirmary, has been trying jaborandi in pleuritic effusion upon theoretical considerations. He says: 'Its mode of action is obvious. Diminishing the watery constituents of the blood vessels, it causes an absorption of fluids from the tissues and cavities of the body, and in fact it is more than probable that the vessels in such cases take up more than is secreted by the skin.' He then proceeds to demonstrate by the use of the hæmatocrator, that the effect of jaborandi upon the blood corpuscles is conformable with this hypothesis." Three cases are given in which the drug gave very satisfactory results.

We may append to this the remark that jaborandi has been frequently used for the purpose of removing serous effusions, in the Hospitals of New York, and, as a rule, with unfavorable results.

THE ADOPTION OF ANIMAL VACCINATION IN ENGLAND.—On June 11th, Dr. Cameron, M.P., introduced into the House of Commons a resolution to this effect: "That as cow-pock lymph, direct from the calf, commonly known as animal vaccine, is of at least equal value as a prophylactic against small-pox with the ordinary human lymph, and as its use affords an absolute guarantee against the propagation of those human diseases occasionally inoculated with human lymph, the House is of opinion that to meet the objections to vaccination founded on the possible communication of other disease through that operation, a supply of animal vaccine should be provided by the National Vaccine Establishment for the use of those who prefer it to the ordinary lymph."

This resolution aroused the anti-vaccination men to opposition, and a resolution was presented as an amendment, to the effect that, in the present unsettled state of medical opinion as to the safety and effectiveness of vaccination, it is inexpedient to enforce it under penalty. One of the strongest arguments which the anti-vaccinationists hold out to the thrifty British mind is that the national vaccine establishment costs the kingdom $3,000,000 a year. The claim that there is any division of medical opinion on the subject is, of course, absurd.

In this connection it may be stated that, after much parturient agony, an anti-vaccination society has been organized in this city. It starts with a little capital, since two or three cases of erysipelas have recently occurred as a result of vaccinations by officers of the city Board of Health. The illustrated weekly, *Puck*, which is sometimes very witty and sometimes very despicable, has published a striking cartoon, showing, by a parti-colored allegory, how the health-officers are filling the systems of our baby population with the virus of all kinds of disease.

MEDICAL STUDENTS IN SPAIN.—The Professor of Clinical Surgery in the Medical School at Seville says, in the *Edinburgh Medical Journal*: "The number of students who matriculated in the last session of 1878 to 1879 was above seven thousand, the number of licenses to practise was one thousand one hundred and more. This number exceeds the requirements of our population, and I don't know what so many medicos as there will be in Spain in the course of four or five years are going to do."

ISOLATION IN HOSPITALS.—The Lancet Medical Society has appointed a commission of five to study methods of obtaining complete isolation in hospitals, of patients suffering from infectious diseases.

THE ANNUAL MEETING OF THE AMERICAN NEUROLOGICAL ASSOCIATION, which held a three days' session in this city last week, was an interesting and successful affair. About the usual number of members was present. One of the most important of its actions was the passage of a resolution recalling the present evils connected with our insane asylums and commending the attempt to secure a reform.

THE INTERNATIONAL OTOLOGICAL CONGRESS.—When the first International Otological Congress met in New York, in 1876, it was decided that the second Congress should meet at the same place with the International Ophthalmological Congress. This place is Milan, and arrangements are going on accordingly. A local committee has been formed, consisting of Professor Rossi, of Rome, and Drs Sapolini and Restelligi, of Milan. Gentlemen who intend to attend the Congress are requested to communicate with Dr. Moos, at Heidelberg; and those who intend to read papers are also invited to inform him of the fact. Although French is to be the language of the Congress, papers can be read in any language. The date of meeting is September 6, 1880.

AN EPIDEMIC OF CHOREA has broken out among the pupils of the Ursuline Convent, Brown County, Ohio. The malady is so severe as to have caused death in one instance. No cause has been assigned.

Obituary.

CHARLES M. ALLIN, M.D., NEW YORK.

DR. CHARLES M. ALLIN, of this city, died at his residence, June 20th, aged 53 years. He was born in Providence, R. I., October 30, 1827. After a suitable preliminary course in the Institute at Sheffield, Ct., he entered Brown University, graduating from that institution in 1847. He afterwards attended the College of Physicians and Surgeons, New York, and received his degree of M.D. in 1851. He then served three years as interne in the Surgical Division of the New York Hospital, and in May, 1852, commenced practice in this city. In 1854 he removed to Flushing, L. I., where he enjoyed an extensive patronage for eleven years, at the end of which time he returned to New York, to form a partnership with Dr. Abram Dubois. From 1852 to 1855 he was physician to the Nursery and Child's Hospital, also physician to the Northern Dispensary; surgeon to the New York Eye and Ear Infirmary from 1855 to 1876; surgeon to the Presbyterian Hospital from 1874 to 1876; and to the New York Hospital since 1865. His contributions to medical literature were mostly confined to articles on surgical subjects in the various medical journals; notably among these contributions was one on Retro-pharyngeal Abscess, published 1851.

INDEX.

A

Abdominal pregnancy, 683.
Abortion, tetanus following, 105; management of, 633; relations of medical and legal professions to, 636.
Abscess of the antrum, 423; brain, 275; cold, treatment of, 295; liver, 268, 587; pelvic, 467; pyæmic, multiple, 129; peri-typhlitic, 64.
Academy of Medicine, French, 130.
Acetabulum, fracture of, 607.
Achromatopsia, traumatic, 416.
Acid, boracic, 499; contamination of, 328; in eye diseases, 140, 220, 328; carbolic, eucalyptus a substitute for, 260; percentage of in jute and gauze, 46, 260; pyrogallic, action of, 204, 232; salicylic, 249; danger of in rheumatism, 540; in phthisis, 596, tannic, and Lugol's solution in diphtheria, 89.
Aconite and opium antidotal (?), 6; recent experiments with, 471.
Adenoma of the breast, 286.
Adenoma-carcinoma nasi et cerebri, 540.
Advertisements, professional, 217.
Ady, Dr. A., a new uterine dilator, 413.
Age, influence of, on the results of amputation, 286.
Agnew, Dr. C. R., the alleged cure of cataract by electricity, 552, 610.
Ague, nitrite of amyl in, 64.
Air, atmospheric, contamination of by arsenical pigments, 129; cells, hyperdistention of as a therapeutic measure, 695.
Albuminuria, latent, 146; without disease of the kidneys, 13.
Alcoholism, treatment of, 52.
Alienist and Neurologist, 248.
Alimentation, rectal, 11, 178, 391; forced, 177.
Alkalies in acute rheumatism, 249.
Allcott, Dr. E. B., death of, 80.
Allin, Dr. C. M., death of, 740.
Alopecia due to fright, 694.
American Journal of Microscopy, 526.
American Laryngological Association, 612.
American Medical Association, 66, 471, 499, 526, 572, 583, 598, 613, 626, 639, 653, 670.
American Medical Editors' Association, 655.
American Monthly Microscopical Journal, 218.
American Veterinary College, 302.
Ammonium, chloride of, in goitre, 429.
Amphitheatre at La Salpêtrière, 108.
Amputations, influence of age on the result of, 286; in utero, 271.
Amyl, nitrite of, action of on the vessels, 232; and ague, 64; in asphyxia of the new-born, 553; in chloroform narcosis, 219, 382, 441; in uterine hemorrhage, 64.
Amyloid degeneration, 485; substance, new test for, 147.
Anæmia, iron and oxygen in, 373; progressive pernicious, 313; simple, 111.
Anæsthesia, fund for the discoverer, 387; impulse of heart in, 91.
Anæsthetic, bromide of potassium as a local, for the genito-urinary apparatus, 540; bromide of ethyl as an, 361, 375, 379; a new, 190; in labor, 213.
Anatomical and Surgical Society, Annals of, notice, 266.
Aneurism, aortic, 221, 433, 434; false, of tumor of the uterus, 7; traumatic mistaken for abscess, 108; treatment of, 523.
Ankle-joint, anatomy of, 597; caries of, 126.
Anomalies, anatomical, 257; arterial, 384; cerebral, 106.
Animation, suspended, 292.
Anti-scorbutic, 191.
Anti-hydropine, diuretic properties of, 682.
Antiseptic dressing, a new, 739; surgery, 65, 607, 694, 696; of head injuries, 347; of compound fractures, 388; vs. simple treatment, 13.
Antiseptics in cataract extraction, 401; in ozæna, 344; surgical treatment without, 694.
Anti-vivisection, 257; failure of bill, 274; enterprise, 291.
Antrum, abscess of, 423.
Anus and penis, absence of, 499.
Aorta, aneurism of, 433, 434; embolism of, in the horse, 463; thrombosis of, 239.
Apomorphia in asthma, 79; in croup, etc., 347.
Apoplexy, 464.
Apothecary vs. Doctor, 96.
Appendix vermiformis, cystic degeneration of, 44; gangrene of, 728.
Arkansas Medical Monthly, 500.
Arm, fracture of, 538.
Army Medical Department, British, 94.
Arnica tincture, effect of on the skin, 146.
Arsenical pigments, contamination of atmospheric air by, 129.
Artery, basilar, aneurism of, 97; external iliac, ligation of, 494; femoral and vein, simultaneous ligation of, 36; subclavian, anomalies of, 257.
Arthritis, strumous, 156.
Arthropathy of locomotor ataxy, 203.
Ashby, Dr. T. A., notice of monograph by, 321.
Asphyxia in the new-born, 409; nitrite of amyl in, 553.
Aspiration in strangulated hernia, 410.
Asthma, apomorphia in, 79; remarks on the treatment of, 605.
Asylums, abolition of private, 387.
Atkinson, Dr. Wm. B., notice of work by, 461.
Atrophy, acute muscular, 288; progressive muscular, 588.
Atropia and pilocarpine, action on the heart, 317.
Atropia in post-partum hemorrhage, 217; in spermatorrhœa, 347.
Audiphone, 190, 298; a failure, 78; another, 135.
Aural disease influenced by the condition of the teeth, 172
Auricle, cardiac, right, importance of recognizing dilatation of, 118.

Antisepsis, 171; the rights of, 614
Aseptic, relative merits of, 170, 209

B

Bachelor, Dr. H. M., the ova-parasite, 541
Backache, complete, from fright, 691, and procaryne, 380
Bagasse, uses of, 536
Balsam of Peru in pruritis, 64
Baltimore Academy of Medicine, prize essay of, 360.
Baltimore, relative to acute cystitis, 172
Barnes, Dr. Joel, 16
Barnett, Dr. S., narrow of amyl in chloroform narcosis, 441
Baths, sea-water, 191; hot, non-use of, 522.
Battey's operation, 149, 622, 673, 697
Beale, Dr. Lionel S., notice of book by, 491
Beard, Dr. George M., nervous diseases and the male genital function, 305, 619, notice of book by, 515.
Beer as a remedial agent, 611
Belladonna in constipation, 91
Bellevue Hospital, 118, 150, 547.
Bellevue Hospital Medical College, 275, 199
Benson, Dr. G. E., multilocular ovarian cysts, 61.
Benzoate of sodium, 684.
Berry, Dr. J. J., articular osteitis of the knee in children, 143.
Bigelow, Dr. Horatio R., the chorda tympani nerve, 57, 162, interesting case by, 636.
Bigelow's operation, 36.
Bile, physiological action of drugs on the secretion of, 173
Billington, Dr. C. E., diphtheria, 331, 383.
Births, compensation for the registration of, 441
Black list, 472
Blackwell, Dr. Elizabeth, notice of book by, 269.
Bladder, detection of stone in, 75.
Blake, Dr. John Ellis, nitrous oxide in melancholia and nervous exhaustion, 118.
Blepharoplasty, 344, 351.
Blodgett, Dr. A. N., malignant degeneration of a fibroid tumor of the uterus, 7.
Blood, defibrinated, as a substitute for extract of beef, 285; transfusion with, 187; microscopic examination of, 527; peritoneal transfusion of, 261; recent investigations on the, 596; repair of, after acute diseases, 294; third corpuscular element in, 458; globules red, stroma of, 92; the size of, 131.
Blood vessels, diseases of, in relation to the genesis of ovarian cysts, 260; inflammation of inner coat of, 263.
Bloomingdale Asylum, 444.
Board of Health, at Nashville, Tenn., 17; New Orleans, 470; San Francisco, 330.
Body snatching, 135.
Bogert, Dr. S. S., bovine disease, 525.
Boll, Prof., of Rome, notice of death of, 217.
Bone setter, 360.
Bone, transplanting of, 514.
Bones, long, spontaneous osteomyelitis of, 261; nerves in the marrow of, 203.
Booth's Theatre, entertainment at, 656.
Borax in phthisis, 596.
Boston Med. and Surg. Journal, 51.
Bosworth, Dr. F. H., a new nasal speculum, 414.
Botany, summer school of, 500.
Both, Dr. Carl, the treatment of tubercular consumption, 202.
Bovine disease, 525.
Bowditch, Dr. A. L., 192.
Bowditch, Dr. H. I., notice of contribution by, 294.
Bowels, obstruction of, 365, 378.
Bozeman, Dr. N., preparatory treatment for ovariotomy, 75.
Brain, abscess of, 275; Giacomini's method of preserving, 315; sclerosis of, 464; tumor of, 731.
Bray, Charles, notice of book by, 576
Breast, a case of, epithelial tumors of, 724
Brickner, Dr. Chas. K., intestinal obstruction from internal hernia, 636
Bridge, Dr. W. T., preventive treatment, 697.
Brigham Hall Hospital for the Insane, notice of report, 548
Bright's disease in children, 635.
Brinkerhoff, Dr. S. B., notice of death of, 612
British Dental Association, 540
British Medical Association, 57, 759
Bromidia, fatal consequences of, in whooping cough, 65
Bromide of ethyl as an anæsthetic, 361, 614, 650, 682, 690
Brown, Dr. L. Arnold, affections of the eye following the use of chloral, 467
Browne, Dr. F. Barton, notice of translation by, 16
Brunet's cotton, recent notice of, 520.
Brunton, Dr. T. Lauder, notice of book by, 515
Buckler, Dr. T. H., notice of notes by, 548
Buckley, Dr. O. A., excess of color on distance, 199, convergent squint, 304
Budd, Dr. Wm., death of, 78.
Bullard, Dr. G. B., bromide of ethyl, 555.
Bullett, Dr. Henry M., death of, 248
Bumstead, Dr. Freeman J., notice of book by, 125; resolutions relating to the death of, 164.
Burke, Dr. Martin, the treatment of empyema by simple incision, 545.
Burns, treatment of, 693
Burrall, Dr. F. A., posture in the treatment of intestinal ulcer and fistula, 457.

Eclampsia puerperal, 211.
Eczema infantile, management of, 170.
Education of the general practitioner, 148.
Educational standard, 218.
Eigenbrodt, Dr. David L., death of, 79.
Elastic bandage, 645.
Elbow, excision of, 707.
Eclectic Medical Institute of Chicago, 218.
Electricity and cataract, 191, 210, 333, 355, 552, 579, 610.
Electric light in surgery, 80; perfected, 106.
Elbow, incomplete outward dislocation of, 525; unusual dislocation at, 397.
Elytrorrhaphy, 253; for prolapsus, 130.
Embolism, air, sudden death from, 454; diffuse, of brain and lungs, 127; fat, in diabetes, 477.
Empyema, new treatment of, 182; treatment by thoracentesis and irrigation, 261; treatment by simple incision, 525; and valvular drainage, 368.
Endocarditis, ulcerative, 44.
Endometritis, treatment of, 596.
Epilepsy, the thermometer in trephining in, 587.
Epileptoid symptoms and Battey's operation, 622.
Epiphysis, fracture of the humeral, 56.
Epithelioma, origin of, 19; of the cervix uteri, 288; of leg, 456; of penis, 486; of the rectum, 326, 518.
Erb, Dr. William, 256.
Erysipelas, abortion of, 470; acute, complications of, 91; in Bellevue Hospital, 163.
Ether, deaths from the inhalation of, 136; hydrobromic, 361, 375, 379, 439.
Etherization, 122, 342.
Ethyl, bromide of, as an anæsthetic, 251, 260, 342, 361, 375, 379, 439, 469, 500, 554, 606, 612; death from, 728; iodide of, 688.
Eucalyptus, oil of, a substitute for carbolic acid, 260.
Eustachian tube, inflammation of, 25; introduction of liquids into the, 638.
Exhaustion, nervous, nitrous oxide gas in, 118.
Extra-uterine fœtation, 109.
Eye, catarrhal affection of, abuse of strong agents in, 297; extirpation of, 517; glioma of, 519; splinter of steel lodged in, 493; effects of chloral on, 2, 89, 163, 357, 115; diseases, boracic acid in, 328; variability of human, 650.
Eye and Ear Hospital, annual report of Brooklyn, 219.
Eye and Ear Infirmary, 163; a new charitable, 265.
Eyelash in a canaliculus, 190.
Eyelid, formation of, 344, 351.
Eye-parasite, 244.
Eczema of nipples preceding carcinoma, 23.

F

Fairbank, Dr. Thomas, notice of death of, 380.
Farr, Dr. William, 331.
Fat in the urine, 289.
Favus, 427.
Feeding, artificial, 455.
Fehr, Dr. Julius, concerning so-called patented articles, 21.
Felt in the treatment of curvatures of the spine, 172.
Female physicians, 655.
Femur, elongating hypertrophy of, 225.

Fenwick, Dr. Samuel, notice of book by, 408.
Ferment, pancreatic, 51.
Fever and ague, Homœopathic springs for, 597.
Fevers, eruptive, 473, 501, 529, 557; growing, 146; Japanese river or flood fever, 289; puerperal, 452; puerperal, high temperature in, 371; puerperal malarial, 158; relapsing, 570; scarlet, 557; spirillum in, 513; typhoid acute nephritis in, 485; typhoid, and swelling of the parotid gland, 90; typhus and typhoid, 128; typhus, epidemic of 1878-9, in Breslau, 541; typho-malarial, 466; yellow, alkaline theory of, 105.
Fibro-sarcoma of the orbit, 269.
Fibroma cutis and sarcoma, 514.
Fibrous tumors of the uterus, 605.
Filariæ, human, and mosquitoes, 514; sanguinis and chyluria, 541.
Fish, nutritive value of, 416.
Fistula in ano, modification of the operation for, 34.
Flint, Dr. Austin, clinical lecture, 249; clinical lecture, acute lobar pneumonia, 277.
Fœtation, extra-uterine, 109.
Fœtus, viability of, after the death of the mother, 106.
Food, prize essays on adulteration of, 248.
Forearm, fracture of, 538.
Foot, apparatus for inversion of, 711; spontaneous gangrene of, 705.
Forceps, a needle and artery combined, 23.
Forceps, Tarnier's obstetric, 69.
Forest, Dr. W. E., asphyxia in the new-born, 410.
Foster, Dr. M., notice of book by, 545.
Fothergill, Dr. G. Milner, notice of book by, 210.
Fox, Dr. Geo. H., 386; a superior quality of green soap, 188.
Fracture of the clavicle, apparatus for treatment of, 173; epiphysis of the humerus, 56; skull, 609; compound and comminuted, of the arm and forearm, 538.
Fractures, compound and antiseptic treatment of, 388.
Francis, Dr. Geo. E., new holder for Sims's speculum, 497.
French Academy of Medicine, 73.
French Academy of Sciences, 73.
French Society of Surgery, 73.
Frey, Prof. Heinrich, notice of book by, 549.

G

Galvani, monument to, 162.
Gangrene of the lung, 346.
Gardner, Dr. R. W., testing pepsine, 409.
Gastro-hysterectomy, 634.
Gastrotomy in extra-uterine pregnancy, 708; in œsophageal stricture, 121.
Genital function, male, and nervous diseases, 545.
Genu valgum, 559, 578, 589; condylotomy for, 398, subcutaneous osteotomy for, 233.
Gibbons, Dr. H., Sen., notice of pamphlet by, 294.
Gibney, Dr. V. P., treatment of sciatica, 643.
Gland, parotid, swelling of, in typhoid fever, 90.
Glioma, double of retina, 465; of the eye, 519.
Globus hystericus, cause of, 651.
Glottis, œdema of, 129.
Glycerine as substitute for cod-liver oil, 684.
Goitre, 389, 641; acute menstrual, 428; treatment by chloride of ammonium, 429.
Goodell, Dr. Wm., extra-uterine fœtation, 109.
Gonorrhœic irido-choroiditis, 717.
Gosling, the case of Abraham, 444.
Gouley, Dr. J. W. S., cystorrhagia from retention of urine, 193.
Gout, treatment of, 421.
Graphic method, 99.
Grateful patient, a, 276.
Gray, Dr. L. C., lunacy reform, 132.
Green, Dr. James S., compound and comminuted fracture of the arm and forearm, 538.
Green soap, 188.
Gross, Dr. S. D., the social position of the doctor, 300, 359.
Gruening, magnet, 651.
Gruening, Dr. Emil, on the removal of particles of steel from the vitreous chamber by means of magnets, 484, 651.
Gummata of the penis, 228.
Gunshot wound of the chest, perforating, 509.
Gustatory nerves, division of, 704.
Guttman, Dr. Paul, notice of book by, 601.
Guy's Hospital controversy, 599, 739.
Gynecology, election of a Professor of, 470.

H

Hadden, Dr. Alexander, treatment of gout, 421.
Hagenbach, Dr. A. W., perforation of the small intestine, 167.
Hamilton, Dr. A. McLane, nitrous oxide gas in nervous exhaustion and melancholia, 118.
Hamilton, Dr. Frank H., notice of paper by, 294.
Hamilton, Dr. John B., drainage-tube carrier, 49.
Hæmatemesis in China, 472.
Hæmaturia paroxysmal, 37.
Hæmometry, clinical, 486.
Hare-lip, 237, 259, 630.
Harnden, Dr. R. S., exfoliative dermatitis, 496.
Hart, Dr. Charles A., a new aspirating and exploring needle, 23.
Hart, Ernest, Esq., notice of report by, 547.
Hart, Mrs. Ernest, 416.
Hartt, Dr. Henry Le Baron, notice of death of, 274.
Harvey, Dr. Alex., notice of book by, 208.
Harvey's treatise on the heart and circulation, 51.
Head, Dr. J. F., tests for color-blindness, 496.
Head, gunshot wound of, 570; injuries, antiseptic treatment of, 347.
Heads, decapitated, vitality in, 51.
Health of New England, 79.
Health-officer of the port of New York, 80, 96, 374, 386.
